VOL. 64.

INAUGURAL ADDRESS

By R. A. CHATTOCK, President.

(*Address delivered before* THE INSTITUTION, *22nd October*, 1925.)

It was with a feeling of pleasure and a consciousness of the great honour you have bestowed upon me personally that I learnt of my selection as President of this great Institution, and I thank you very sincerely. It is worthy of note that this is the first occasion on which a municipal electrical engineer has been selected to fill this high position, and I feel therefore—and I know that my brother municipal engineers agree with me—that my selection also reflects a great honour upon the municipal side of the electricity supply industry, which has now reached such large dimensions and is continuing to grow at such an accelerating rate.

It is an illuminating fact that two chief engineers of large electricity supply undertakings have been selected during the past session and the present session to this high office, and I cannot help thinking that the intention underlying this was largely influenced by the fact that at the present time His Majesty's Government is interesting itself in the present position and the future of this particular section of the industry, and in consequence the subject is becoming one of great public interest. The views, therefore, of engineers of supply undertakings are perhaps of especial interest at the present time.

My predecessor, Mr. W. B. Woodhouse, in his admirable address a year ago, discussed at considerable length the progress that has been made in all branches of the electricity supply industry. I do not therefore propose to traverse the ground that he covered so exhaustively, but I will confine myself to one or two matters in connection with that industry which I think are of special interest just now, and which will bear being elaborated.

REPORT OF THE ELECTRICITY COMMISSION.

This Report, embodying as it does such a vast amount of statistical matter in connection with the generation and supply of electrical energy in this country, is, in my opinion, a most valuable book of reference for supply engineers. Its compilation has obviously involved an enormous amount of work, and the thanks of the industry are due to the Commissioners for preparing and issuing it.

It is satisfactory to know that these Reports will in future be issued annually and without the delay that has necessarily occurred in connection with the first volume, because if information of this kind is to be acted upon it is essential that it should be available as soon as possible.

The general review deduced from the statistics and embodied in the Report is particularly valuable, including as it does average figures for the whole country dealing with the growth of the industry, the operation of the undertakings, and the financial results. It is gratifying to know that these figures are year by year improving, and that the cost of production is coming down, with the natural result that the cost to the consumer is being lessened.

Although it is early days yet to suggest that this is a result of the establishment of the Electricity Commission, yet it is, I think, obvious that the improvement year by year has been materially assisted by the general policy of the Commissioners, whose avowed object has been to provide for the country a " cheap and abundant supply."

The sympathetic advice and assistance which the Commissioners bring to bear upon the numberless schemes submitted to them, based as such advice is upon high technical knowledge and tempered with sound financial judgment, are most helpful in promoting that co-ordination of the industry from which only the best results are to be anticipated.

Such results cannot be obtained all at once. Considerable time is required to reconcile the many interests involved, and to ensure that existing developments are

properly utilized and the money already spent upon them is not wasted.

The task that the Commissioners are carrying out, involving as it does such a heavy responsibility and requiring the consideration of so much detail, can only be regarded as colossal. One hears complaints that things are not moving fast enough, and that after six years only one Joint Authority has so far come into existence. In my opinion, far better and more lasting progress can be made by going slowly and thoroughly considering each step. I should like to suggest to the Commissioners in a spirit of friendly criticism that, when far-reaching and costly changes are contemplated, a free and frank discussion with the interests involved would be of far greater value to the commercial community than the production of a cut-and-dried proposal that has to stand antagonistic criticism, which might quite easily have been disarmed by reasonable compromise.

Coal.

The available statistics go to show that 95 per cent of the units generated in this country are derived from steam-operated generating plant, and that practically all this energy is derived from coal or coal products. A comparison of the performance of these stations year by year is a very helpful stimulant to economy in their operation, but it seems to me that to compare the performance of steam-operated stations on a "pounds of coal per unit generated" basis only is rather misleading. What we are all aiming at, and what the Commissioners' statistics are designed to promote, is to produce and distribute units of electricity as cheaply as possible.

A station using fuel of a very poor calorific value at a low price per ton can produce a unit of electricity quite as cheaply as, and even at a lower cost than, a station using a high-priced fuel of high calorific value, although the fuel consumption per unit and the thermal efficiency of such a station may compare unfavourably with those of the station using the expensive fuel.

Again, if the distillation of coal proves to be a commercial possibility, from 30 to 70 per cent more weight of coal will have to be handled to produce a given quantity of electricity, and whilst it may pay handsomely to adopt this process, the number of pounds of coal used per unit will of course compare very unfavourably with the figures obtained in a station burning coal to destruction.

I think, therefore, that a better method of comparison would be the cost, rather than the weight, of the fuel per unit generated, and this cost would have to take into account the sale of any by-products obtained in any process of distillation.

While on the subject of coal distillation, I should like to emphasize the reference that Mr. Woodhouse made to this matter—that the selling price of these products depends on world-wide competition with products obtained from sources other than coal. It also depends on the demand for these products in the available markets.

It is well known that the gas industry at the present time is suffering very severely from its inability to dispose of the by-products at a remunerative figure, with the result that it has not recently been possible to lower the price of gas in accordance with expectations; it has even been necessary in some cases to increase the price of gas to meet this difficulty. It is therefore very desirable to realize that if processes of this kind are adopted, a serious commercial risk is run which may have an adverse effect on the selling price of electricity.

Our ideas as to the best method of using fuel to produce steam are constantly changing. New processes, such as the use of pulverized fuel, are being developed to obtain more perfect combustion and higher furnace temperatures, and boiler-house efficiencies of 90 per cent can now be obtained, compared with 80 per cent a few years ago.

The difficulty of obtaining, for lining the furnaces, a refractory material that will stand up to these high temperatures without undue maintenance cost has now been solved, by screening the furnace walls with water tubes which are coupled up to and form part of the boiler itself. The circulating system through these tubes is kept distinct from the main circulation through the boiler, and very high rates of evaporation—in some cases as much as 50 lb. per square foot of heating surface—are obtained from these tubes, apparently without any consequent disadvantages.

There are five great advantages in the use of pulverized fuel as compared with boiler-house practice up to the present. These are :—

(1) Greater efficiency in operation, to which I have referred above.

(2) Greater capacity of individual boiler units—it being possible to install boilers each having a capacity of 300 000 lb. of steam per hour, with single combustion chambers. One such boiler would be capable of running a 25 000-kW turbine, and this would realize the dreams of some engineers who advocate the advisability of such an arrangement. I consider, however, that the steam-generating plant in a station should be pooled in order to obtain maximum reliability in operation, and this would necessitate the use of boiler units of somewhat smaller size.

It would not, in my opinion, be advisable to equip such large boilers with mechanical stokers. Several stokers would be required for each boiler, and the proper regulation of the fires would become a difficult matter; in addition to which the breakdown of any one stoker would have the effect of shutting down the whole boiler unit.

This brings me to—

(3) Greater reliability of the pulverized-fuel furnace—there being no moving parts to get out of order and to cause stoppages, whilst the regulation of the temperature in the furnace can be controlled with wonderful accuracy and consistency.

(4) The reduction in the cost of labour in operating such boilers is nothing less than extraordinary. Automatic control can be fitted, and although this is costly it is justified in connection with such large boiler units. Even where this is not fitted, one attendant can control the operation of a battery of boilers having a combined capacity of 1 million lb. of steam per hour.

(5) The efficient use of all classes of fuel is rendered possible. This is an advance on stoker performance, as the same grate area and air supply are not suitable for both rich and poor fuels when burnt on mechanical stokers, whilst it is a simple matter in a pulverized-fuel furnace to adjust the supply of air to suit the class of fuel that is burnt. In addition to this, it is possible to use efficiently the poorest classes of fuel, which have hitherto been looked upon as refuse and cannot be burnt at all on mechanical stokers.

Such a development will be of national importance, as it will make available for service the refuse heaps of old colliery workings which have been accumulating for many years.

When one compares these advantages with what we have been used to in boiler-house practice in the past, I think it is evident that considerable economy, both in capital cost and in operation, can be looked for in the future.

We are now told that the pulverization of fuel has to be combined with low-temperature carbonization of the coal in order to obtain a still further reduction in the cost of production. Any process of this kind must, as I have explained above, be dependent upon the market obtainable for the by-products. On the face of it, however, the proposal sounds more attractive than the ordinary low-temperature carbonization process, as the resultant fuel is obtained in a pulverized form and can be sent direct to the boiler furnaces. This eliminates the necessity for pulverizing the coke or semi-coke that is produced in the ordinary process, with the consequent heavy cost of upkeep of the pulverizing machinery when this material is passed through it.

The process, however, has yet to be demonstrated and proved before it can be accepted for general use.

Load Factor.

All supply engineers are fully aware of the extreme importance of obtaining a good load factor in order to cheapen the cost of production. Unfortunately, statistics show that in this country the load factor obtained in the majority of the undertakings is between 15 and 30 per cent. Those undertakings which are the fortunate possessors of a higher load factor have the benefit of long-hour demand, such as is created by railway traction, colliery pumping and similar loads. It is unfortunate, however, that loads of this nature are only available at present in certain districts.

Experience on the big systems in America also goes to show that a load factor of 45 to 50 per cent can be obtained where these long-hour loads are available.

The statistics issued by the Electricity Commission show that only six undertakings out of 470 in this country obtain a load factor exceeding 45 per cent, whilst the conclusion may be drawn that the combined load factor for the whole generating plant of undertakings in Great Britain was of the order of 28 per cent in 1922–23. There has, of course, been a big drop since the war in the load factor obtainable.

The Birmingham Corporation undertaking is typical of the supplies given in large industrial areas without the benefit of railway or colliery loads, and the load factor on its generating plant, based on units generated, has varied as follows:—

	Per cent
1916	37·0
1917	39·1
1918	38·7
1919	35·7
1920	27·8
1921	27·8
1922	25·0
1923	25·3
1924	26·2
1925	26·0

The reduction in load factor that has occurred during recent years has been due to three causes:—

(1) The bad condition of most manufacturing industries.
(2) The reduction in working hours.
(3) The phenomenal increase in the lighting connections in residential districts.

I should say that the reduction in working hours in factories has had the greatest effect in reducing the load factor, and if this is felt so severely on the capital charges of the supply undertakings, how much more must it be felt on the capital outlay of factories. One can only hope that, when trade does revive, it will be possible to run two or three shifts of men in the factories and so improve the serious position in which we are all placed at present.

Experience shows that the load factor of a residential lighting supply is approximately 10 per cent. It is obvious, therefore, that if this supply is increased to a relatively much greater extent than the power supply, it will have the effect of reducing the average load factor on the system and, in consequence, of increasing the cost of production.

It is therefore incumbent upon supply engineers to do their utmost to foster the use of electricity for cooking and heating, as in this way only can the residential load factor be improved.

The most telling way of developing the cooking and heating load is to arrange an attractive tariff, and the one that seems to find most favour with the average householder is that termed the "contract rate of charge" under which the consumer pays per quarter a fixed sum, generally based upon the rateable value of his house, and a low rate of charge per unit for every unit used in the house—whether for lighting, cooking or heating—the only proviso being that the house must be wired for all three services and a reasonable use made of them.

I believe it is true that the high load factor obtained in some of the large undertakings in this country is largely contributed to by the fact that their residential supply is practically negligible in amount compared with the industrial supply.

The suggestion that has been made in certain quarters, that the general load factor throughout the country can be improved by linking up all the big centres of supply and by taking advantage of the better diversity factor so created, is in my opinion outside the realms of possibility.

This proposal has been tried to a certain extent in America, and experience has shown that the peak load rose as fast as, or even faster than, the output. The expansion of these large systems by means of heavy trunk lines running long distances has not had the effect of improving the load factor on the system, but, on the contrary, it is tending to decrease this as the area of supply grows larger.

In this country there is no evidence that the habits of the population vary as between one large industrial centre and another. The hours of work in the factories are approximately the same, and there is no reason for believing that the peak load in one district would occur at a substantially different time from that in another.

It does not therefore appear, from the point of view of improving the load factor, that there is any justification for incurring the enormous expenditure that would be necessary to link up all the big centres in the country with trunk mains of sufficient capacity to enable their effect to be felt in the operation of the generating stations.

Standardization of Frequency.

To discuss this proposal is rather like trying to play *Hamlet* without the Prince of Denmark, because the long-looked-for Report of the Committee set up by His Majesty's Government is not yet available. From articles that have appeared in the Press it is, however, fairly clear what the proposal is in principle, i.e. to change over to 50 periods those districts in the country that are at present being supplied with alternating current of periodicities other than 50.

Let us try to imagine what is the reason or justification for doing this, and make a rough estimate of the cost.

Again we have nothing definite to go on, as the Report is not available: however, from articles that have appeared it is possible to form some idea that the proposal is designed :—

(1) To make it possible to exchange current between districts by means of large-capacity trunk lines linking them together ; and in this way generally to increase the reliability of the supply, and at the same time obtain greater economy in operation by concentrating the demand on a few of the most economical stations at times of light load.

(2) To reduce the range of apparatus that now has to be manufactured and stocked, and so cheapen the purchase price of all electrical apparatus.

(3) To do away with the necessity of converting alternating current to direct current for general distribution and so take advantage of the cheaper method of four-wire alternating-current distribution.

Considering (1) first, trunk lines for this purpose would require to have a capacity of at least 20 000 kW, and run at a voltage not less than 110 000 between phases. The length of the lines required to connect up all large centres of supply would be roughly 1 900 miles, and the cost would amount to approximately £5 700 000.

It is obvious that the bulk of the supply in each district must be derived from stations on the spot, as the loss in transmission over 50 or 100 miles would cancel out any problematical saving that might be effected through better natural facilities. Such stations having high economy of operation can be designed, and in fact are coming into existence, and it is becoming apparent that each district can economically serve itself and provide its own stand-by plant without any necessity for drawing supplies from other districts at such an enormous capital cost.

By all means link up the individual stations in each district, at a fraction of the cost of linking up nationally, and take advantage of the high economy of operation of the best station in each district at times of light load.

It has been stated that such trunk lines will open up the rural districts throughout the country. It is, I think, obvious that such large-capacity lines cannot be safely tapped except at well-defined centres, and that the opening up of rural districts must depend upon a network of thin overhead lines radiating from the large centres of supply. The rural demand can never justify a heavy expenditure on distribution, and the greatest care and economy will have to be used in designing such distributing systems.

Turning now to (2), there should be an average saving of 15 per cent in the cost of 50-period electrical apparatus, such as generators, motors and transformers, over 25-period apparatus. This is to some extent counteracted by the higher speed at which 50-period motors run, necessitating speed-reduction gear. 50-period induction motors also create a lower power factor on the system, the difference being about 5 per cent, and this curtails the carrying capacity of the distributing mains and necessitates the installation of larger transformers.

There does not therefore appear to be much real advantage in this claim.

As regards (3), it is admitted that there is a very slight flicker noticeable on the lights when supplied with low-tension 25-period current. This can, however, be largely eliminated by suitable shading in living rooms, and it is only in these that there can be any reasonable objection raised. In factories and business premises, and even in drawing offices, it is being very largely used without any inconvenience.

In most large towns direct-current distribution is already in existence, and the recent development of the mercury-arc rectifier, whilst being admittedly rather

more expensive that a.c. transformer distribution, has solved the problem of the high cost of rotary-converter substations and the necessity of employing labour to run them for supplying outlying residential districts.

It must be admitted that direct current is safer than alternating current for domestic apparatus, and now that this apparatus is coming into such general use this point should receive careful consideration.

If railway electrification becomes general in this country—and there is strong evidence that this is coming in the near future—it seems certain that direct current at a pressure of 1 500 volts will become standard. This is being largely adopted on the Continent, and military considerations will probably weigh heavily in the matter. If so, rotary converters or mercury-arc rectifiers will probably be used, and for these 25-period current is far preferable to 50-period. We must not forget that we want the railway load to improve the load factor and reduce the cost of supply.

I have so far dealt with the suggested reasons for such a change. Let us now consider the probable cost.

It would be necessary to replace the whole of the electrical generators, transformers, rotary converters, motor-generators, motors and other a.c. apparatus with new 50-period plant. This would apply not only to the plant belonging to the supply undertakings, but also to that installed on consumers' premises.

It is estimated that about 25 per cent of the electrical plant installed in the country is other than 50-period plant.

I have made a close estimate of the capacity of the a.c. plant that would have to be replaced in the Birmingham area. This amounts to 486 870 kW belonging to the Birmingham undertaking, and 337 350 kW belonging to its consumers.

Total .. .. .. 824 220 kW

	£
The cost of this at £3 10s. per kW would be	2 880 000
Allowing scrap value for the old plant of 6¼ per cent, because there would be no market for it, would realize	180 000
The net cost of replacement would therefore be	2 700 000
There would be other costs, such as the provision of duplicate mains and switchgear to make the change-over possible, the salaries of a considerable staff, compensation for interference with consumers' business, etc., which I have estimated at ..	4 000 000
The total estimated cost for Birmingham would therefore be	6 700 000
Applying this estimate to the rest of the areas in the country using periodicities other than 50, we get a figure for the country of approximately	27 000 000

Can such a colossal expenditure be justified, for the reasons I have indicated above, reasons which, as I have shown, will not really bear investigation ?

If the Government want to develop the electrical industry and to cheapen the cost of supply, it would be far more profitable to spend the money on improving the load factors throughout the country. This could be done by electrifying the railways and equipping the coal mines with complete electrical plant for getting the coal and pumping and ventilating the mines.

Expenditure of this kind would prove to be remunerative, and could be regarded as a compulsory loan to cheapen and foster what are, after all, public utility services.

One word in conclusion on this subject. The United States of America are frequently held up as an example to be followed as regards the wonderful development of their electric supply undertakings, the large number of units they supply per head of population, and so on. I quite agree that they are long-headed, far-seeing business men, keen on efficiency and with a well-known desire for standardization where it will pay. But they run two frequencies in America—25 periods and 60 periods—and they are not contemplating changing over one of these to the other, as far as I have heard. Let us therefore take a leaf out of their book and leave well alone.

Distribution.

A year ago Mr. Woodhouse called attention to the growing cost of distribution, and to the effect that this is having on the cost to the consumer.

It may be of interest to call attention to a development that has recently been introduced in Birmingham, which has had the effect of relieving the ordinary direct-current three-wire network and its system of feeders. I refer to the arrangement that is now made to couple small power consumers to the extra-high-tension three-phase system. Hitherto this system, which is supplied at a pressure of 5 000 volts between phases, has been confined to consumers who have at least 100 h.p. installed, as each service entailed the use of three oil-switch panels for controlling the incoming and outgoing cables and the supply to the consumer. A special type of service connection has now been developed at a very much reduced cost, which makes it possible to supply power consumers whose demand is only 30 h.p. and upwards, the only difference between this and the larger consumer being that the connection is teed off the main instead of being looped in and out, so that there is no alternative source of supply. This is, however, only comparable with the ordinary power consumer off the d.c. network. It is found that this arrangement is likely to have a very beneficial effect upon the cost of distribution generally.

Training of Engineers for Supply Undertakings.

I am frequently asked by anxious parents whose boys are leaving school and propose to take up electrical engineering, what kind of training I should recommend to fit them for the profession, and I expect that the same requests are made to brother engineers in the industry. It may therefore be helpful if I outline my views on this matter.

As a broad principle, I think that a boy should enter a technical college when he leaves school. He is used to class work and to school discipline, and he can follow on along the same lines more easily than he could come back to class work after receiving practical training.

He should spend not less than three years at college, and while there he should endeavour to obtain the degree of Bachelor of Science, or some Engineering degree equivalent to it.

The necessity for demonstrating that he has a good general education as well as a thorough technical education is very important, as he will find that after he has passed through the junior stages of his career, which of course chiefly require technical knowledge, he will have to undertake duties of a managerial nature, which require a more general knowledge and the power to conduct correspondence with lucidity. This can only come easily to a man who has had a good general education, who is conversant with literature, and who is able to convey his ideas with conciseness.

After finishing his technical course at college, he should then spend at least two years in practical work in some large engineering manufacturing works. In some colleges arrangements are made for this practical training to commence during the last year of the technical training, and if this is done it is possible to shorten somewhat the total period.

The works chosen should cover the manufacture of steam-generating plant as well as electrical generating plant, and some drawing-office experience should also be included.

When this training is completed, the boy should be about 21 years of age, and he should be capable of taking a position as junior engineer in any electric supply undertaking. His advancement from this position to higher positions must, of course, depend largely upon his own ability and the impression that he makes upon those in control of the undertaking. Opportunity, however, generally plays a considerable part in his advancement. If a junior does not receive any advancement within a period of five years, it may be taken to indicate that he is not likely to progress in that undertaking, and it would be advisable for him to try to move to some other undertaking. A change of this kind will probably be beneficial to him, in that it will broaden his experience and give him better opportunities for advancement.

It is interesting to note that the Electrical Power Engineers' Association are arranging for those of their members who have passed a certain standard to be allowed to call themselves "Qualified Electrical Engineers." Before they become so qualified, they must have had a certain number of years' experience in supply undertakings of a certain size, and they must have passed the Examination required for Associate Membership of this Institution or some examination equivalent to it. I think that this is a very valuable step in the right direction, in that it will tend to ensure that engineers of supply undertakings can demonstrate that they have been properly trained.

I may say that in my own undertaking in Birmingham it has been the rule now for some years that engineers who have not passed the A.M.I.E.E. Examination or its equivalent cannot rise higher in the technical staff than a certain grade, and those men who do not so fit themselves will find in a few years that younger men will be passing over their heads. I know that it is a hard task for a man who is approaching, say, 40 years of age to turn back and take up subjects that he has not perhaps touched for many years. In the case of old servants, however, a certain amount of latitude should be allowed as long as there is proper willingness and endeavour on the part of the individual to fall in with this very necessary requirement.

I should like to take this opportunity of urging those controlling not only electric supply undertakings but also manufacturing concerns to consider very carefully whether it would not be to the ultimate benefit, both of their own undertakings and of the industry as a whole, to make it compulsory that men on the technical staff have passed a certain standard. The necessity for this is clearly demonstrated by the fact that when one advertises for a technical assistant, out of the 150 to 200 applications that are received only about 20 per cent are of any real use. The rest, whilst they have had some experience, are generally either limited in such a way that they can be trusted to handle only one particular section of the work, or they are obviously unfitted for even as much as that.

If all employers had required a certain standard, men of this kind would never have got as far as they have, and the material available to be drawn upon, while being less in quantity, would be greatly improved in quality.

I am convinced that, by the methods I have outlined, the profession will be able to obtain and maintain a supply of properly trained engineers who can, when the time comes, take up and properly fill those higher positions that will become available as the older men drop out.

Conclusion.

In conclusion, from what I have said there appear to be two main points to which supply engineers should give special attention. It is apparent that great improvements have been and are being made in practically all other directions but these two. I refer to improving the load factors of our undertakings, which have to all intents and purposes stood still for so long, and to decreasing the cost of distribution, which has recently tended to increase and to counteract the economies that are being practised in other directions.

WESTERN CENTRE: CHAIRMAN'S ADDRESS

By J. WILLIAM BURR, Member.

(*Address delivered at* SWANSEA, *5th October*, 1925.)

I was recently reading, with great interest, a return of engineering and financial statistics relating to authorized electricity undertakings in Great Britain, compiled by the Electricity Commissioners. It is a most interesting and valuable compilation of returns submitted by all the authorized undertakers in the country. In their general view of these statistics the Commissioners point out many matters which should have the serious consideration of all engineers in charge of electricity supply undertakings.

I propose to take as the subject of my address one of the sub-headings in this review, namely,

THE CONSUMPTION OF ELECTRICITY IN RELATION TO POPULATION.

We are told that in 1922–1923 some 80 per cent of the undertakings had not reached a stage of development corresponding to a sale of 100 units per annum per head of population, and that sales of 300 units, or over, per annum per head of population had been attained in a few cases only.

The Commissioners also state that on the basis of the census of 1921 the aggregate population of the areas of supply of the local authority undertakings included in the return was approximately 22·8 millions, thus denoting an average sale in 1922–1923 of about 98 units per head of population in such areas. The corresponding average figure for the supply companies' areas is not given, owing to the incompleteness of the figures for the population. I think we may assume, however, with some degree of accuracy, that it does not differ from the above figure to any appreciable extent.

Compare these figures with those given by Continental engineers at the World Power Conference held at Wembley last year.

In Norway, for example, it was stated that the estimated annual consumption per head of population was 2 000 units, or 20 times the annual consumption per head of population in this country. I am quite aware that these figures apply to hydro-electric stations; all the same I see no reason why the difference should be so great. I want to discuss this point to-night and I want to discuss it from a manager's point of view rather than from that of an engineer's. The two aspects are not always the same, as we shall probably see later.

From the figures given it would appear that we have undoubtedly barely touched the fringe of the domestic load in this country, and it is certainly up to us engineers to discover the reason.

(1) Do we grasp the consumers' conditions and requirements?
(2) Is electricity available to all who require it?
(3) Have we a suitable domestic rate of charging for electricity?

Taking the first of these, do we realize that domestic consumers can easily become the greatest and most important of all users? When we do so, we shall, I have no doubt, pay them more attention in the future than we have done in the past. Most of us pay much more attention to power consumers than to domestic consumers. I am beginning to think, however, that our future demands will come from the use of domestic appliances and, after all, the business risk is certainly not so great with the domestic consumer.

We should therefore study their requirements, and should lose no time about it. We must be prepared to give the consumers what they want and not what we think they ought to have. If we think the public are wrong in their demands, it will be necessary to educate them in order to convince them that it is to their advantage to buy and use any particular piece of electrical apparatus. Educational publicity is in my opinion necessary, together with enthusiasm. We must be enthusiastic and, after all, we have reason to be. We must of course temper our enthusiasm by scientific knowledge. We must know what we are talking about. It is not the slightest use to try to mislead the public; that does more harm than good. We must find out our consumers' requirements and then put forward something which we honestly think will satisfy them.

Let me now deal with the next point: "Is electricity available to all who require it?" The answer is decidedly in the negative.

Many people in this town could not at present have a supply of electricity, whatever their wishes might be, and this remark I have no doubt applies equally to other towns, and particularly to rural districts. Why is this? Simply because the cost of running mains or transmission lines is so high that the annual return on the capital involved would not justify the expenditure in these particular districts.

Is there a way out of this? I propose to divide the prospective consumers in question into two classes: (1) Those living in the towns; and (2) those living in rural districts.

Electricity could be made available for practically all townspeople if the Unemployment Grants Committee would allow a grant in aid of the work of mains-laying, which could be carried out principally by unemployed labour.

In regard to the supply in rural districts, it is a question as to whether, even with a grant in-aid from the Government Department mentioned, it would still be a paying proposition.

It therefore means that if a supply is to be available in these districts the Government should be asked to increase the grant, or the cost of the work must somehow be reduced. I admit that the latter can only be done by co-operation with the cable, transformer and switch manufacturers. We want good and cheap cables suitable for operating at high pressure; we want cheap and reliable transformers suitable for mounting at the top of the posts carrying the line; and we want simple, cheap and reliable outdoor switchgear.

I believe that great reductions in prices can be made if the manufacturers will only take the matter in hand. Further, I would point out to manufacturers that this is a problem for them to solve and not for the supply undertaking, as the cost of generation does not enter into the matter to any great extent.

I often wonder whether or not it will be possible in the near future to transmit power cheaply without the aid of wires. I know that I shall be accused of talking nonsense, but all the same the matter has been in my thoughts for a long time, and it must be understood that I am referring to the transmission of only small amounts of power, suitable no doubt for rural districts.

In my student days I was deeply impressed by an experiment carried out by the late Dr. Silvanus Thompson, which consisted of an alternating-current electromagnet placed near a vessel of water in which floated a closed coil of wire, to which was connected a small electric lamp. I remember that the magnet was a perceptible distance away when the lamp lighted, and although I think I know some, if not all, of the difficulties in the way, I have often wondered whether or not this experiment could be extended.

In regard to legislation, I am decidedly of the opinion that the Electricity Supply Acts restrict real expansion, and that attempts should be made to remove many of the restrictions which not only hamper the industry but are, in my view, unnecessary.

I now propose to deal with the third point: "Have we a suitable domestic rate of charging for electricity?" In other words, have we a suitable tariff for domestic apparatus and, if not, is it possible to obtain one?

While I consider that the present tariffs in this country justify the use of electricity for lighting, cooking, intermittent heating and small power-consuming devices, I do not consider that they justify, except in special circumstances, the use of electricity for all domestic purposes.

Generally speaking, tariffs can be grouped under two heads: the "flat rate" system and the "two part" system of charging. In the former, one flat rate is fixed for lighting and another for other purposes. In the latter, that is the "two part" system, a primary or annual charge per kilowatt is made to cover the standing charges, and a secondary charge or small charge per unit is made for current consumed.

The idea of the "two part" system of charging is to encourage consumers to use electricity for purposes other than lighting, as the actual charge per unit is small and the more units they use the lower is the average price per unit paid.

In view of the Commissioners' remarks it would appear that there is in this country at present no tariff which would induce the domestic consumer to use electricity for all purposes, and it may of course be partly due to the cost of the apparatus.

Let us see whether there is any likelihood of the tariffs being reduced in the near future. I propose to take first the cost of generation. Is it possible to reduce this? At the present time electricity is being generated in power stations many of which are fairly old, and although they may have modern plant installed it may be that much of the obsolete plant has not been paid off. In other words, the total cost per kilowatt of available plant is considerably higher than it would be with a new station.

As our generating costs are made up of the two factors, (1) annual charges on capital expended, and (2) running costs, it necessarily follows that this fact will increase the total cost of generation. The outstanding debt on the old plant would disappear in the course of time. The question is, however, should the existing stations be allowed to extend in order to meet increased demands, or should suitable stations be erected at various parts of the country to supply this load and eventually take over the load from the existing stations?

I suggest that as soon as a new station could show a saving on the cost of supply to the consumer equal to the annual capital charges on the old station, the latter should be shut down forthwith, as by that time it has outlived its usefulness. I also think that no interest, municipal or company, should be allowed to stand in the way of this being done. In my view the Electricity Commissioners should have compulsory power in this respect, and their decision should be absolutely final.

One effect of this would be that the generation engineers of the existing stations would do their best to keep their production costs as low as possible, which is all to the public good.

When I referred to the erection of new stations I was not talking of super-stations but of medium-sized generating stations with modern plant and situated about 20 or 30 miles apart, the exact distance depending upon the electrical density of the area. These stations should be suitably interconnected, provided the generating stations are not too far apart, as not only would the expenditure on generating plant be reduced thereby but it would also improve the load factor and reduce the operating costs. It would further secure, to a great extent, continuity of supply.

Speaking generally, the economic result of any particular case could be studied before the interlinking mains were run.

In regard to the much-talked-of super-power station and its possibilities of reducing the costs of generation, I have always held the view that while the thermal efficiency of a medium-sized station, i.e. one with a plant capacity between 25 000 and 50 000 kW, might

be less than the thermal efficiency of a modern super-power station equipped with all the heat-saving appliances, it may easily be that the actual cost per unit sold will be actually higher with the more efficient plant.

The annual charges on the additional capital required to purchase the special heat-saving apparatus may absorb the value of the saving in fuel effected by the use of the plant. It may also be that the larger station has to distribute electricity over a wider area and, as a result, will have to bear higher capital charges for main transmission lines and also higher I^2R losses. It is possible for these conditions to neutralize the difference in thermal efficiency between the two stations.

When I make this statement I am assuming that the super-power station is striving for the highest thermal efficiency, and that its plant would probably consist of boilers suitable for a working pressure of between 350 and 500 lb. per square inch and a total steam temperature between 700° and 750° F., of air heaters instead of water economizers, and of water heaters for raising the temperature of the condensate on its way to the boilers, fed with exhaust steam and steam bled from the turbine at various stages.

The turbine units would, I have no doubt, have as large a capacity as possible and run at the highest speed to conserve space. The steam between the high and intermediate turbine stage would probably pass through a reheater. The exhaust pressure of the steam would naturally be kept as low as possible.

With all the heat-saving apparatus and the best modern plant it is not possible for any super-station to obtain an operating thermal efficiency of more than 25 per cent. It will be noticed that I use the word "operating" thermal efficiency, as the thermal efficiency of any plant obtained on test does not interest me.

Briefly, then, I consider a medium-sized station, well equipped with modern plant of the ordinary type, and well situated in regard to the electrical centre of gravity and the supplies of coal and water, can supply consumers as cheaply as any super-station distributing over wide areas. I would also say that in my opinion the storage of large quantities of coal, the removal of ashes, and the provision of a plentiful supply of cooling water are problems it is often difficult to solve.

In regard to generating stations generally, it is interesting to note that the maximum thermal efficiency of the most recent station was slightly under 20 per cent.

In view of the low thermal efficiency of our generating stations it may be that attempts will be made to discover a cheaper method of generating electricity. It may be that the electrically-constituted atom will be made to give up the enormous energy which it is said to possess. This may or may not be possible; time alone will tell. I do think, however, that there are great possibilities in other directions; for instance, in the carbonization of coal. It may yet be a commercial proposition for the coal to be carbonized at the power station and the liquid products and smokeless fuel marketed.

I now propose to consider the distribution costs. Is it possible to reduce these? I think so. The present costly method of laying cables is wrong. We dig up the roadway, and often the cost of reinstating it exceeds the cost of the cable. Cannot some method be devised for putting cable underground without disturbing the surface of the roadway? Thrust boring has been tried with a small measure of success. The present boring plant, however, is not suitable for all subsoils, and reliable information in regard to the nature of the subsoil and obstructions is not always obtainable. The idea, however, is good and needs developing. Co-operation is required between the Post Office and the electrical, water and gas departments so that in the event of one department opening up, the others could take advantage of the excavation if required. When a roadway is made up or relaid it will probably pay to lay ducts on both sides of it, even if the prospective demand in the district does not justify the laying of a main at that particular time. Every effort should be made to reduce the annual capital charges on the distribution system (not by "skimping" the copper, which may be false economy, but by reducing as much as possible the cost of laying). The running costs should also be reduced to a minimum.

As much attention should be paid to the possibility of reducing the distribution costs as to the generation costs. Let us assume that our generation and distribution costs are reduced to an absolute minimum—and I should like to say here that in my view this does not always depend upon the plant but often upon the operation of the same. That is where an engineer who is also a manager comes in. The manager not only studies engineering and aims at obtaining the highest possible efficiency for his station, but also studies all factors which contribute to a reduction in the working costs by careful administration and by educating all the employees. An employee interested in his work is worth two who watch the clock. The manager should know a little of psychology—many do by intuition. He must put the right men in the right place and aim for team work.

I think that it is not generally realized what difference it makes in the works costs if the staff and men all work together instead of against each other. Whilst I have no wish to favour the workmen unduly, I would say that if more time were spent in trying to get the employees interested in their work and to pull together than in reducing wages, I think it would be better for the undertaking generally. Low wages do not, in my view, necessarily mean low costs.

Having produced our units at the lowest possible cost, we must see that they are sold at a price which will give a reasonable return on the capital expenditure involved.

In municipal electricity undertakings the income need not be more than is required to cover all costs, including the capital charges and an adequate sum to be placed to reserve. If the capital necessary for municipal undertakings were secured by the Government there would be no excuse for allocating profits to the relief of the rates. Any profit should, I consider, be returned to the consumer by reducing the price of electricity. In the event of a loss, this would of

course have to be met by an increase in the price of electricity per unit.

I am afraid, however, that I am getting off the track. The point now is: Having produced electricity at the lowest possible cost, can we frame a tariff which would be acceptable to domestic consumers for all purposes? Can we frame a tariff similar in any way to the tariff which attracts consumers on the Continent and makes them use practically 20 times the amount of electricity that we do in this country?

The usual tariff on the Continent is, I believe, an "all-in" one; that is, one in which the same charge is made for electricity irrespective to the use made of it. It is so much per kilowatt-year. If, therefore, anyone pays for one kilowatt-year he may consume 8 760 units if he likes and he may use them for any purpose he desires. For example, if the charge were £10 per kilowatt-year, a consumer could use 8 760 units, for which he would pay an average price of approximately a farthing. My information, however, indicates that the diversity factor is usually 2, so that the actual cost per unit would be a halfpenny.

Somebody will no doubt point out that the charge is only obtainable in districts supplied with electricity from hydro-electric stations and that it is easy to understand why this method of charging is adopted, as the capital charges in this type of station practically constitute the total costs of production, so that within the capacity of the station the output of units effects very little the running costs.

I agree, but in view of the much higher capital charges incurred with hydro-electric stations than with steam-driven stations, and of the fact that the only seriously increased cost in the steam station with an improved load factor is the coal, I often wonder whether or not an "all-in" charge could not be made in this country. I am inclined to think that it could, under certain conditions, and I feel, rightly or wrongly, that a reasonable "all-in" charge for electricity for all domestic purposes is a big step towards the realization of our slogan "Electricity for Everybody and for All Purposes." The simplicity of the charge and the simplicity of the wiring would, I am sure, appeal to the consumer, and the exit of the integrating meter and the fact that he would not be called upon to explain the maximum-demand system to the consumer would, I am sure, appeal to the engineer.

I am assuming then, rightly or wrongly, that our problem of domestic electrification is made much simpler if we have a suitable "all-in" tariff for this purpose.

In order to solve our problem completely we must deal with two further points. The first is the wiring of premises, and the second is the equipping of the same with electrical apparatus for all domestic purposes.

I estimate the cost of suitably wiring and fully equipping a villa residence of, say, seven rooms to be £115. I include for a liberal amount of copper in the wiring and for the installation of 3 fires, 1 cooker, 1 vacuum cleaner, 1 clothes washer, 1 ironer, 1 heating element for hot-water tank, 1 small motor for cleaning knives and boots, and various pieces of small apparatus such as quick-boiling kettle, toaster, etc.

I think that the majority of people would not be prepared to pay the sum mentioned, although it would undoubtedly be saved in a very short time. We must therefore look to the manufacturers for their co-operation in this matter, with a view to a reduction in the price of the various apparatus, particularly the cooker, clothes washer and ironer. I believe that by mass production they could reduce prices enormously.

If the undertakers are prepared to take a risk by offering a suitable low "all-in" tariff to all consumers proposing to use electricity for all purposes, I think that the manufacturers should also be prepared to take a risk by producing electrical apparatus in mass at a low price and to chance the market.

The undertakers would also have to be prepared to wire premises and supply apparatus on easy terms. It may be that the manufacturers would co-operate in this way also.

I feel sure that this, in itself, would give a great fillip to the electrical industry.

Let me briefly summarize my remarks.

In order to increase the use of electricity for domestic purposes in this country we must eliminate all waste, both in time and in material, inside and outside our generating stations, and deliver electricity to the consumer at the lowest possible cost.

If we could obtain a supply of electricity in bulk from another source at a cheaper rate than our cost of generation, after taking into consideration the annual charges on any displaced plant, we must do so in the public interest and, incidentally, in the interest of the electrical industry. The Electricity Commissioners should have compulsory powers in this matter.

As far as possible the supply should be available to all who require it.

We should formulate a tariff which will encourage the increased use of electricity for all purposes by all sections of the community.

The tariff should be easily understood by the consumer and, if possible, be an "all-in" charge per kilowatt-year, so that integrating meters could be dispensed with.

A hire, or hire-purchase, scheme for installation work and electrical apparatus should also be instituted.

Manufacturers of electrical apparatus should supply apparatus and replace parts at the lowest possible price, and the undertakers should be prepared to maintain the apparatus at actual cost.

We must educate the public to use electricity in their houses for all domestic purposes. It is not sufficient to advertise freely; we must get into direct contact with the consumer.

We must have fully-equipped showrooms and demonstration rooms, and make it worth while for the public to visit them.

We must see that all our consumers are satisfied. A consumer who appreciates the value of the electric service is an excellent canvasser.

In conclusion, I ask the members to consider for a moment what it would mean, both to the electrical supply industry and to the community as a whole, if electricity were used as freely in this country for domestic purposes as it is in many others.

SOUTH MIDLAND CENTRE: CHAIRMAN'S ADDRESS

By F. J. MOFFETT, B.A., Member.

"IMAGINATION IN ENGINEERING."

(ABSTRACT *of Address delivered at* BIRMINGHAM, 21*st October*, 1925.)

Imagination is commonly associated, in the mind of the man in the street, with those possessed of an artistic talent—poets, painters, dramatists and such like. The engineer is not, as a rule, credited to the same extent with this power—at least that is my impression. He is in the minds of the general public the man who depends, for the solution of the problems set before him, partly on the use of mathematics and partly on rules and laws formulated as a result of the experience of generations of engineers. He is considered to be a matter-of-fact, sensible sort of being with whom it is slightly absurd to associate any imaginative characteristics. I fancy that even engineers themselves are to a certain extent guilty of this attitude, and I trust that in the course of my remarks I may do something to modify it.

In the most general acceptation of the term, imagination may be defined to be the power or process of producing mental pictures or ideas. According to John Stuart Mill, "I am said to have imagination when I have a train of ideas, nor is there any train of ideas to which the term 'imagination' may not be applied."

When the train of ideas simply reproduces without any material alteration the image or picture of past experiences or phenomena the process is called "reproductive imagination." When by a process of selective combination of ideas a new picture is produced, we have creative or productive imagination. In the child the imagination is usually purely reproductive: it can only pass into productive imagination after sufficient experience has been gained to create a new mental world.

Tyndall, in his essay on the scientific use of the imagination, says: "Philosophers may be right in affirming that we cannot transcend experience: we can, however, magnify, diminish, qualify and combine experiences so as to render them fit for purposes entirely new. In explaining sensible phenomena we habitually form images of the ultra sensible. There are Tories even in science who regard imagination as a faculty to be feared and avoided rather than employed. They have observed its action in weak vessels and are unduly depressed by its disasters, but they might with equal justice point to exploded boilers as an argument against the use of steam. With accurate experiment and observation to work upon, imagination becomes the architect of physical theory. Scientific men fight shy of the word because of its ultra-scientific connotations, but the fact is that without the exercise of this power, our knowledge of nature would be a mere tabulation of co-existences and sequences."

In the above words Tyndall aptly describes the creative or constructive imagination, which is composed of three factors, the emotional, the intellectual and the unconscious.

The emotional element, or the element of feeling, is the origin of all invention and discovery. There must be some urge to induce action. We all have wants, cravings, unsatisfied impulses. Frequently the need of bread and butter exerts a powerful drive. Many men have the desire to wrest secrets from nature, and others are fired with the ambition to do something to improve the conditions of life for their fellow men.

Creative imagination is accompanied by many emotions—pleasure or pain, hope or depression. Anyone who has made even a minor discovery knows the fine glow of satisfaction which results from it, the joy of success or perhaps the dejection of failure. It is a well-known fact that many inventors, in spite of continual failure to achieve success, refuse to be daunted and persist in their efforts though these are unrewarded.

A classic example of the emotional element is the discovery by Archimedes, the Greek philosopher, of the method of determining the specific gravity of gold. Hiero, King of Syracuse, was anxious to know whether the crown which was supposed to be of gold did not contain some silver. Archimedes puzzled over the problem till one day he was stepping into his bath and observed the water running over. It at once occurred to him that he could ascertain whether the volume of the crown was the same as that of an equal weight of gold by putting them separately into a vessel of water and observing the overflow. So overjoyed was he when this thought struck him, that he ran home naked through the streets of Syracuse crying "Eureka, Eureka!"

The intellectual factor involves two processes, dissociation and association.

Dissociation, the preliminary process, takes a train of ideas or concepts which it analyses, sorts out and makes suitable for the formation of new combinations. Association, the final or positive process, chiefly depends on the principle of contiguity and resemblance. The most important element in the intellectual factor is the capacity for thinking by analogy, that is, by partial and often accidental resemblance.

An illustration of the power of thinking by analogy is the discovery of the Gothic style of architecture. We can imagine an architect in the days of King

Stephen setting out to find some improved design for the construction of churches and cathedrals, and being struck by the resemblance of an avenue of trees meeting overhead to a beautiful roof. This, I believe, was the origin of the wonderful Gothic nave in some of our cathedrals.

The unconscious factor is in many ways the most wonderful of the three, as its working appears so mysterious. Very frequently this factor is spoken of as inspiration, which implies that the ideas are supplied by some external power.

We all, I fancy, are in the habit of saying at times when faced by some knotty problem, that it is better to sleep on it. This means nothing but that we are deliberately giving the unconscious element an opportunity to come into action. I am so firm a believer in the value of the unconscious element that I much prefer, when engaged on any specially difficult work, to call a halt for some few days and allow my mind to put in what I may call its automatic work. In this connection change of scene and complete rest greatly assist the process, and I feel sure that most members will agree that holidays are by no means waste of time, even when judged simply by the criterion of achievement.

Ribot, a French philosopher, asked an engineer of his acquaintance to describe how his imagination worked, and this is his description: "The so-called creative imagination surely proceeds in very different ways according to the temperament, aptitudes, etc. We may, however, as regards mechanical inventions, distinguish four sufficiently clear phases—the germ, incubation, flowering and completion.

"By germ I mean the first idea coming to the mind to furnish the solution for a problem that the whole of one's observations, studies and researches has put before one, or that put by another has struck one.

"Then comes incubation, often very long and painful or, again, even unconscious. Instinctively, as well as voluntarily, one brings to the solution of the problem all the materials the eyes and ears can gather.

"When this latent work is sufficiently complete the solution suddenly bursts forth, it may be at the end a voluntary tension of mind or on the occasion of a chance remark. But this image always appears simple and clear.

"In order to get the ideal solution into practice there is required a struggle against matter, and the bringing to an issue is the most thankless part of an inventor's work. In order to give consistency and body to the idea caught sight of, one must have patience and perseverance through all trials. One must view from all sides the mechanical agencies that should serve to set the image together until the latter has attained the simplicity that alone makes invention valuable. Thanks to a profound acquaintance with known mechanical methods, the inventor succeeds through association of ideas in getting novel combinations producing new effects, towards the realization of which his mind has in advance been bent."

The above description indicates clearly the stages on the road to competed achievement of the creative or constructive imagination.

In the realm of scientific discovery Michael Faraday stands out as one of the great figures, and it is very fitting to refer to his methods when addressing a gathering of electrical engineers. It will be seen that imagination played a great part in his achievements.

As many of my audience will remember, Faraday at the age of 13 was apprenticed to a bookbinder in London with whom he served for 8 years. During this time he was greatly interested in science and devoured any scientific books which came into his hands. Amongst the books which he bound were some scientific works, which he took the opportunity to absorb. At the age of 22, to his great joy he was appointed assistant to Sir Humphrey Davy at the Royal Institution, and 18 years later at the age of 40 reached the crowning point of his career, when he made the epoch-making discovery that a conductor when moving through a magnetic field had current generated in it. The 18 years at the Royal Institution had been spent largely in wide reading and in confirming by experiment the phenomena described in the books he read. This was the preparatory period during which the facts and material necessary as a basis for the due operation of his imagination were collected and absorbed. His mode of attacking any problem was intuitive rather than logical, though when on the track of a solution his reasoning, proceeding by the process of elimination, of trial and error, was sound and logical enough. Helmholtz in his Faraday Lecture of 1881 stated: "It is in the highest degree astonishing to see what a large number of general theorems, the methodical deduction of which requires the highest powers of mathematical analysis, he found by a kind of intuition, with the security of instinct without the help of a single mathematical formula. The fundamental conceptions by which Faraday was led to these much-admired discoveries have not received an equal amount of consideration. They were very divergent from the trodden paths of scientific theory and appeared rather startling to his contemporaries. His principle was to express in his new conceptions only facts, with the least possible use of hypothetical substances and forces."

Faraday himself in a note on the margin of one of his papers warned himself to be practical: "I must keep my researches really experimental and not let them deserve anywhere the character of hypothetical imaginations."

Tyndall in his address on "Faraday as a Discoverer" says: "When an experimental result was obtained by Faraday, it was instantly enlarged by his imagination. I am acquainted with no mind whose power and suddenness of expansion at the touch of new physical truth could be ranked with his. Sometimes I have compared the action of his experiments on his mind to that of highly combustible matter thrown into a furnace: every fresh entry of fact was accompanied by the immediate development of light and heat. The light which was intellectual enabled him to see far beyond the boundaries of the fact itself, and the heat which was emotional urged him to the conquest of this newly revealed domain. But though the force of his imagination was enormous, he bridled it like a mighty rider

and never permitted his intellect to be overthrown. In virtue of the expansive power which his vivid imagination conferred upon him, he rose from the smallest beginnings to the grandest end."

Faraday admitted that he was no lover of mathematics, and pleaded almost pathetically in a letter to Clerk Maxwell for some easier mode of expressing scientific ideas. "There is one thing I would be glad to ask you," he wrote: "When a mathematician engaged in investigating physical actions and results has arrived at his own conclusions, may they not be expressed in common language as fully, clearly and definitely as in mathematical formulæ? If so, would it not be a great boon to such as we, to express them so—translating them out of their hieroglyphics, that we also might work upon them by experiment?"

I feel sure that many of the members of this Centre will sympathize with Faraday in his appeal. Surely many of the papers read before this Institution could with advantage leave out the pages of symbols and substitute, as Faraday says, common language.

Tyndall comments on Faraday's lack of mathematical training in the following words: "It is impossible to say how a certain amount of mathematical training would have affected his work. We cannot say what its influence would have been upon that force of inspiration which urged him on: whether it would have daunted him and prevented him from driving his adits into places where no theory pointed to a lode. If so, then we may rejoice that this strong delver at the mine of natural knowledge was left free to wield his mattock in his own way. It must be admitted that Faraday's purely speculative writings often lack that precision which the mathematical habit of thought confers. Still, across them flash gleams of prescient wisdom which will excite admiration through all time: while the facts, relations, principles and laws are sure to form the body of grand theories yet to come."

This anticipation of Tyndall's was amply fulfilled. Clerk Maxwell and Kelvin who followed him worked out fully and completely the theories underlying the discoveries of Faraday.

In his aversion to the use of mathematical methods Faraday is a striking contrast to Newton. Sir Isaac Newton as a boy was extremely interested in mathematical and mechanical problems, and on this account was sent to Trinity College, Cambridge, at the age of 19. Four years later the method of fluxions, as he called it, occurred to him, and during the subsequent three or four years he worked out the theory of the fluxional calculus. At the same time he was experimenting with prisms and lenses and also with chemical apparatus, showing that he had an experimental as well as a mathematical side to his nature.

At the age of 25 he was elected Fellow of his College, and two years later wrote a mathematical paper which resulted in his being appointed Lucasian Professor of Mathematics.

The science of optics now attracted his attention. He invented a reflecting telescope the lenses for which he prepared in his own glass-works, and while experimenting with this discovered that white light was a mixture of differently refrangible rays of various colours.

In his optical work Newton used what may be called the experimental-mathematical method, in which there were three steps. First, determination of the fundamental concepts by experiment from the phenomena. Second, mathematical elaboration of these concepts, usually by the aid of the calculus; and last, the verification of the mathematical deductions, again by experiment. In spite of his great mathematical powers, he was accustomed to confirm his deductions by experiment. His great work in the discovery of the laws of motion and of gravity may, however, be said to be almost entirely the achievement of his wonderful mathematical imagination.

In commerce again there is a great field for the imagination. In fact the stories of the development of some of our great commercial enterprises read like romances. Many instances will no doubt occur to my hearers, but I propose briefly to refer to the career of Henry Ford. He was born on a farm at Dearborn, Michigan, U.S.A., and it was intended that he should follow his father's calling. Apparently from his early years it was borne in upon him that there was too much hard hand-labour on farms. This feeling set in motion his imagination, which led him to suspect that much of the work might somehow be done in a better way. The better way appeared possible through the application of mechanics, for which he had a strong bent. When quite a boy he had a workshop with home-made tools—in fact his toys were all tools.

At the age of 12 occurred a big event—Ford says the biggest event of his early years. While his father and he were driving to town one day, they met a portable engine and boiler used for driving a threshing machine. Ford had previously seen many of such engines drawn by horses, but this was the first he had seen which was self-propelled by means of a chain between the engine and rear wheels of the wagon on which the boiler was mounted. It was this encounter which suggested to him by analogy the possibility of automotive transportation, as he calls it. His first idea was to develop a tractor which would take the place of horses in the hard labour of ploughing and also be suitable for hauling a wagon along a road. He found, however, that people were more interested in something which would travel along the road, and he accordingly devoted his energies to the production of a car. The first he built was a steam car, which was not satisfactory owing to its weight. The idea of an internal-combustion engine was suggested to him by the Otto "Silent" gas engine which was being developed in England, and after being called in to repair one of these engines he built a small model to see that he understood the principle. This model worked well, and in 1890 he commenced a two-cylinder engine. In 1892 he completed his first motor-car, on which the two-cylinder engine was fitted, and this ultimately ran to his satisfaction. This was the first and, for a long time, the only motor-car in Detroit, and Ford was the first licensed chauffeur in America. Encouraged by this success, he determined to devote his energies to the manufacture of motor-cars, and a company was formed to exploit his invention. The methods adopted by the company did not commend themselves

to him. As he himself says in his autobiography, "The most surprising feature of business as it was conducted was the large attention given to finance and the small attention to service. That seemed to me to be reversing the natural process, which is that the money should come as the result of work and not before the work. An article was not built with reference to how greatly it could serve the public, but with reference solely to how much money could be had for it. A dissatisfied customer was regarded, not as a man whose trust had been violated, but either as a nuisance or as a possible source of more money in fixing up the work which ought to have been done correctly in the first place. The automobile business was not on an honest basis, to say nothing of being from a manufacturing point on a scientific basis.

"I determined absolutely that never would I join a company in which finance came before work or in which bankers and financiers had a part. And further, that if there were no way to get started in the kind of business that I thought could be managed in the interest of the public, then I simply would not get started at all. Business as a mere money-making game was not worth giving much thought to and was no place for a man who wanted to accomplish anything. The only foundation of real business is service. A manufacturer is not through with his customer when a sale is completed. He has then only started with his customer. The sale of a machine is only something in the nature of an introduction. If the machine does not give service, it is better for the manufacturer if he never had the introduction, for he will have the worst of advertisements—a dissatisfied customer. It is the function of business to produce for consumption and not for money or speculation. Producing for consumption implies that the quality of the article produced will be high and that the price will be low. The producer depends for his prosperity upon serving the people, and money comes naturally as the result of service."

If time had allowed I might have referred to Ford's general methods, his factory system, his treatment of his workers, his labour-saving devices—but I consider that the greatest discovery Ford has made is the principle of service.

I have referred to Faraday and Newton in scientific discovery, and to Ford in commercial discovery. These are men who stand out above their fellows. We cannot all be Faradays or Fords, but all of us in whatever department of engineering we are engaged require the creative imagination. The layout of a power house and a system of distributive mains, the manufacture of machinery for the generation and transformation of electrical energy, the design of switchgear, the installation of electric power and light, the provision of telegraphic, telephonic, and wireless communication, the development of furnaces and welding appliances—all the wide range of constructive problems which confront the electrical engineer—involve the faculty of discovery and invention in a greater or less degree.

It is often said in a semi-jocular strain, that an engineer when called upon to produce a scheme has only to take from the pigeon-hole the appropriate specification. This statement is wide of the truth. In each new scheme much of the work will proceed on the lines of previous schemes, but there are always new problems which demand the assistance of the imagination for their solution. Seldom, if ever, are the solutions of two apparently similar problems identical, apart from the fact that with the increase in our knowledge new methods of solving any particular problem are continually becoming possible.

Recently I paid a visit to the Belfast and Edinburgh generating stations. Both are of approximately the same size, both are placed on the sea coast, both were erected about the same time, and yet the layouts differ very considerably, showing the drift of different creative imaginations dealing with a problem in which the general governing factors were identical.

The field open to the electrical engineer with creative imagination is enormous. Take the steam-driven generating station. It is well known that the overall efficiency from the heat energy in the fuel to the electric energy at the switchboard is dismally low, not more than, say, 10 per cent in the average station, and 20 per cent in the most recent super-station. Surely there must be some means of reducing this enormous waste of heat energy, from 80 to 90 per cent of the total energy in the fuel. On a small scale much higher overall efficiency has been obtained through the utilization of the waste heat in the exhaust. No remedy, however, is yet forthcoming for the large station.

Take the question of storage. The lead accumulator has held the field almost without threat of competition for the last 30 or 40 years. It is the weak link in any scheme which involves the storage of energy, since it has an extremely low capacity compared with its cost and weight, and its life even when treated with the utmost care is very short. The discovery of a more efficient method of storing electrical energy which would compare favourably with the gasholder would greatly facilitate the generation of power by means of the tides or the wind. Want of a better means of storage of electrical energy is the chief obstacle in the way of deriving vast supplies of power from the energy of the wind.

Take the question of atomic energy. This may be looked upon as a subject which concerns the physicist rather than the electrical engineer, but at any moment it may become of vital importance to the latter. As is well known, some of the most able and acute minds in this and other countries are devoting their energies to this question, and new light is continually being gained through their efforts. Sir William Bragg says: "I am of opinion that atom energy will supply our future need. A thousand years may pass before we can harness the atom or to-morrow might see us with the reins in our hands. That is the peculiarity of physics—research and accidental discovery go hand in hand."

I have suggested one or two fields in electrical engineering where there is unbounded scope for the creative imagination, but I am sure it will be agreed that there is practically no limit to the number of scientific problems awaiting solution.

Imagination is possessed in some degree by all normal persons. I would venture to claim that the average engineering designer's imaginative power is above the common level, but in view of the nature and scope of his work I consider that the development of this faculty has not kept pace with his technical powers.

There is endless scope for the exercise of the imagination by the designer, as practically the whole of his creations are intended for the use of other people. Granted a sufficiently lively imagination, many of the troubles due to inaccessibility, inadequate protection, want of provision for renewal of wearing parts, in fact to failure to realize the point of view of the user, might be largely overcome.

In electrical apparatus in particular there appears to be a boundless field for imagination, especially in connection with appliances in which means have to be devised to circumvent the unconscious human tendency to commit suicide. The designer must in fact bring himself to realize that the desire to gratify the sense of touch has not yet been eliminated, even in the trained electrical attendant. To still greater lengths must the use of the imagination be carried in the design of apparatus for domestic use. The designer must by full use of his imaginative faculty suppress for the time being the instincts of his training, so as to adjust his focus to see, say, a griller switch, through the eye of the average cook.

In no sphere is the need for imaginative enterprise more immediately apparent than in industry, where the search for an explanation of trade depression is engaging so many minds. Lack of imagination in catering for foreign needs and conditions may not be the principal course, but I suggest that it may be a strong contributory factor in the decline of overseas trade: the time has passed when our wares will sell on the strength of their place of origin.

In the conduct of human relationships the necessity for what may be termed the sympathetic imagination is truly enormous. The relations between employers and employed are at the present time in a very strained condition. I suggest that one of the principal obstacles in the way of a solution of many of our difficulties is simply lack of imagination on both sides.

On the present occasion I have only glanced at these questions: to deal with them in detail would require another paper.

What are we doing to encourage the growth of the imagination? The child is father of the man and we needs must start with the child.

Professor Welton in his work on the psychology of education writes as follows: "From the simple contrivances of the child to the invention of the most delicate or the most powerful machinery or of the most elaborate instruments for aiding advance in science, each is the realization in appropriate material of an ideal plan adapted to an ideally conceived end. For such inventions the mind must not only be stored with all pertinent knowledge but must have a particular bent. We all make our little inventions in daily life, but those who first imagine, then produce—it may be in successive stages each more perfect than the last—instruments that change profoundly the condition of men's lives or knowledge, are few. Nowhere can we better learn the lesson that ideals cannot be taught.

"Material and, it may be, inspiration and encouragement may be given, but the inventive mind can only work when free and untrammelled. The course of the school is obvious. In all constructive work it should leave as free a hand as possible in the planning: should welcome originality even if it spoil material: and should give to those who show they can imagine new constructions generous opportunity to carry out their practical ideals."

Sanderson of Oundle made it his life's work to develop a system of education in public schools which would appeal to the constructive and creative instincts of the boy. Many will be familiar with his methods, but for those who are not I will endeavour to give a brief description of them.

The root idea underlying all his work was that science did not hold the position it should in modern education. In teaching, the method of research should be adopted as far as possible: boys and even quite young children should be allowed to discover things for themselves. Whilst holding that language and literature must always form the basis of education, he believed that science properly taught supplied something which could be obtained in no other way.

Sanderson was a great believer in using what he called the romance of science as a stimulus to his boys. Faraday was a great source of inspiration to him—in fact Faraday may be said to have been constituted the patron saint of Oundle School.

Sanderson's methods, as would be expected, aroused great opposition from the traditional type of school, but he steadily proceeded along the path he had chosen, and there is little doubt that he has considerably influenced the methods not only of the public schools of the country but also of the elementary schools.

In my opinion every possible effort should be made in all schools to rouse the interest and enthusiasm of the scholars, in other words to stimulate to the utmost their imagination. In the majority of public schools the zeal for sport of every kind is tremendous. Is it not possible to awaken similar zeal for the pursuit of knowledge?

As a final word I would say that imagination is one of the greatest faculties with which we are endowed. If we give full scope for its exercise and have the courage to follow its lead, we shall have added power to deal not only with the technical problems which confront us as engineers but also with the wider problems of human relationships, to the solution of which engineers can make valuable contributions.

NORTH-EASTERN CENTRE: CHAIRMAN'S ADDRESS

By R. W. Gregory, Member.

(Abstract *of Address delivered at* Newcastle, *26th October*, 1925.)

I have often felt that an essential part of a Chairman's address should be a plea of justification for the continued existence of the profession to which he belongs.

Engineering is one of the oldest professions. Throughout the ages the principal justification for the existence of the engineer has been that he has made it possible for large numbers of people to live together more or less healthily in towns and cities. By living in cities, by rubbing shoulders with his fellow men, by a mixed process of competition and combination, man has progressed in the arts and become civilized; in fact he has become urbane.

Cities have been a necessity of civilization, not only because of this rubbing of shoulders and crossing of wits, but also because the gregarious habit reduces the cost per head of the necessities and the desirable comforts of life. Owing to this, life can be won more easily in the city, there is more leisure for the practice of the arts and more wealth available for the establishment of schools and universities and for investment in capital works to make life still easier.

Living in cities, however, especially in the industrial cities of this country, does not yet provide the perfect life. We engineers have still a great deal to do towards the improvement of our cities—to being in sunlight and quiet, and pure air and cleanliness.

The present trend of engineering appears to be towards bringing urbanity to rural surroundings, making it possible for the rustic, living in the sweetness of the country, to obtain many of the services which in the past were only obtainable in the smoke-laden air of the city. Electricity is perhaps the brightest of the magic buttons which are being rubbed to attain this end. It is, I think, a safe thing to predict that during the next decade electricity and the automobile will radically alter the life of rural England.

I sometimes wonder whether we English are as enterprising a people as we like to think ourselves to be. When one has travelled abroad, one sometimes returns with the feeling that our old country is not quite as agile as she was in her younger days during the great Victorian period. She appears to be hampered with a load of existing capital works and legal restrictions which, in the electrical industry at least, prevent her from getting on with the business as quickly as she ought to do. In fact, she is really overburdened with her own civilization.

I remember when I returned from a visit to the United States two years ago, full of the tonic effect which is vulgarly called " beans," and which all engineers, but particularly electrical engineers, must experience when visiting that engineer-made country, feeling just a little depressed by this, my home town—with its little, low, smoke-grimed buildings, its antiquated hotels and generally its lack of light and sparkle, both by day and by night; and it was a little galling for me, an engineer, to have my faith in the old country restored, not by the urban enterprises of the district, but by the marvellous organization and wonderful exhibits of the Royal Agricultural Show. I am not using this as an argument for rural electrification or a return to the simple life, but merely to emphasize my point that in matters of engineering enterprise, particularly electrical engineering enterprise, we are tending to follow rather than to lead—although perhaps not so much in design as in application.

We have to keep clearly in mind that electrical development is a world movement. The whole world, civilized and uncivilized, is crying out for electric power. The men in the bush and the backwoods, the inhabitants of the high veldt and the uttermost islands of the Empire, are developing their electric supply systems as fast as or faster than we are, for they all see in electricity the means of obtaining the service they need to increase the output of their industries and to improve their existence. Whatever England does in the practice of electrical development may have little effect on the rest of the world, but a large effect on England herself. The rest of the world is not waiting for England to electrify, and unless she is practised in the art at home she cannot reasonably expect to get her share of the world trade in electrical machinery and appliances, a trade which is bound to grow in volume year by year.

The reluctance of our railways to electrify their main lines may be justified by the economics of the moment, but it is conceivable that the electrification of a British main line would have far-reaching effects on our foreign and colonial trade in railway-electrification material. Moreover, as a training ground for men who could take the home country practice and tradition abroad, it would be invaluable to the Empire.

Again, we have to remember that the engineering of the backwoods is not yet to be learned in England. The essentials of such engineering are high voltages and low capital cost, involving cheap methods of construction and risks balanced against service.

Experience at home in rural distribution and the development of cheap methods of supply would surely have its effect on our export trade; for, when given the chance, British engineering brains are capable of producing an engineering practice which rivals the world.

Rural electrification deserves the study of all supply engineers. The characteristics of rural loads are that they are sparsely distributed and small in quantity. The capital cost per kilowatt connected must therefore be larger than in the towns and industrial areas,

and the essential to the solution of the problem is the reduction of the capital cost, even at the expense of the service given. A 99 per cent service is considerably cheaper to give than a 99·9 per cent service, and the former is all that is necessary, at least during the pioneering period.

During the past summer our city and district were honoured by official visits from the Institution of Mechanical Engineers and the Royal Institute of British Architects. The Mechanical Engineers during their visit paid homage to the memory of that great Tynesider, George Stephenson, when they celebrated the centenary of the first steam railway, the construction of which, to our everlasting honour, was due to the brains and enterprise of North-East England.

The visit of the Royal Institute of British Architects interested electrical engineers in many ways. There are many interests which are common to the two professions, and at the present time the views of the one profession of the work of the other are bound to cause a reaction which will affect the community at large.

At the Conference in Newcastle there were those who expressed sorrow at the manner in which Dobson's classic façades had been treated by the men who worked behind them. Shop fronts had been pierced into them which ignored altogether the architectural form of the buildings of which they were part. Gaunt gilt letters sprawled across the rows of fluted pilasters, and vulgar night-signs were being erected in growing numbers, which showed a lack of reverence for the classic tradition and spoiled the effect the architect had intended his buildings to produce.

It is easy for the student and specialist to follow and to agree with the architect's point of view, but to the man in the street, and particularly to the man who owns a shop, this point of view is obscure. If he could express himself in architectural language he might retort that this apparently sad state of affairs is brought about by an endeavour to force a dead art upon a living people.

Those of us who have seen the effect of flood-lighting on some of the business buildings in other countries, know how electricity and architecture can combine to make advertising beautiful. Even the much-maligned electric night-sign of the pills, whisky and beef-extract order is not without its charm. It is not all ugliness, and in this clouded climate of ours it does add a little sparkle and gaiety to an otherwise drab outlook. I am not alone in thinking this and I would ask you to listen to the words of Mr. G. K. Chesterton * when he was taken on to Broadway by night :—

> "When I looked at the lights of Broadway by night I made to my American friends an innocent remark that seemed for some reason to amuse them. I had looked, not without joy, at that long kaleidoscope of coloured lights arranged in large letters and sprawling trademarks, advertising everything from pork to pianos through the agency of the two most vivid and most mystical gifts of God—colour and fire. I said to them in my simplicity—'What a glorious garden of wonders this would be to anyone who was lucky enough to be unable to read.'"

* G. K. Chesterton: "What I saw in America."

Are we to give up all this joy and wonder because we *are* able to read and would be pleased if pills were prohibited, beef extract banished and whisky winked at ?

The outstanding characteristics of the majority of our industrial towns and cities are their darkness, dinginess and dirtiness.

Our architects give us buildings rivalling the ancient models which inspired them, but under our sunless skies and in our smoke-laden atmosphere they lose much of their charm, even when fresh from the mason's chisel. After a few years they become black, the effects of light and shade disappear and with them much of the impression which the architect intended to obtain. Small wonder, therefore, that the man in the street ceases to respect the architecture of his town and gives that lack-lustre look when talked to by an enthusiast. Dr. Dunn tells us that the annual sootfall on Newcastle is 6 500 tons, and Newcastle is a comparatively clean town. This is the root of the evil.

The art of Greece reared in sunshine was not made to be transplanted into mirk. Venus with a sooty face is a slut, and Eros a street urchin. We may not acquire a Mediterranean sky or a vertical sun, but we surely ought not to defile our atmosphere or to add deliberately to the fogs and mists to which our country is subject.

For the sake of cleanliness and the health and cheerfulness of the community, everything should be done to encourage the use of smokeless heating systems, of which there are so many available. Gas engineers, electrical engineers and heating engineers together can provide for both domestic and public buildings means of heating which do not foul the atmosphere, and the general use of these systems would, I am convinced, do more for the general happiness of the community than a dozen Acts of Parliament.

The electric supply industry in Great Britain is at present in a state of rapid development, both technically and economically. The economic trend in generating-station practice is towards the large station with a plant capacity of the order of 200 000 kW, and with a site of sufficient area to double this capacity. The generating unit is growing, 40 000-kW machines exist in this country, and manufacturers are prepared to quote for sets of 60 000 kW or over. A plant of this capacity has already been built on Tyneside to an American order, and is now in commission in Chicago.

The reason why development is in this direction is, of course, an economic one. The increase in demand itself forces up the size of the machine. One cannot imagine a power station containing two hundred 1 000-kW sets—its operating costs would be enormous. In addition to this, the efficiency of the plant tends to increase when the size is increased, and, within limits, the cost per kilowatt of plant capacity decreases. The saving in capital is perhaps more vital than the increase in economy.

The fact that the large steam turbine is still the most efficient prime mover affects the economic position of the generating station, for the efficiency of the machine is vitally dependent upon the vacuum obtained by the condensing plant; and, with the present state of the art, to obtain a good vacuum an ample supply of water

is required. This, of course, is common knowledge among engineers, but now that the electric supply business is becoming of interest to the politician and is one in which the man in the street will very soon consider himself a competent authority, it is as well to state here that in this country, where distances from the sea are short and the coal widely distributed, in the interests of general economy it is more important to place our generating stations on our estuaries and larger rivers that it is to build them at the pit-head. The American National Electric Light Association, a very live body which understands the value of publicity, has issued a series of pamphlets on this subject to the general public. Here is an extract from one of them :—

> "Certain publicists have already given fresh currency to the old suggestion that all electricity should be generated at the mouth of the coal mines and distributed from there. They do not know that (1) Electricity can be economically generated by steam, only near a large supply of pure water. For every ton of coal burned in an electric light and power plant 400 to 600 tons of water must be pumped to condense the steam that drives the big turbines. Most coal mines are not near water. (2) The longest distance that electricity can be transmitted economically over wires at present and compare favourably with local power is 250 miles. (3) The cost of generating electricity is only about 20 per cent of the total bill (just as the cost of raising and slaughtering a steer is a small fraction of the cost of your beefsteak). The other 80 per cent is the cost of delivering the service from the power plant to the consumer.
>
> "Electricity is a magic thing—very stimulating to the imaginations of orators and self-appointed friends of the people. But the business men who have built up the electrical industry are not overlooking any bright ideas. They are alive to every possibility of reducing costs and improving service."

The large generating station brings in its wake increasing problems of control and distribution, and certain branches of this side of the electric supply industry have a little difficulty in keeping pace with the rapid growth of the generating station.

Since 1914 the size of the generating unit has grown from about 12 000 kVA to 60 000 kVA, and the size of the generating station has grown from 50 000 kVA to 200 000 kVA. During the same period the rupturing capacity of the largest circuit breakers has grown from 500 000 kVA to not more than 1 500 000 kVA, and the carrying capacity of the largest transmission cables from 11 000 kVA to 18 000 kVA.

In 1914 the rupturing capacity of generating-station switchgear was sufficient to cope with a short-circuit on the station without fault-limiting devices. To-day it is not. Also, in 1914 one transmission cable was able to carry practically the load of one generator. To-day three or four cables are required for this duty.

The capacity of the generating plant has grown more rapidly than the rupturing capacity of the circuit breakers controlling these plants. The 200 000-kVA station has arrived; the 2 000 000-kVA circuit breaker has not. The reason is well known. The generating unit can be thoroughly tested out before being put into commission. The data obtained provides the knowledge for advancement in design. The switchgear manufacturer, however, has never been able to achieve this happy condition of affairs. It is only comparatively recently that any organized scientific research has been done on the behaviour of oil circuit breakers and the rating of rupturing capacity.

The present state of large circuit-breaker design is that it is possible to obtain from most of the reputable manufacturers circuit breakers with a rated rupturing capacity approaching 1 500 000 kVA. This is not a tested-out rating, but is based upon the experience of the designers. The general trend in the use of such circuit breakers is to limit their duty to a figure well inside their rated capacity. This is done by the employment of reactances and neutral resistances, and by designing and arranging the gear to make it difficult for a fault between phases to occur in the precincts of the station.

Pending further experience and knowledge of circuit-breaking phenomena, these methods of limiting the breaking duty, which are well tried out and comparatively simple to apply, will no doubt be the practice in large stations for some time to come. By limiting the fault current at the power station the duty of the switchgear on the system is also eased. This is very desirable, because it is not economically possible to employ maximum-rated circuit breakers at all points of high-tension service.

The recent development in switchgear which is most interesting to us on Tyneside is that of the wider adoption of switchgear of the metal-clad type for first-grade duty. This type of switchgear originated on Tyneside, is now built by most of the important switchgear manufacturers in England for use at all voltages up to, and including, 33 000, and I believe that I am speaking truthfully when I say that there are some who have ambitions to build metal-clad gear for higher voltages than this. Logically this type of switchgear should, and in practice it does, tend to follow the development in underground cable design, for it is a fitting termination to the lead-sheathed cable.

Before leaving the consideration of heavy-power switchgear I should like to plead for an increase in the national facilities for research in circuit-breaker phenomena. Excellent work is being done under Mr. Wedmore's guidance by the Electrical Research Association, but the scope of their research would be considerably increased if they were allowed to "experiment" with a really large plant capacity. The larger manufacturers of switchgear in other countries have themselves realized the necessity of expensive heavy-powered testing plant, and it is time that a similar plant was erected in this country. Could not the larger switchgear manufacturers combine to provide a proving house which would be worthy of the industry and the country? The organization to make such a venture possible already exists. A well-equipped research

laboratory would hasten the day, which I feel is bound to come, when the ferocious arc (our modern Lambton worm), which is now a necessary evil, will be at least tamed, and the breaking of an electrical circuit will not be explosive.

The art of cable-making and cable-using is at present in a wonderfully interesting state of development, and although it is, perhaps, true that this section of the industry lags behind those of generation, transformation and overhead transmission, yet the increased knowledge of dielectric phenomena now available has so widened the field of vision of the cable engineer that he is endeavouring to rival the feats of the pole-line man and to turn out cables for use at voltages which, in the past, could only be applied to bare conductors hung on insulators.

The economic problem is, of course, well known. High voltages are advantageous, not only to transmit power over long distances, but also to transmit large quantities of power into the centres of our large cities. Roughly speaking, the economic unit of transmission corresponds to the unit of generation, and, whereas in the past we were content to carry some 10 000 kW per line, we shall in the near future carry on one line some 50 000 or 60 000 kW, which will mean the use of three-phase voltages of 100 000 and over.

Whether the cable makers will achieve this end by the use of lead, paper and oil, it is perhaps too early to say. If a consistent, imperishable, homogeneous and flexible dielectric should be discovered it is probable that it would, in time, supersede paper and oil.

Power-transformer design continues to keep pace with the developments in other sections of the industry. Transformers can be built of capacities equal to those of the largest generators, and for use at voltages as high as can be dealt with by the transmission lines. Moreover, the modern large transformer is usually sturdy enough to withstand the stresses of short-circuit and surge potentials.

One of the primary problems of transformer design is that of the cooling of the windings to maintain the insulation, and this resolves itself into knowing all about the "hot spots" which determine the rating of the transformer. What the user wants to know is the relation between the "hot spot" temperature and the temperature of the oil.

There is not much published information on this subject in this country, and manufacturers as a body do not yet encourage the loading of their transformers on the basis of oil-temperature measurements. The point is one of great importance to the transformer user, for if degrees Centigrade and not amperes were the measure of the safe load on the plant it would generally result in the reduction of the capital cost of a service. If the manufacturers would sell their transformers on the understanding that they would be safe so long as the temperature of the oil as indicated on the thermometer provided with the transformer did not exceed a stated figure, then full advantage could be taken of the variations of load factor and ambient temperature. Rotary converters for traction work in automatic substations are entirely controlled by temperature-indicating instruments. Then why not transformers? The time is ripe for the distribution and use of such knowledge.

In the largest transformers the heat generated by the losses is extracted from the oil either by water or by forced air. A characteristic of the time, however, is the rapid increase in the sizes available of "self cooled" transformers. Transformers up to 10 000-kVA capacity can now be obtained which keep themselves cool by the natural circulation of the oil through nests of pipes or radiators hung on the sides of the tanks containing the transformers.

Overhead transmission lines as now constructed are remarkably reliable. The mechanical and electrical problems of design are well understood and on the first-grade lines throughout the world little trouble is experienced from the effects of wind and weather.

The main enemies to continuous service are birds and lightning, and, of the two, birds are perhaps the deadlier. We know of bird troubles in this district, and "crow guards" are an essential part of the construction of our high-tension lines. In India many of us have heard of delays to service caused by crows building nests on cross-arms and pole tops, the nesting material, sad to relate, sometimes being the scrap ends of armouring wire left from underground cables being laid in the district. On the famous Big Creek 220 000-volt line in California the most numerous interruptions to the service in the early days were caused by the matutinal evacuations of large vulture-like birds who had spent the night on the cross-arms above the insulator strings.

Lines designed for 100 000 volts are practically immune from lightning troubles. It is uneconomic, however, to insulate all lines and the apparatus connected to them for 100 000-volt working, and so, at the moment, the lightning problem resolves itself into the protection of the line insulators against destruction from arc-overs, and the protection of the insulation of the apparatus connected to the line.

The study of lightning and the effect of lightning on transmission lines is still being actively pursued, particularly in Sweden and America. The wider knowledge of high-frequency phenomena now available from radio research and experience also helps in the attack on the problem, and it is probable that lightning and surge protection will ultimately be achieved by connecting, directly in the line, apparatus which will absorb the energy of the surge before it reaches the apparatus to be protected and without any power current leaking to earth, that is, the line will not be shut down even temporarily when under the influence of lightning.

The problem of the day, however, in this country is not the construction of first-class high-grade high-pressure lines, but the construction of cheap high-pressure distribution lines which would enable the supplies to be given economically to farms, villages and sparsely loaded districts. Small capital cost is essential for this class of work, but it is difficult to say how this can be attained under the existing Regulations covering the construction of high-pressure lines.

The use of conductors of high-tensile metals such as

steel and silicon bronze in place of copper or aluminium helps a little towards cheapening the lines, but it seems impossible in this country ever to get the cost down to the £200 or £300 a mile so common in America. We should be pleased if we could only get lines constructed at double this figure.

There has been much said previously both in the Press and from the platform on the desirability of easing the various Regulations and restrictions which govern the construction of British overhead lines. These Regulations and restrictions certainly do keep up the cost of our high-tension overhead lines, and reasonable proposals for their modifications are worthy of consideration by the authorities.

The cost of rural high-tension overhead lines could be considerably reduced if the figures for ice-loading specified in the Regulations were modified. People are not often working in the fields when ice-loading conditions prevail, and therefore I suggest that the danger to the public would not be seriously affected if high-tension lines across fields and along hedgerows, away from the public roads and railways, were constructed to meet the reduced ice-loading allowed in the Regulations for low-tension lines. This modification alone would bring down the cost of rural lines some £50 or £80 per mile, and in view of the rarity of the worst ice conditions in this country, and the fact that our low-tension lines seldom fail from this cause, I feel that the suggestion is reasonable and worthy of consideration.

For transmitting large blocks of power, overhead lines are less than half as costly as underground cables. The conclusion one draws from this is that in a country where the demand for power is large and the available capital is scarce the use of overhead lines should be considered wherever possible, even in the centres of the towns.

There are, of course, obvious difficulties in the erection of transmission lines in the centres of densely populated districts, but if the roads are not available there are often routes into towns such as those along railways and canals which are quite feasible for overhead work, and I maintain that an enlightened but hard-up people, such as we are, should allow these problems of power supply to be settled on their engineering merits, keeping in mind the service given rather than antiquated legal prejudices and æsthetic standards which are too often false.

Probably the most notable development during the last few years is the automatic converter substation. The general tendency in power and lighting distribution is to give alternating current for all services, but for railway work—owing probably, and if so rightly, to the fact that for the usual frequencies of power supply a satisfactory alternating-current traction motor is not yet obtainable—pending this desirable development it is necessary to convert the power as generated from alternating to direct current. This means the employment of substations containing rotating plant.

The automatic substation has been made possible by modern improvements in the design of rotary converters and the protective and control gear for rotary converters. It is now possible to obtain commutating machines which are practically unaffected by dead short-circuits on their terminals. With apparatus such as this a converter substation can now be run entirely unattended; it takes charge of itself and runs accurately to meet the load conditions.

It is now generally accepted that a properly designed automatic substation, because it eliminates many of the chances of human error, which occur particularly at critical times, is more reliable in its service than a manually operated substation, and its employment can be economically justified, not only in districts where the standard of intelligence and the wages of the substation attendants are high, but also in districts where the standard of intelligence and the wages of the substation attendants are low. For example, the automatic substation is commercially and technically sound both in America where labour is costly and in India where labour is cheap.

The long-tried and popular rotary converter has, during the last few years, received a challenge from a new rival—the mercury-arc rectifier. At the present time the capital cost of a rectifier installation is not less than that of a rotary-converter installation to do the same duty, and its claims for justification can only be based on such factors as efficiency, simplicity and reduced maintenance costs. Whether these factors are sufficiently strong to eliminate the more tried-out, old-established rotary converter for railway work, it is perhaps too early to say at the present time.

Whether the electric supply industry will continue to prosper depends, of course, primarily upon the general state of industry of the country and, secondly, upon the education of the public in the uses of electricity—that is salesmanship. The number of units generated per head of population in America is more than three times the corresponding figure in this country, and the curve is still rising.

It is possible in these days that the electricity used in any manufacturing country is a measure of the output of the industries of the country, and whether we shall ever approach the American figures of consumption of electricity depends very much upon whether we are able to bring the output of our factories and mines up to the American standard.

Our aim must always be "Service," a hackneyed term but nevertheless a true one. We must always remember that the justification of our calling is that we improve the lot of the people, and we do this, not only by increasing the product of their industry—a most essential thing at the present time—but also by reducing drudgery and toil.

Amongst ourselves we have to aim at continually increasing economies, not only in the use of coal but in the use of capital. The pound of coal must be made to hand over its maximum of usable energy, and the pound sterling its maximum of service.

We electrical engineers are a young fraternity. One of the joys of our existence is that we have no tradition. What we shall do to-morrow we never have done before.

Let us not forget that we are young, and do not let us affect the foibles of old age before our time. Toil

and adventure are still our part, not limitation of output and over-much "Safety First."

We are told of the ancient Greek that:—"His methods were direct, his endurance unlimited and his energy tireless. He could call a spade a spade without self-consciousness, he could worry at a problem until he solved it, or thought he had solved it, and he was always ready to consider and deal with something new." *

I have delved into an ancient field and I find that I have unearthed, unsoiled and unscarred, an elegant model of a modern electrical engineer.

* STANLEY CASSON: "Ancient Greece" (Oxford University Press).

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE: CHAIRMAN'S ADDRESS

By A. E. MALPAS, Member.

"ELECTRICITY IN THE ARTS."

(*Address delivered at* LIVERPOOL, *2nd November*, 1925.)

I have been asked to choose as my subject to-night that of electricity as applied in the electro-chemical and electro-metallurgical industries.

The reactions involved can be divided into two classes: (1) Those which absorb energy, and (2) those which give out energy, usually as heat, while the reaction is taking place.

Under class (1) fall such processes as the manufacture of calcium carbide, the oxidation of atmospheric nitrogen, the extraction of metals such as sodium, aluminium and magnesium, and electrolytic processes in general.

The second class includes the exothermic reactions such as are involved in the manufacture of calcium cyanamide, and the oxidation of ammonia to nitric acid.

It is obvious that in the short time at our disposal this evening it will be impossible to review at all completely such a wide field of activity, and it will perhaps be as well to abbreviate the descriptive matter and illustrate the subject as far as possible by means of lantern slides.

THE MANUFACTURE OF CALCIUM CARBIDE AND ITS DERIVATIVES.

It is within the memory of most of us how Moissan, the French physicist, in an endeavour to produce artificial diamonds, failed in his immediate object but laid the foundations of the modern processes involving the use of the electric furnace. The most important of these is that of the carbides, principally calcium carbide which forms the starting point of raw material for a large series of organic compounds including acetylene, now so largely used for lighting and welding purposes.

The fundamental equation is quite simple

$$CaO + 3C = CaC_2 + CO$$

and the process consists in heating these two materials together in the electric furnace. The reaction with water gives acetylene

$$CaC_2 + 2H_2O = Ca(OH)_2 + C_2H_2$$

in which the lime originally used reappears as a waste product.

The largest outlet for calcium carbide is in the manufacture of cyanamide, by treatment at a temperature of about 1 000° C. with nitrogen gas, obtained usually by the rectification of liquid air.

The reaction is

$$CaC_2 + N_2 = CaCN_2 + C$$

one half of the carbon content being thrown out of combination in the process. The air after being dried and purified is refrigerated to about $-194°$ C., when the two constituents, oxygen and nitrogen, can be separated by means of a rectifying column.

Other derivatives of carbide are cyanide

$$CaCN_2 + C + NaCl = CaCl_2 + 2NaCN$$

which is used on a large scale for the extraction of the precious metals in the gold-mining districts and for the fumigation of ships, etc.

The capacity of the American Cyanamid Company at Niagara Falls is 75 000 tons per annum, and other plants in Germany and elsewhere are in operation on a more or less similar scale. The world capacity for the production of cyanamide is estimated at about 300 000 tons per annum.

Although at least 40 different compounds are produced from cyandamide as a raw material, probably the largest outlet is as nitrogenous fertilizer, and in this field it enters into competition with Chile saltpetre.

Ammonia also is obtained from it

$$CaCN_2 + 3H_2O = CaCO_3 + 2NH_3$$

by heating under pressure in presence of an alkali.

Nitrates can further be produced by the oxidation of the ammonia by means of the Ostwald process referred to below.

On the screen are shown lantern slides from one of the Norwegian water-power plants on the Hardanger Fiord, which was extended in 1914 to a capacity of 200 tons of cyanamide per day, absorbing some 50 000 h.p. for the manufacture of the carbide and some 6 000 h.p. for the conversion to cyanamide.

Running on 100 per cent load factor it is probable that the cost of generation does not exceed 0·04d. per unit. The selling price of the high-tension energy metered at the works transformer substation was 0·07d. per unit on the pre-war contract.

Oxidation of Atmospheric Nitrogen.

In this process a means is found to avoid the somewhat roundabout method involved in the carbide-cyanamide process, by combining the two constituents of the air directly to form nitric acid. The reaction is quite simple

$$N_2 + O_2 = 2NO - 43\,000 \text{ calories.}$$

The principal adopted is to force a current of air into intimate contact with a high-tension arc and to withdraw and cool as rapidly as possible the nitric oxide so formed, in order to prevent decomposition of the product, since the equation is a reversible one.

Various types of furnaces, etc., are shown in the lantern slides.

The home of this process is also in Norway at Notodden, where over 400 000 h.p. is installed and 13 000 tons of air are blown through the furnaces every 24 hours. About £8 000 000 has been spent on the development of the power plant and the equipment of the factories, which is equivalent to about £32 per kilowatt installed.

Owing to the low efficiency of conversion, only $1\frac{1}{2}$ per cent of nitrous oxide being formed, a large quantity of heat is carried away by the gases leaving the zone of the arc. The air blast is regulated to give a temperature of about 1 200° C., above which nitric oxide is decomposed. The gases leave the furnace at this temperature and are cooled down to 200° C. by passing through steam boilers. On cooling, a further reaction takes place

$$2NO + O_2 = 2NO_2 + 27\,000 \text{ calories}$$

more oxygen being taken up. The gases are finally absorbed by passing through a series of towers over which weak nitric acid is circulated, the final equation being

$$2NO + 3O + H_2O = 2HNO_3.$$

The heat recovered by the steam boilers per kilowatt-year expended in the furnace is equivalent to that of one ton of coal and is sufficient to supply the whole requirements for steam of the chemical processes involved.

The nitric acid produced is used in producing calcium nitrate by reaction with limestone, ammonium nitrate and other products. The calcium nitrate is known commercially as Norwegian saltpetre in contradistinction to the sodium nitrate obtained from Chile, with which it also enters into competition as a fertilizer.

Other Solutions.

Other solutions of the nitrogen problem have been found, more particularly that known as the Haber process and its modifications, in which nitrogen and hydrogen are combined directly to form ammonia by means of a suitable catalyser.

$$N + 3H = NH_3 + 11\,900 \text{ calories.}$$

Since this reaction is exothermic, no great amount of power is required to maintain it once the reaction is started, so that the process is one that can be economically worked without the aid of cheap water power. The heating element consists of a coil in the reaction chamber through which current is passed for the control of the temperature of the reaction.

There are certain mechanical difficulties that have had to be got over in applying the equation in practice, for example the difficulty of working a process at a pressure of 200 to 1 000 atmospheres and a temperature of 500 to 700° C. These difficulties have, however, been solved in different ways by Haber and, later, by Claude in France and by Casale in Italy. The process is also being worked now on a large scale in England.

Ostwald Process.

This was originally an electric process for oxidizing ammonia to nitric acid. The equation is

$$4NH_3 + 5O_2 = 4NO + 6H_2O$$

the nitric oxide on cooling and treating with water giving nitric acid. This reaction is exothermic and the original apparatus has been much simplified and is now worked without the aid of electricity.

Electrolytic Production of Gases.

We come next to consider a class of reaction quite different from any of the foregoing, namely, one in which the changes produced by the electric current take place in aqueous solution, and here it is that we begin to refer to ions.

The simplest case is that of water itself. Having been made conducting, preferably by the addition of caustic soda, the alkali is electrolysed, giving OH (the hydroxyion) at the anode and Na (metallic sodium) at the cathode. Interactions take place, finally, giving oxygen at the anode and hydrogen at the cathode. Thus

$$2OH = H_2O + O \text{ and } Na + H_2O = NaOH + H.$$

This is one of the oldest applications of the electric current, but one that is to-day becoming of great industrial importance. The mixed gases form, of course, a detonating mixture and must be kept separate.

Lantern slides show the Janbert cell, the Knowles cell and the column cell. The Knowles cell is to-day probably the most widely used of the many variations of the early types that have been evolved from time to

time, and it is gratifying to note that this is almost a local product, in that it is manufactured on a large scale at Chester.

As a result of Sabatier's work on the hardening of oils by means of hydrogen, on which our supply of synthetic butter so much depends, the demand for hydrogen largely increased and was met partly by electrolytic methods and partly by other means, notably the Lane steam-iron process. To-day the electrolytic method appears to be displacing the other processes.

Still more recently, the demand for synthetic ammonia has increased to such an extent as to necessitate further supplies of hydrogen and, therefore, plant for producing it. Knowles cells capable of absorbing 20 000 kW and producing 8 tons of hydrogen per day are at work, or shortly will be at work, not only in England, but also in France, Italy, Russia, Chile and other countries.

Of minor importance, but still of interest in view of Moissan's researches, is the fact that there is a small Knowles installation erected at Bodio in Switzerland for the production of synthetic rubies. Oxy-hydrogen muffle furnaces are used, the supply of gases being produced electrolytically.

Taking the cost of energy at 0·1d. per unit, the cost of hydrogen represents one halfpenny per metre cube for the power used.

Chlorine.

Other gases besides hydrogen are produced electrolytically by using an appropriate solution. The most commonly used is sodium chloride, giving chlorine at the anode and caustic soda and hydrogen at the cathode. In some cases sodium carbonate is produced instead of caustic soda.

There are three types of cell in use: (1) the flowing-cathode type, (2) Bell cells, and (3) diaphragm cells. Of these, the last-mentioned is most widely used to-day, although the Italians appear to be developing more along the lines of the mercury cell.

In the flowing-cathode type a stream of mercury is caused to flow at the bottom of a trough below the anodes suspended above it, the whole being immersed in the particular salt solution used. In the case of sodium chloride the passage of the current liberates chlorine at the anode and metallic sodium at the mercury cathode, with which it amalgamates and is removed from the anode compartment. The amalgam on treatment with water gives the hydrate NaOH, with liberation of hydrogen.

Of the diaphragm cells there are many varieties, of which the best known are the Nelson and the Gibb cell.

In pre-war days, chlorine was absorbed in slaked lime and marketed as bleaching powder. During the war this gas was largely used in liquid form in chemical warfare. It is one of the most easily liquefiable of the elementary gases, condensing under atmospheric pressure at a temperature of about − 40° C. To-day it is becoming more the practice to use chlorine in the liquid form, thus displacing to some extent the more cumbersome bleaching-powder method of transportation of the gas. The largest installation in the world is said to be the plant put down by the United States Government at Edgeware Arsenal, where 3 500 Nelson cells were installed for war purposes to give 100 tons chlorine per day and the equivalent of caustic soda.

Many other products are produced electrolytically, such as hypochlorites, chlorates, and perchlorates, which are obtained by suitably varying the conditions of the process or the design of cell.

The lantern slides show the evolution of the process.

Extraction of Metals.

The cells used for the extraction of sodium, calcium, magnesium and aluminium, work with a fused electrolyte at temperatures ranging from 300° to 1 000° C.

Sodium.—The Castner sodium cell shown uses fused caustic and works at about 320° C.

Fused salt, which requires a much higher temperature of about 800° C., is said to be successfully used at Basle, the cell being heated internally by electric resistances.

The Ashcroft cell uses a double compartment with fused lead to form a sodium-lead alloy, chlorine being liberated in the first compartment and the metal sodium being discharged from the second.

Magnesium.—Magnesium is produced in a cell of much the same type using fused lead as a carrier. It is said that cells for the production of magnesium have been operated by the Magnesium Company at Wolverhampton at 5 000 amperes, each taking 5 volts, giving an output of 100 lb. of metal per 24 hours, or 6 kWh per lb. of metal.

It is thought that magnesium has a future before it for the production of light alloys and that it may some day compete with aluminium.

A large plant is now in course of erection on the Continent for the production of 80 tons per week of the metal.

Calcium.—Metallic calcium is obtained in a cell of the type shown on the screen.

The output of these three metals being relatively small it is probable that no great amount of power is absorbed in their production. The case is, however, different with aluminium, the output of which has grown to very large dimensions.

Aluminium.—The electrical process for the extraction of aluminium was first operated by the Pittsburg Reduction Company in America in 1889, a similar process being operated in France about the same time. The reaction itself is, as usual, quite simple.

$$Al_2O_3 + 3C = 2Al + 3CO$$

the raw materials used being bauxite and carbon. Bauxite is mined in the south of France, being named from the town of Baux where the most suitable quality was first obtained. To-day large deposits of suitable material have been discovered in other parts of the world. The crude material contains about 60 per cent alumina, and to refine it sufficiently for use requires the expenditure of 8 tons of coal per ton of finished metal. This, no doubt, explains why the manufacture of aluminium has developed to the extent that it has done in England, the ore being first brought to the

coal-fields for refinement and afterwards treated in electric furnaces at one of the hydro-electric power plants.

The refinement process consists in treating the crude ore with caustic soda and filtering and roasting. At the furnace each ton of metal requires 25 000 kWh, so that at 0·1d. per unit the cost for current comes out at £10 per ton.

Aluminium was first isolated in 1828, but it was not until 60 years later that the electro-chemical process for its economical extraction was more or less perfected. The process consists in the electrolysis of a 15 per cent solution of Al_2O_3 in a bath of fused cryolite which is a complex sodium-aluminium fluoride, Na_3AlF_6. The carbon used in the reaction is supplied largely by the amorphous carbon anodes, the wear and tear of which is very great and supplies practically all the carbon required by the chemical equation.

The furnace used is of simple rectangular construction and is lined with carbon to form the cathode, the anodes being of amorphous carbon suspended in the fused electrolyte. Each furnace may be 8 ft. × 4 ft. 6 in. × 2 ft. deep and will carry 8 000 to 10 000 amperes at about 6 volts. The working temperature is about 1 000° C. and the current efficiency about 75 per cent.

The molten aluminium, as it is formed, sinks to the bottom of the bath and is run off from time to time by means of a tapping hole.

Members of the Institution have at different times visited both the hydro-electric installations in this country producing aluminium. As pointed out earlier, the proximity to the coal-fields makes aluminium a more economical proposition for the small amount of water power available in this country than would be the case with other electro-chemical products. The two installations to which I refer are that of the British Aluminium Company at Kinlochleven and that of the Aluminium Corporation at Dolgarrog, North Wales.

Some of the lantern slides show general views of Kinlochleven and the power house where 35 000 b.h.p. is installed. The new installation at Lochaber will bring the total capacity up to 107 000 b.h.p. in a year of average rainfall.

The Dolgarrog installation is capable of extension up to approximately 33 000 electrical h.p.

Both plants together should, when fully loaded, be able to turn out about 36 000 tons of metal per year and thus supply a large part of the world's consumption, which was said to amount to 45 000 tons in the year 1911.

From figures published in 1910 * it was estimated that the cost of power delivered to the Kinlochleven factories was 0·1d. per unit, including all charges from the dam to the switchboard, and that the cost would fall as the load increased. The cost of the power plant is given as £600 000 at that date, and of the chemical plant £650 000, the equivalent of £17 and £18·5 per kilowatt installed respectively.

It is of interest to record that an installation built during the war at one of the hydro-electric plants in Italy for the production of aluminium has since been shut down and is turning over to the manufacture of synthetic ammonia.

It would seem, therefore, that, so far as aluminium is concerned, we shall be able to hold our own, but that in order to foster other electro-chemical industries everything possible should be done to reduce the cost of power production in this country. This is a large question which does not fall within the scope of my subject, but it is one that we should always have in mind, and our constant endeavour should be in the direction of the reduction of power costs.

[The Address was illustrated by 50 lantern slides.]

* Discussion on "The Hydro-Electric Plant in the British Aluminium Company's Factory at Kinlochleven," *Minutes of Proceedings of the Institution of Civil Engineers*, 1911-12, vol. 187, p. 97.

NORTH-WESTERN CENTRE: CHAIRMAN'S ADDRESS

By A. G. Ellis, Member.

(Abstract *of Address delivered at* Manchester, *3rd November*, 1925.)

In this Address I propose to put before you some considerations which, I think, are at the moment worthy of attention, as concerning the well-being of the electrical industry.

Although recent progress compares favourably with progress before the great war, and the electrical industry has been remarkably well maintained in the face of general depression in other engineering trades, it is essential to its stability and success that more rapid and immediate expansion be attained.

Since the World Power Conference held at Wembley last year, electrical engineers have begun more generally to realize the position of Britain as compared with other countries with regard to electrical development. It is now becoming common to compare different countries on the basis of what might be termed an "electrical development coefficient," viz. the consumption of electrical energy per head of population per annum.

The scope for expansion of the use of electricity in this country is emphasized by realizing that the figure for Britain is only about 130 B.O.T. units per annum per head of population; * in America (U.S.A.) the consumption is over three times this figure, in Switzerland over six times, and in Norway, I believe, even higher.

Of course, it will be said, such results can easily be reached in countries having the advantage of cheap water power. The latter is, however, rather a fallacious and elusive thing; and an examination of the facts shows that the British consumer pays, on the average, less for his electricity than many of his Continental neighbours in "water-power" countries. The cost of harnessing the water power is largely responsible for this. The reason for the extensive use of water power (apart from the lack of coal) is probably a psychological one; the potentialities of the river or waterfall are thrust daily before the population, and their utilization for electric power generation is a clean and wholesome business, free from coal mining, stoking, ash-handling and the smoke nuisance.

There is no doubt that electricity is now recognized as a vital economic factor in the welfare of the nation, and the appointment and work of the Electricity Commissioners has stimulated this aspect. The late Government had in preparation a scheme for the further coordination of electricity supply, and there are indications that this is likely to fructify under the present Government. The Electricity Commissioners † have estimated that if all the electricity generated in the country were produced by modern and efficient stations the total saving in coal would amount to some 20 per cent, or for the same coal consumption 25 per cent more electrical energy might be generated. If the granting of wider and compulsory powers to the Commissioners can effect this, there is sufficient reason for legislation to this end.

* This represents energy sold; the total energy generated by all public suppliers and private plants is of the order 200 B.O.T. units per annum per head.

† Fourth Annual Report, p. 9.

The anticipated new legislation with regard to electricity supply will again bring electricity prominently to the public notice, and the electrical industry would be well advised to take the opportunity of concurrent action in the education of the public. The occasion would be opportune for a widespread national campaign organized, I suggest, jointly by the Electrical Development Association (which is already doing excellent propaganda work), the I.M.E.A., the B.E.A.M.A., the newly formed Women's Electrical Association, and this Institution, to carry the gospel of electricity to the multitudes.

It will doubtless be argued that the speeding up of electrical development is mainly a financial question. This though true is not an impediment, as there is no difficulty in raising money for electricity supply undertakings. The capital expenditure on electricity supply has practically doubled during the past five years, and the dividends of the supply companies have shown a steady increase, now averaging over 6 per cent.

Progress in the electricity supply industry during the past five years (ending March 1925) has resulted in an increase in the total kilowatt capacity of plant installed from about 2½ million kW to 4¼ million kW; the total energy generated from 5 167 million to 7 415 million B.O.T. units per annum (this includes generation for railways, tramways, etc., in addition to public supply), and the total energy sold from 3 086 million (for 434 reported undertakings) to 5 124 million B.O.T. units per annum (for 491 reported undertakings).* The latter figures represent an increase of 66 per cent for the 5 years; but a strict comparison cannot be made, as the available statistics for each year do not relate to exactly the same number of undertakings. Allowing for this divergence, it would appear that the increase in units sold for the past year (March 1924–March 1925) has been roughly equal to the total increase for the four preceding years put together, which is a most encouraging result.

The new plant involved has been almost exclusively of home manufacture, and, so far as the manufacturers are concerned, there is no doubt that they are ready to meet any demands for new plant put upon them due to speeding up of electrical development.

During the past five years great strides have been made in "heavy" electrical manufacture, and it may safely be asserted that the British manufacturer has

* I am indebted to the publishers of Garcke's "Manual of Electrical Undertakings" for the 1925 figures.

caught up his "angle of lag" of some 10 to 15 years, and is now in phase with the American and Continental manufacturer. This is testified by the important orders secured by British manufacturers in the Colonies and in Russia, against American and Continental competition.

Recent progress relates principally to large turbo-generators, extra-high-tension transformers and switch-gear, and automatic and supervisory control of stations. This country has recently exported a 50 000-kW 1 800-r.p.m. turbo-generator, and 35 000-kW and 40 000-kW units at 1 500 r.p.m., also for export, are in hand. In extra-high-tension transformers and switchgear for pressures of 100 kV and over, British manufacturers have recently built, for export, apparatus aggregating over half-a-million kVA.

At home we have outdoor substation installations of British manufacture in operation at 66 kV and 33 kV, some of the latter plant having withstood for several years the most severe test possible for outdoor electrical apparatus, viz. the climate of Manchester. Testing-transformers of 300 kV and 500 kV, for the commercial testing of cables and insulators, have been built and are in successful operation, and 1 000 000-volt testing-transformer equipment is under construction.

Perhaps the most remarkable development for some years is the automatic substation equipped for wholly automatic or remote supervisory control. The first automatic substations in this country were put down only three years ago, and the excellent service obtained is vouched for by the engineers concerned and by the rapid spread of this type of plant.

The automatic or remote controlled substation offers a solution of many distributing problems in congested or isolated areas where either the cost of land and buildings or attendance is prohibitive. As an illustration of the saving in space and buildings, I might mention a subterranean station which is being put down in London, containing two 300-kW rotary converters with fully automatic control. This substation measures 28 ft. × 15 ft. and is entered through a 5-ft. × 3-ft. manhole in the pavement.

Rotary converters up to 4 500 kW for 1 500-volt d.c. traction load, with automatic control gear, have been supplied to the Colonies. These machines are capable of supplying direct current two minutes after receiving the starting impulse.

The previously prevailing impression that Britain was not capable of doing these things is now dispersed, and this country is recognized as an established competitor in contracts for large and extra-high-tension gear, which hitherto went without question to America or the Continent. However, in many lines of standard electrical machinery and apparatus, under present conditions, the British manufacturer compares unfavourably with the American and German manufacturers. The reason is not far to seek; it is the advantages derived from the much greater total volume of electrical manufactures in these countries. The cure for this is to boost up the total electrical business in England, and get the benefits of manufacturing in larger quantities.

To achieve this we have to look to expansion of the home market. We are already in the position of exporting about one-third of our total electrical manufactures, whereas the U.S.A. export only about one-tenth of their total, although the total cash value of the American and British electrical exports is about equal.

Of the total exports of electrical machinery and apparatus (including cables) from five leading industrial countries in 1924 (amounting to £53 000 000) Britain supplied 29 per cent, U.S.A. 31 per cent, and Germany 27 per cent, whilst France and Switzerland were responsible for practically the remaining 13 per cent.* Thus, we are at present securing with the U.S.A. and Germany practically an equal share of the world's total electrical business; and, although our proportion has shown a slight increase during the past few years, no increase of great magnitude is to be expected in the near future.

Competition in the Colonial markets is very keen, and will become still more severe as soon as our principal competitors, America and Germany, no longer absorb the bulk of their electrical manufactures in their home markets, as they do at present.

Another influence which may have a serious effect on the Colonial markets for electrical apparatus is the possibility of protective legislation, on the lines of the anti-dumping duties in Australia, being adopted by other Dominions. The aim and effect of these duties is to create and build up a manufacturing industry in the country concerned. We have, therefore, for salvation to look to the home market to develop in similar proportions to those obtaining in America and Germany.

Intimately bound up with this matter is the imperative necessity of cheaper cost of production of electrical apparatus. Without entering into the complexity of factors which are involved in this question, I consider that the key-note is quantity production; and herein the important factors with which we are concerned are: (I) increase in demand, and (II) standardization.

(I) Increase in Demand.

In the industrial field further application of electricity to mills and collieries is making steady progress, judging by the number of industrial electric motors produced annually. No great expansion is to be looked for, however, until a general industrial revival sets in in earnest. There are, however, new fields of application to be exploited, such as electric ovens for bakeries and electric heating processes in other industries.

An intensive programme of railway electrification would react favourably on the development of public electricity supply.

The Southern Railway group have given a lead in their programme of extensive suburban electrification, which is the largest piece of electrification yet undertaken in this country, involving 647 track-miles and costing nearly £8 000 000. Apart from this, however, in spite of the good case for main-line electrification made out by Colonel O'Brien in his paper last Session, there is little indication that any comprehensive efforts will be made in the near future.

We have, therefore, to look for more immediate expansion to the domestic and rural fields of application.

In the domestic field the importance of the heating

* The contribution of other industrial countries was only a small percentage.

and cooking load as a means of improving the load factor renders the consumer taking power for these purposes as well as lighting, the most valuable for the supply undertaking to cultivate. The all-electric house (on which we are to have a paper and discussion this Session) should be established as an accepted integral part of any new housing scheme. In this matter great assistance can be rendered by the Women's Electrical Association, recently formed "for the promotion of wider use of electricity in the service of Women."

Another matter worth more attention is the simplification of house wiring and the provision of facilities for "free" wiring. A small domestic consumer who hesitates about capital outlay for an electrical installation would not feel the payment of the interest on, or repayment in instalments of, the capital, if included in his quarterly electricity bill.

Development of rural electricity supply for agriculture is a field which is at last receiving in this country the attention it deserves. The politicians have already started to bring electricity into their schemes of land policy, so it behoves the engineer also to get busy. Nearly one-half the total area of Great Britain is farm land, comprising nearly half a million farms and small holdings. At present there are, in Great Britain, only about 400 farms electrically equipped, although it is anticipated that this number will be doubled in another year. Here we lag far behind other agricultural countries, which are jointly responsible for about 1 000 000 electrically-equipped farms throughout the world. There is thus awaiting exploitation in this country an enormous new field, of which the potential total demand for electrical energy is estimated at between 500 million and 1 000 million B.O.T. units per annum.

Apart from the problem of providing cheap and abundant power supply, the principal matters calling for present consideration appear to be :—

(1) The education of the farmer in electricity, and the electrical engineer in agriculture.

(2) Close co-operation between the supply undertakers, the Commissioners and the Post Office to remove any difficulties in the way of the running of inexpensive overhead transmission lines.

(3) The manufacture of simple and inexpensive switch and transformer installations for tapping the high-tension transmission lines.

(4) An adequate system of hire-purchase and maintenance of electrical plant for farm installations.

An enormous amount of educational work among farmers has already been done, and I may mention the pioneer work of Mr. Borlase Matthews. On his model electric farm at East Grinstead, Surrey, which has been in operation for six years, electricity is utilized for 67 different purposes, of such variety as lighting the byres, milking, ploughing, producing artificial daylight for egg-laying poultry and making hay while the sun does not shine. The economy of labour and reduction in wastage obtained, results in such an increase in food production per man as to justify the question being considered as a national one.

Cheap power supply is largely dependent on the cost of transmission lines and of tapping them. Any revision of existing rules and regulations should be in the direction of facilitating the obtaining of way-leaves for, and simplifying the standard of construction of, overhead high-tension transmission lines, rather than in the framing of special regulations; and it is to be hoped that the Electricity Commissioners will exercise a beneficent influence in this direction. Certain regulations are no doubt requisite to ensure the general safety of the public and livestock, but they should be as simple and unrestrictive as possible. It can surely be left to the common sense of electricity undertakings who are endeavouring to develop the rural supply to see that any lines and installations they put down are both safe and sightly, constituting, as such installations do, one of the best forms of propaganda.

The setting up of small industries on the land, or transference from the towns, should be stimulated, so as to improve the load factor of the farm load and conduce to economic supply.

It is appropriate that I should, by way of example of what can be done with small rural consumers, refer to the pioneer development work in rural supply which has taken place recently within our own area, on the Mid-Cheshire Electric Supply Co.'s system in the Northwich district, and also on the Chester Corporation system.

On the Chester system there are some 15 miles of three-phase 6 600-volt overhead line, with 13 open-air substations, stepping down to 400/230 volts and supplying 20 miles of 4-wire overhead distribution lines. The area served is about 70 square miles and already nearly 600 consumers are connected, representing a load connection of 952 kW.

On the mid-Cheshire system, with its centre at Northwich, there are in use or under construction 21 miles of overhead three-phase transmission line at 33 000 volts, covering an area of 120 square miles and designed to feed 3 towns (Knutsford, Winsford and Middlewich) and about 25 villages within a radius of about 6 miles. The village and country lines in use represent a load of about 150 kW and 100 000 units sold per annum, but within a few months this will increase. The charges in the country areas are the same as in Northwich and the other towns.

For distribution to the small towns and larger villages adjacent to the transmission line the pressure is stepped down from 33 000 volts to 400/230 volts, three-phase, by outdoor transforming units of the simplest possible composition, comprising oil-immersed self-cooled transformer, horn-type air-break switches, and horn-type high-tension fuses. The smaller villages are dealt with in connection with country lines, which are supplied at 3 300 volts single-phase from outdoor substations on the 33 000-volt routes.

The country lines feed villages, mansions and farms through pole-mounted single-phase transformers at 3 300/220 volts. The cost of running these country lines for three-phase distribution would be prohibitive; and no difficulty has been experienced in the use of single-phase motors, as they are rarely required to start under load.

Even with single-phase two-wire lines the cost of extending to small consumers some distance from the main high-tension line is too high and only the larger

consumers, or small ones *en route* between large ones, can profitably be taken in. To reach outlying consumers, Mr. Fennell proposes, as soon as the necessary authority can be obtained, to run an experimental single-phase 3 300-volt single line with earth return. This system, if authorized, will go a long way towards transmitting cheap power to small consumers over widely distributed areas.

Apart from the capital cost of the transmission line, the cost of tapping it for a small amount of power is an important factor, which will have a decided influence on the transmission voltage chosen. It is not economical to build a 33 000-volt transformer for a smaller rating than about 20 kVA single-phase, or 30 kVA three-phase; but at 3 300 volts the limits are about 2 kVA and 3 kVA respectively.

For these smallest economic ratings the equipment (including transformer) for tapping a 33 000-volt line need not cost more than £150 for single-phase and £200 for three-phase, or for a 3 300-volt line £35 for single-phase and £60 for three-phase.

The small outdoor substation can be mounted on a single pole for sizes up to 30 kVA at 3 300 volts; 33 000-volt gear is naturally heavier and requires an auxiliary pole with a wooden platform or, alternatively, a concrete raft, with switches and fuses mounted on a pole.

(II) Standardization.

The second factor on which we need to concentrate in the obtaining of cheap production is standardization; and to effect any influence on national economy the question must be viewed in the broadest sense. A comprehensive scheme of standardization for electrical machinery involves the standardizing of :—

(1) Quality of materials;
(2) Performance of electrical machinery;
(3) System voltages and frequencies and machine ratings; and
(4) Designs.

(1) *Quality of materials.*—The common materials essential to the construction of electrical machinery have to-day reached a uniform standard necessary to the production of competitive products. Every manufacturer purchases such materials as electrical sheet steel, steel castings, copper wires, insulating materials and insulating oil, to a purchasing specification drawn up by himself or jointly with the supplier.

The imposition of special conditions on materials or design may, and often does, act to the detriment of the purchaser of the plant, and the tendency to prescribe such conditions would be obviated if a set of standard purchasing specifications for the principal materials were available. Such specifications should be drawn up jointly by the suppliers and the users of the materials, and they would form the national standards for the industry.

Excellent work has already been done in this direction by the British Engineering Standards Association and the Electrical Research Association, and experience so far shows that those concerned are prepared to abide loyally by such specifications if drawn up on an equitable basis.

(2) *Performance of electrical machinery.*—Standard specifications governing the performance of electrical machinery are in a much more advanced state than those for materials. Thanks to the persistent and untiring work of the B.E.S.A. these specifications are now no longer regarded as the pious opinions of a self-constituted committee, but the generally accepted national standards of reference. We are in sight of the day when long and tedious individual specifications will disappear and machinery will simply be purchased on the basis of the British Standard Specification. The effect of this on the possibilities of highly standardizing the product, and its natural effect in reducing the cost of production, cannot be too strongly insisted upon.

The Verband Deutscher Elektrotechniker Rules in Germany have long been established in this position, and this has been one of the most important causes of the position of Germany in the world's electrical markets.

Of equal importance with the consideration of these matters nationally is their consideration internationally. Standard international specifications will do much to lighten the burden of the British manufacturer in the export market. International standards would put world competition on an equitable basis and effect economy of effort and expense, which could be directed into more profitable channels. The International Electrotechnical Commission is now sitting again regularly and progress in this matter may be hoped for.

(3) *System voltages and frequencies and machine ratings.*—The terrible jungle of voltages and frequencies in this country has been one of the most serious impediments to effective standardization of electrical machinery. Although the efforts of the B.E.S.A. and the authority of the Electricity Commissioners have at last enabled us to see daylight, we are still confronted with 45 different system voltages (excluding low-tension distribution voltages below 600 volts) and 16 different frequencies. It is noteworthy that rather more than one-quarter of the total alternating-current plant installed in this country is for frequencies other than 50 cycles.

These conditions, and the relatively small demand at any one time for quantity orders for any particular system, make it impossible for the manufacturer to stock wound and finished motors, transformers, etc. The advantages of mass production as regards cost, stocking in large quantities and speedy delivery, are out of reach. By way of illustration of what we have to contend with, I recently analysed orders for transformers over a period covering 1 705 transformers manufactured, aggregating 750 000 kVA. For the home market the number of different h.t. voltages was 36, and of l.t. distribution voltages 44. For the export market (covering all parts of the world, except America) the numbers were:—h.t. voltages 46 and l.t. distribution voltages 38. These figures covered a range of voltages as follows:—

	H.T. volts	L.T. volts
Home	2 000 to 66 000	100 to 670
Export	2 000 to 132 000	100 to 600

For the same batch of orders the total number of different kVA ratings was 88 for single-phase trans-

formers and 97 for three-phase transformers, the range of rating covered being

Single-phase ..	..	2 to 7 833 kVA
Three-phase ..	..	1·8 to 12 000 kVA

Had these orders been all for standard voltages such as those recommended in B.S.S. No. 117 and for standard ratings in reasonable, well-defined steps, I estimate that the total saving in cost would have amounted to approximately 15 per cent; and this in spite of the fact that the total kVA supplied would have been appreciably higher, by reason of selecting the nearest standard rating to the one actually specified.

The trouble with electrical machinery is that it is so flexible as regards design. Before standardizing was thought of, the user of electrical machines dropped into the habit of specifying the exact power he thought he required (howbeit this might be incorrect by anything up to 50 per cent), and the manufacturer accommodated one of his already executed sizes accordingly. This flexibility has been a good servant but a tyrannical master.

(4) *Standardization of designs.*—Standardization of designs of the numerous manufacturers is a field which has, as yet, been little explored. Such a proposition is likely to be regarded with suspicion or as outside the range of practical policy. It is, however, quite conceivable that it may become, in the not distant future, a national necessity, to enable this country to hold its place against world competition.

I have already referred to the advantageous competitive position of America and Germany in certain lines of electrical machinery and apparatus. The benefits of quantity production and resulting lower material and labour costs, and the large home demand, enable these countries to undersell Britain.

Particular examples to which this applies are industrial motors and small and medium sizes of distribution transformers. The total annual output of the U.S.A. in industrial motors and transformers is something like 10 times that of Britain; and in face of this we have in this country no less than 80 firms manufacturing industrial motors and 15 firms manufacturing distribution transformers (both these numbers including the large firms who make all sizes).

The position we are faced with is that all these firms carry equipment and staff for handling a great variety of sizes and types, *and none of them are manufacturing in really large quantities.*

If designs could be standardized all round and the industry so organized that work was distributed to the individual firms with reference to their equipment for the most efficient handling of each particular range of sizes and types, great benefits would accrue in cheaper cost, more efficient production, shorter deliveries, reduction in spare parts, and prolongation of life to the harassed designer.

Such a step would not be as revolutionary as might be supposed at first sight. The design and the general construction of the standard types of electrical machinery are nowadays based on certain well-defined and similar lines for all manufacturers. (The dissemination of information through the medium of this Institution has contributed largely to this.) The materials used are practically identical, often being bought from a common source.

The designer's art in standard electrical machinery has reached nearly the top of its saturation curve, as is shown by the fact that weights and efficiencies of machines of different makes are very near to one another. The only differences are in details of construction and dimensions, bound up with the standard sizes of cores and tools which the individual manufacturer has adopted.

Unification of designs would not involve the revelation of any jealously guarded secrets. The designer's art to-day does not involve such issues, but is mainly a matter of designing to fit his particular shop conditions and limitations.

By way of illustration of the gain that could be effected under such a scheme, I estimate that, given sufficient total demand in standard sizes and voltages, distribution transformers up to 1 000 kVA could be produced at from 15 to 20 per cent lower cost. As regards industrial motors, a writer in a recent issue of the *Electrical Review** estimates that a particular size of motor could be turned out at from 20 to 30 per cent less cost.

The conservative and tradition-laden mind will doubtless regard these figures with scepticism and will probably raise such objections as the following:—

(1) The difficulty of distributing the work when there is not enough to go round, or when there is a dearth of orders in any particular range of sizes or types.

(2) There will be less employment for workmen and staff.

(3) Some of the existing plant and tools will be rendered idle in certain firms.

(4) Stagnation in design will set in.

(5) The smaller firms will tend to be exterminated.

Well, difficulties are made to be met, and my reply to these criticisms would be:—

(1) The problem of distribution would be less difficult than the problem every manufacturer is faced with—that of filling his shop under present conditions.

(2) The argument of reduced employment is scarcely worth considering: it was faced, and successfully, when machine tools were introduced to supersede hand labour.

(3) Tools no longer required would be scrapped as, and when, they became obsolete or worn out; the change over would necessarily be a gradual one.

(4) Design would not stagnate—foreign competition would see to this.

(5) The small firm would have additional strength given to its position, as it can often, even under present conditions, produce small machines, in quantity, cheaper than the large firm.

The gist of the matter is that co-operation is more conducive to progress than competition. Rank heresy as this may appear to some, the national aspect must be put before the parochial one. What is needed is to cut out internal national competition and combine the engineering brains and resources of the nation to meet foreign competition. Higher efficiency of production and cheaper costs are, at the moment, vital to the prosperity of the industry and of the community.

* *Electrical Review*, 1925, vol. 17, p. 606.

Registration of Engineers.

By obtaining a Royal Charter this Institution has made a great step towards the realization of the time when all who profess and call themselves engineers must comply with a definite and high standard of qualifications. One step further is, however, essential, namely the registration of engineers by Act of Parliament. The result of registration would be that only registered persons would be permitted the use of the title "Engineer" (or "chartered electrical, civil or mechanical engineer"), and only registered engineers would be recognized by law.

The standard of entry and qualification would be made quite definite, to the benefit of the whole profession as regards the quality and efficiency of engineering work and the status of the technical engineer, and to the benefit of the public in protecting it from unqualified practitioners. It would also aid in dispelling the appalling ignorance of the public regarding a profession on whose efforts it is dependent in one way or another for practically all its conveniences and comforts.

We may then look forward to the time when the public (and the "learned" professions) will have been educated sufficiently to distinguish intelligently between a "chartered electrical engineer" and a "registered plumber and electrician."

What is needed is the setting up of a statutory General Engineering Council (analogous to the General Medical Council) which would determine the standard of training and qualifications required and would keep the register for the profession. Such a body should comprise representatives of all the interests involved, principal among which would be (1) the profession, as represented by this Institution and the other leading engineering and scientific Institutions and the (so-called) protective organizations, such as the Society of Technical Engineers, and the Electrical Power Engineers' Association, (2) the engineering employers, as represented by their leading Associations, (3) the universities and technical colleges, (4) the Government.

As regards the standard of qualification, this should not merely be on the basis of examination or academic degree, but I think the requirements of the Institution for chartered membership are now on such a comprehensive scale that they could be adopted as a basis for registration.

Technical Training.

Closely allied with this subject is that of technical training. The educational training of the technical engineer has now practically become standardized to a technical university course of 3 or 4 years, with 2 years of workshop training either before, after, or sandwiched.

From observation and inquiries made at a number of representative technical universities, I gather that the standard of ability and intelligence of students has somewhat declined since the immediate post-war years, although it is generally higher than the pre-war level. The number of students is on the whole above pre-war, which is only consistent with the development of the industry.

The industry is, however, absorbing all the students who complete their courses of training, so that there is very little competition or room for selection. The industry needs more than ever the best men in order to compete with foreign competitors, whose activities are gaining in strength every year. To maintain and elevate the standard in all grades of technical occupation it is necessary to attract the best type of men and in greater numbers.

Registration of engineers would ultimately conduce to this end, but meanwhile we might, with advantage, concentrate more on the means of selecting and training the best brains from all sources. Scholarships and evening classes are supposed to offer such means, but the available scholarship facilities are inadequate and, without in the least disparaging the extensive and laudable work of the evening technical classes, I am inclined to think that they attempt to carry too great a burden.

Evening classes originated in a movement to give opportunities for artisans to obtain instruction in the scientific principles underlying the manual operations they carried out during the day; and the more technical and scientific knowledge the craftsman has, in his sphere, the better the standard of work. But the evening classes now aim at offering a complete course extending over 5 or 6 years, for apprentices engaged at a works all and every day, as a substitute for the 3 or 4 years' day course open to those more fortunately placed financially. With the enormous amount of ground covered by electrical engineering, and under present-day conditions, this system has become too strenuous mentally and physically to equip and produce finished engineers of the type of which we should wish to see the profession composed.

Here, in Manchester, a start at tackling the problem has been made by one large manufacturing firm, by providing facilities for the most promising apprentices to attend one whole day per week at the College of Technology, thereby reducing the amount of evening work by an equivalent amount. Far-sighted and commendable as this is, it is only a half-way house; the steps I would advocate are:—

(1) To restore the evening classes to their original sphere and encourage artisans and draftsmen to attend courses of specialized instruction;

(2) To provide greater facilities in scholarships for full-day training;

(3) To provide an adequate number of technical schools with a 2-year day course at reasonably low fees (similar to the Continental "Technikum"), for the training of draftsmen, test hands, etc., after or sandwiched in their works apprenticeship.

It is perhaps not generally known that the B.E.A.M.A. have established a number of scholarships in engineering, an example which might well be emulated and extended by other such bodies, as it is doubtless a sound investment for the industry.

Institution Activities.

It is gratifying to note an increase in the number and variety of the papers offered to the Institution, but the number accepted as suitable for reading and discussion is still low. There is, I think, some degree of

reticence in offering short and pithy papers on practical subjects, engendered by the feeling that the voluminous and classical type of paper has become the accepted standard. I think that much would be gained by the reading and discussion of groups of short papers on specific subjects, presented simultaneously by a number of experts in the particular subject.

Another direction in which advantages would accrue is the elimination of overlapping with other Institutions. The mass of meetings of different societies which might be attended by an engineer wishing to keep abreast of progress in all branches with which he is concerned, would easily fill up all his leisure time. The time is over-ripe for an organized system of joint meetings between the leading engineering Institutions and scientific Societies, whereby the efficiency of the whole business may be improved. Many useful joint meetings have been held, but these efforts need to be systematic instead of spasmodic. There are many subjects of common interest, and this course would produce discussions of greater real value and breadth of view.

Another matter to which I suggest the Institution might give its attention is the organization of juvenile lectures on the fundamental ideas of electricity and its applications. One or two lectures each year, by an eminent and popular lecturer, to a large juvenile audience would be of great educational and missionary value; the surest way to get the public mind right as regards electricity is to get hold of the younger generation.

The popular lectures in this Centre have been a marked success, and I think also that we might, with advantage, devote one evening each year to a lecture on the historical side of our faculty. By reason of the enormous ground that has to be covered in the modern university course, this aspect of electrical engineering is crowded out and little appreciated by our younger men; and with the commercializing of electrical engineering the splendid work and tradition of the great pioneers are all too apt to be forgotten. We commemorate each year the work of the great masters, Faraday and Kelvin, and I think that periodic orations, essentially historical and biographical, would stimulate our efforts and keep green in our memory the achievements associated with such names as Volta, Maxwell, Tesla, Hertz, Ayrton, Silvanus Thompson and others to whom we owe our foundation and heritage.

NORTH MIDLAND CENTRE: CHAIRMAN'S ADDRESS

By S. DERWEN JONES, Member.

(*Address delivered at* LEEDS, *10th November*, 1925.)

It is now six years since the passing of the Electricity (Supply) Act, 1919, which was expected to revolutionize speedily the supply of electricity. We heard a great deal about 16 super-power stations, and great schemes for harnessing the tides so that we should have "a cheap and abundant supply of electricity." Much good work has been accomplished, but progress has been steady rather than phenomenal.

The aim of legislation has been to get unity of control, which necessitated joint working. This could have been effected if the original Bill had been passed, but very conflicting interests have made themselves felt. Only one Joint Board so far has been formed. As the Boards have not compulsory powers, it has not been possible to get the best results. Complaints are sometimes made that municipal electric undertakings are a monopoly, but this is almost of necessity, as with gas and water.

The view is held that to safeguard against monopoly there ought to be representative control, which is the case in municipal work. Unfortunately, in municipal matters there is a great amount of inertia and also a lack of vision and of a bold policy, except in those cases where there is a strong, far-seeing engineer backed up by a sympathetic Council, and especially by an energetic chairman of Committee having business experience.

The weakness in towns making a combined effort to further electricity supply is that there is a lack of driving force. The various Councils keep changing in personnel, their interests are not continuous and consistent, they are wanting in initiative and the Councillors individually lack a direct personal interest. A company has the advantage of a steady, consistent policy from year to year, the administration has a freer hand, and the board of directors have a very strong personal interest in the success of the undertaking. If companies are, however, given monopoly rights they would not be human if they did not take advantage of it; and once fully established in those rights, and with the fear of competition removed, they would tend to cease moving with the times.

Many people who look to a sane individualism to bring Britain into a new era of prosperity would gladly entrust private companies with the supply and main distribution of electricity if they knew that they had a sufficient check upon the companies' operations. They feel that merely to limit the amount of the dividends is not sufficient. Municipalities have to make public all the results of their undertakings, and if companies are given any powers of monopoly their profits would not be grudged if the operation of their undertakings were open to an impartial supervision by keen men of business who had the confidence of the general public.

The Electricity Commissioners in their last Report deprecate the fact that the spirit of the 1919 Act has not been carried out owing to the attitude of authorized undertakers, and that they have been unable in any district to secure a thorough re-organization of electricity on the lines of that Act. They suggest that the whole position requires reviewing; and, if rumour be correct, the Government are bringing forward new proposals to strengthen that Act.

I think the lack of progress has been largely due to two or three causes. In the first place, I consider that a mistake was made in not compensating those authorities whose generating plant was to be closed down, for their outstanding capital account on their generating plant. It can also, I think, be maintained that before any authorized undertaking should be compelled to give up its rights to generate electricity, after having through many years of struggle built up a good load, such undertaking should be guaranteed that the new conditions should not be a little better than the old, but that within a reasonable period it should be at least 15 or 20 per cent better off after surrendering its autonomy.

Again, many of the smaller municipalities would readily take their supply from a larger municipality or from a public representative body, but view with distrust the taking of a supply from companies having a monopoly. In the case of a public representative undertaking, the financial and technical results are available to the public, but this is not the case with companies. It is quite natural that, as business undertakings, they do not care to publish all their results, but they cannot, or should not, have it both ways. If they desire to have a monopoly they should be open to criticism. We are assured that in case of unfair treatment the Commissioners can be appealed to, but however highly the Commissioners may be regarded, both for their knowledge and for their impartiality, an appeal to them or their successors cannot be regarded with as much favour or confidence as the right of the purchaser to buy in the open market in which he has some representation.

Considerable progress has, however, been made since 1919. The total capacity of the generating plant in Great Britain was then about 2 310 000 kW, and in the next two years some 180 000 kW of obsolete and inefficient plant was scrapped. The present total of plant amounts to approximately 4·5 million kW, an increase of 90 per cent. At the same time, whilst in the year 1924 the units increased 16·4 per cent,

the consumption of coal increased 11·2 per cent, and it is significant that this improvement was shared by many comparatively small stations and was not due entirely to the supply from super-stations.

We have heard with wearisome reiteration the parrot cry of "a cheap and abundant supply of electricity" uttered by politicians and the "stunt" Press who have little knowledge of what they are stating. Electricity supply is becoming cheaper and consequently more general, but the time has come when the question of coal, upon which electricity supply so much depends, is of overwhelming importance to the prosperity of our country.

In the last 50 years the output of coal in Great Britain has doubled, but that of America has increased tenfold. In the same time the total world production has increased ten times, but Great Britain's share has fallen from two-thirds to one-fifth of the total production. Many estimates have been given of the life of British coalfields, but it is more important to consider their economic life, and judging by the number of unworked-out pits that have been closed down during the last two or three years, this is a very serious consideration indeed. Many causes have contributed to this, the increasing depths at which they are worked, the thinness of the seams, and the reduced demand for British coal.

We have now to compete in a far greater degree than hitherto against American coal; South Africa now supplies a part of the wants of the southern hemisphere; China has immense coalfields and also cheap labour; and, in Europe, Sweden, Italy and France have tremendously increased their power supplies by the use of hydro-electric undertakings, making them more independent of British coal. France alone has increased her water power since 1914 from 800 000 h.p. to over 2 million h.p. The very economies that are being made in the use of coal at home are in themselves contributory to the depression of our coal trade.

It is said that water and oil will not mix, but they can combine in their effect upon the coal trade. It is computed that oil consumption doubles every 10 years and the world production of oil has reached 120 million tons per annum. Our Navy as well as other Navies once depended upon anthracite coal from South Wales, but are now largely run by oil, and with the improvements in Diesel engines our mercantile marine is gradually turning over to oil and Britain is paying £45 000 000 per annum for oil from abroad. Our first line of defence draws its oil supply largely from Persia, which is too near to Bolshevist Russia for our comfort. A striking instance of the change-over to oil is the case of an American liner which formerly carried 3 000 tons of coal and burnt 300 tons per day and now carries 2 500 tons of oil and burns 250 tons per day, the staff employed with coal being 242 and with oil only 84.

And this depression does not stop at our coal trade, for dear coal means reduced and less economical shipping, dearer transport for our imports, less shipbuilding, and, in its turn, less work for steel furnaces and engineering.

These facts require to be realized not only by the miners, but also by the whole country. The former, despite the slackness with which they are, I think, in many cases rightly charged, are not too highly paid, considering the irksomeness and danger of their work. And I appeal more especially to the whole engineering profession, for it is to our gas, electrical and chemical engineers to whom we must look for a lead, not only in stemming the decline in our country's prosperity but in helping it to take again its due and honourable share in the world's work.

Considerable research and practical work, which bids fair before many years are over to revolutionize the use of coal, has been, and is now being, done on the burning of pulverized fuel and on low-temperature carbonization with the recovery of by-products. Much of this work is being done in America, but it is pleasant to know that successful experimental work is being carried out in Great Britain, and perhaps what may prove to be the most hopeful work in connection with pulverized fuel and low-temperature carbonization is now being carried out by British engineers in America.

In Great Britain, up to quite recently, it has been a commercial proposition to generate electricity only by burning coal in its raw state, but from a national point of view, with the increasing knowledge gained, this is a great waste. The fact that a public-utility concern procures its gasoline to run its omnibuses from the coal which fires its boilers is a good popular lesson against the wastefulness of burning raw coal.

It has been proved that any bituminous coal can be burnt efficiently in the powdered form, even with a very high percentage of ash. There is a large amount of fine coal at the collieries which is expensive to transport, but would be available for use in the pulverized form at a low cost if used on the spot, and would go far to offset the advantage of putting the generating station where water is plentiful for condensing purposes but where coal has to be conveyed at added cost.

It is maintained by some authorities that we cannot get out of coal of low calorific value any more heat by one method than by another. One eminent engineer, however, states that in one plant of which he knows, they burn as many as 25 different kinds of coal in a month, and that when pulverized it can be handled with a precision and uniformity impossible with very dirty coal on chain grates and mechanical stokers; and further, that they are enabled thereby to buy coal to greater advantage in a varied coal market. Banking or stand-by losses are also largely done away with—surely a very important point in a system of interlinked stations, where one or two stations would take up the night or week-end loads.

Despite the fact that coal dust when only partially consumed may become covered with a glaze from the ash, whereby the carbon is not thoroughly burnt and its heating value lost, it is claimed from actual practice that the loss is extremely small when compared with the ash in mechanical stoking; and even when there is a deposit of fine ash on the ground in the neighbourhood it is free from sooty or tarry matter. Great overloads can easily be carried and accurate control maintained to suit all variations of load, and the smoke problem is overcome.

Labour costs are low and it is stated of the boiler-house of the Ford motor works that "eight large boilers are installed, completely operated by two firemen in spotless white suits and seated in front of a control switchboard, cool atmosphere, no speck of dust anywhere, all fittings nickel-plated, floors enamelled and with rubber covered paths."

One advantage of the above method is that the boilers can be fired at the same time with pulverized coal and blast-furnace gas, the top burners taking the pulverized coal and the bottom burners dirty blast-furnace gas. Tar and other fuels, even sawdust, have also been used with the coal.

In the case of the Ford plant at Detroit the normal fuel consumption of the plant of three working boilers is given as approximately 67 million cubic feet of blast-furnace gas and 275 tons of pulverized coal for 24 hours.

Though up to the present mostly operated in America, there are now important plants in operation in England, such as the plant at the Nechells power station of the Birmingham Corporation, and it will be very interesting to watch the progress of these installations.

A very hopeful method is the combination of the production of pulverized coal with low-temperature carbonization. When it is considered that instead of burning raw coal, involving great national waste, it is possible to obtain pulverized fuel giving efficient smokeless combustion, motor spirit, fuel and Diesel oils, sulphate of ammonia and rich gas for power or heating purposes, the overall saving would check the decline in the coal trade, in a more positive manner than dangerous subsidies. Even if the saving did involve by its greater efficiency a reduction in the coal output, the increased national manufacturing and agricultural output would steadily absorb the surplus mining labour, thereby saving the great waste of unemployment pay with its demoralizing effect.

It has been estimated that the raw coal for one 50 000-lb. boiler per annum could produce by low-temperature carbonization 27 500 gallons of motor spirit, 206 250 gallons of oils, and 92 tons of sulphate of ammonia, with the balance of gas and solid fuel for the boiler.

When it is considered how much we spend on imported oil on the one hand, and that we pay £300 000 000 per annum for imported food, is it not time that there should be a more combined effort to check—nay, to stop—this national waste, which we cannot at our peril allow to go on.

Perhaps the most hopeful development in this direction at present is the method adopted in the new McEwen–Runge process of combined pulverization of coal and low-temperature carbonization. Hitherto low-temperature carbonization methods have required a long period for the operation, necessitating the use of small retorts. The coke produced also was too friable, especially for transport. Mr. McEwen has got over this difficulty by dispensing with retorts. The coal, after it is pulverized, is raised to the top of a tower and in falling is met by a current of hot inert gases. By this method carbonization is effected by the time it reaches the bottom of the tower, the process being very simple. The volatile gases pass out at the top and the finely divided coke passes out at the bottom to be fed to the boiler in the same manner as pulverized fuel. The method is being put into operation at the Lakeside power station, Milwaukee, and it is claimed for it that the powdered semi-coke is superior to pulverized fuel for boiler furnaces. It can easily be transported and also pumped through pipes like oil. High claims are made for the quantity of tar per ton of coal and for the heating value of the gas, the latter figure being 750 B.Th.U. per cubic foot.

This powdered coke will be of no use for the domestic hearth, but the Glasgow Corporation are, from the account of Councillor Smith, Convener of the Glasgow Health Committee, given at the Royal Sanitary Institute Congress at Edinburgh, doing good work in that direction. After long experiments on a smaller scale, a large plant at the Dalmarnock gas-works for the low carbonization of coal has been installed, and they have succeeded in producing :—

(*a*) Smokeless fuel that will burn in any type of grate as easily as raw coal, and as cheap as raw coal under equal conditions ;

(*b*) Gas suitable for industrial purposes.

The capital and working costs are low, and from tests made, taking coal at 20s. per ton, excluding the cost of handling, the price of gas would be about 1·01d. per therm.

Councillor Smith states that they hope to carbonize 500 000 tons of coal per annum, from which, in addition to the gas obtained, they would produce 275 000 tons of smokeless fuel for domestic purposes and 7 800 000 gallons of oil.

Many electrical engineers are hopeful of the coming of all-electric houses, with the saving clause that one room will have a grate for burning smokeless coal or coalite ; and in Glasgow I understand that they are taking very successful steps to electrify workmen's cottages, in which all the water-heating is done with a small coal or coke stove. I venture to suggest, however, that fires, either coal or gas, could be abolished from the houses. It seems to me that up to the present only the middle and upper classes have, in the main, had the advantages of electricity supply. In Glasgow, out of 200 000 houses, only 9 per cent have electricity installed, and by far the greater proportion of this percentage belongs to people comparatively well off. In all our large towns there are thousands of houses—one can hardly call them homes—which an enlightened community should not tolerate. Without going into the question as to who are, or what is, responsible for the existence of these dreary regions where the sunshine only makes more apparent the drabness of it all, I venture to suggest that there is a way to make a clean, healthy neighbourhood where there is now only squalor and dirt. I do not think it can be gainsaid that smoke from domestic fires is responsible for half the pollution of the atmosphere ; and over 5 per cent of the coal so burned escapes into the air.

Many will remember the clearness of the air during the last coal strike, and in the Batley area during the

late strike in the woollen trade the towns seemed transformed, even ugly buildings seeming less repellent, and one breathed a purer, serener air. This is no mere matter of sentiment. As Dr. Vernon Sinclair has stated in the *Electrical Review*, speaking of " Combustion and Atmosphere and Their Relation to Disease " :—

" Heating in greenhouses is always so arranged that no products of combustion enter the greenhouse, because every gardener knows that the plants wither and die if they are given air to breathe which is impregnated with gas and coke combustion products."

He further condemns heating and cooking by gas in houses because of the formation of carbon monoxide. Is it any wonder that a C3 population grows up in the congested area of our towns? And it must be remembered that it is just in these areas that there is by far the greatest proportional increase of our population. The doctors further inform us that the clouds which form round the dust particles of our northern manufacturing towns, creating our muggy depressing atmosphere, also prevent the most health-giving portion of the sun's rays reaching us.

I have laboured the effect of our smoke-laden atmosphere on the general health of the people, but I hardly think that it is necessary to point out to engineers the enormous cost of this pollution, both in labour and in material, which it would be difficult to estimate, and the prevention of which would release a great source of wealth that could be used in more remunerative ways, not to mention the great increase in the means of leisure and the joy of life.

I think that the time has come when electricity and gas should combine their forces and endeavour to do away with this great evil. I was greatly pleased when our Past-President, Mr. Woodhouse, spoke of the need of co-operation between gas and electricity, and I hope that steps will be taken before long by our Institution towards that end. Let us have a keen friendly rivalry by all means, but it must not be forgotten that as electricity has progressed, gas has also, and will continue to do so, though no doubt along new lines.

One way of cleansing our slums is on the lines now being experimentally carried out in Glasgow, Woolwich, Gateshead and, in the near future, Leeds. I refer to the construction of all-electric houses, and in this work Glasgow is contributing, by producing " coalite " for burning in domestic hearths. With the experience gained, however, I think that there is a need for bold schemes to be initiated in order to ensure success. To this end I venture to suggest that gas could largely contribute. But I would keep gas outside all premises. Let the houses be all-electric, with no coal fires. The general heating of the houses, I think, could be done by hot-water radiators.

From the curves given in Technical Paper No. 12 of the Fuel Research Board, on the heating of rooms, Dr. Margaret Fishenden shows that hot-water radiation is the cheapest form of heating rooms of about 1 000 cubic feet capacity, i.e. the size of rooms in the type of house we are considering. Would it not be possible to build these houses in blocks of, say, 20 or more, with a common hot-water supply at a temperature suitable for warming the rooms, and supply all requirements for baths and general washing and cleaning? All hot water for drinking purposes would, however, be electrically heated, as the main hot-water supply would not be suitable for that purpose. The hot water would not be metered, but there would be a general supervision to prevent waste in the same manner as is now done in some cases where electricity is supplied on the current-limiter system. I think that the whole matter would become normal as the users became educated to the advantages and realized that waste would be injurious to their best interests. The cooking, lighting and occasional use of an electric radiator in any room to supplement the hot-water radiation would give a large electric load with a good diversity factor.

The water for the hot-water radiators could be heated by gas in a small building near the houses and thermostatically controlled. Gas for this purpose could be distributed in specially laid mains, and at a cheaper rate than that now supplied for gas lighting. According to an eminent gas engineer, Mr. George Helps, Leeds was offered a supply of gas from collieries at 7d. per 1 000 cubic feet, or under 1½d. per therm; and Sheffield is buying gas at 4½d. per therm, i.e. cheaper than she can produce it herself. Glasgow, as already pointed out, can, by the McLaurin process, produce gas for 1·01d. per therm. Mr. Finn, manager of Manvers Mains coke ovens, has stated in a paper read before the Society of Chemical Industry, at their meeting in Leeds last July, that gas could be supplied from coke ovens at a much lower rate than it is now supplied by gas-works of a standard type, and that it could be carried considerable distances, natural gas having been pumped as far as 200 miles. He also makes the suggestion that gas could be conveyed from the coal-fields to the towns by means of pipes along the railways.

As there would be no ashes from coal fires in the houses, there would only be the ordinary refuse to deal with, and provision could be made for this by having in the building for the gas boiler a gas incinerator, to which all the refuse in that block of houses could be brought, thereby doing away with the unsightly refuse bins and lessening the great cost of refuse collection and destruction. It will be maintained that the householders would not look after the gas-burners, but if there were a considerable colony of such houses it would pay the authorities to employ a man to go round the district for this work, and with moderate care the refuse not only could be burnt without causing a nuisance, but in burning could contribute towards the heating of the water. There would be considerable saving in the building of such houses, in one town such saving on the building of electric houses being estimated at between £30 and £40 per house, and the comparative capital costs of electric mains would be much less because of the density of the area of supply, and the gas mains would also be shorter and simpler.

Among other improvements in the generation of electricity is the use of preheating of flue gases, as exemplified in the Howden-Ljungström air preheater, by which very considerable economies are made in steam-raising. The preheater takes up about 60 per

cent of the available heat in the flue gases, which would otherwise be lost. With the balanced draught used in this method air leakages are very much lessened and the whole working is under easy control.

The revision of qualifications for entry into the Institution is now under consideration. With the greatly increased responsibility of electrical engineers to-day, and the wide scope of their work, it follows naturally that our Institution, with its growing prestige, should demand a higher standard of entrance into its ranks. It is not always easy to define what constitutes a competent engineer. Some year or two ago the Electrical Power Engineers' Association issued a report which gave in a very able manner the requirements in the training of electrical power engineers.

Many of the large electrical engineering firms have an excellent system for the training of young engineers, and, now that generating stations and transmission systems are developing on such a large scale, it should be possible to give not only a thorough training to the young engineer in his particular department, but also, if he shows special ability and industry, the opportunity of obtaining a larger knowledge of the undertaking in its various branches.

I think, however, that in the training of youths to-day there is a danger of too great a diffuseness, and their knowledge is not sufficiently in touch with the facts of life. Professor Perry laid great stress on the need for experimental work and a quantitative grasp of the subjects which the student has learned from books. There is no doubt that the familiar handling of an object leaves a firmer impression on the mind than any amount of description of it. The present-day youth has a very keen insight into many mechanical problems, from the upkeep of his motor-cycle or car, and as for electrical knowledge, the young wireless enthusiast is wonderfully versed in the intricacies of his subject.

A striking illustration of practice preceding theory is to be found in the very interesting book of Henry Ford entitled "Story of my Life." At his works he started a trade school in 1916 for boys between 12 and 18 years of age who leave school early, and it followed these lines:

The boy is to be kept a boy;
The academic training is to go hand in hand with industrial instruction;
The boy is set to work on articles which are afterwards to be used.
One week is spent in class, then two in the shops, and the teachers are the works staff.

Geography is taught from the shop orders and the handling of goods to all parts of the world. Physics and chemical laboratories are in direct contact with shop practice. On the school machines boys work solely on articles needed by the works, and the articles are purchased by the company; if turned out badly the loss is borne by the school. The school started with two boys and has now expanded to 700 scholars; and an important point, in my opinion, is that it pays its way.

It was stated recently in the electrical Press that there is no public monument to Faraday in our country. This being the centenary of his discovery of benzine. it would be fitting that there should be some tangible memorial of him.

The feeling has often been expressed amongst us that it is desirable that there should be a closer bond between the various engineering societies in Yorkshire. A step has already been taken in that direction by the joint meetings which have been held, but I venture to suggest that the bond can be drawn still closer.

The University of Leeds is now appealing for funds to enlarge its borders. Would it not be possible for the Institutions of Civil, Mechanical and Electrical Engineers to combine and have a joint meeting-place under the wing of the University, and to use a scientific and engineering library instituted there? This would require a generous contribution towards the needs of the University, but a joint meeting-place and library devoted to the advancement of science in the service of man would be a happy memorial to one who devoted his whole life to the cause of science and the service of his fellows.

SCOTTISH CENTRE: CHAIRMAN'S ADDRESS

By Professor MAGNUS MACLEAN, M.A., D.Sc., LL.D., Member.

"THE EARLY HISTORY OF THE GLASGOW LOCAL SECTION (NOW SCOTTISH CENTRE)."

(*Address delivered at* GLASGOW, 10*th November*, 1925.)

With your good will on this semi-jubilee occasion, I am privileged to be your Chairman. The chief reason assigned, I understand, has been that I was in at the start and largely instrumental in getting our Local Centre formed.

I do not deny the soft impeachment, that I was a prime mover in the matter. On the contrary, I glory in it. All the more, therefore, do I appreciate and thank you for the high honour you have conferred on me in making me your Chairman for a second time. Such recognition I value more than I need express.

It is unnecessary to say that I was not alone in the initial endeavour. There were other ardent coadjutors, though they have not all survived to this day.

In looking over the Minutes of Committee and General Meetings, as well as of the Students' Section, it has occurred to me that from these, and Press and personal recollections, it might be interesting to give on this occasion a short account of the earlier history of the Centre.

Prior to its inception, towards the end of 1899, the late Mr. Henry Mavor and I drew up a petition to the parent Institution in London, which was circulated among the resident members and signed by them, stating cogent reasons why we should be allowed to form a Local Section, and the sanction of the Council was obtained on the 14th December in that same year.

It was on the evening of Thursday, the 18th January, 1900, that a meeting of the electrical engineers resident in Glasgow and the West of Scotland took place at 207, Bath-street, to form a Glasgow Local Section of the Institution. At this meeting, Prof. Perry, the senior Vice-President of the Institution, presided, Mr. McMillan, the Secretary, also being present. Prof. Perry gave an interesting and entertaining address on the objects and work of the Institution, and Mr. McMillan some explanations regarding the working of Local Sections. Lord Kelvin was unanimously elected first President (we say Chairman now). For the other offices, there were several nominations, and, after a vote, the following were declared the successful nominees :—

Vice-President: Prof. Magnus Maclean ;

Hon. Secretary: Prof. W. H. Watkinson ;

Members of Committee: W. A. Chamen, H. A. Mavor, W. W. Lackie, W. B. Sayers, Thomas Young, J. M. M. Munro, Prof. Andrew Jamieson, and Francis Teague.

At the first Ordinary Meeting in February, 1900, in the old Technical College, Bath-street, a paper was read by Mr. W. B. Sayers on the "Problem of Arc Lighting from 250-volt Supply." At the next, it was announced that no lengthy reports of the proceedings of the Section should be communicated by anyone to the electrical or other journals until the decision of the Council of the Institution as to the propriety of such publication had been received by the Section. Mr. W. W. Lackie contributed a paper on "Methods of Charging for Public Supply of Electricity," the subsequent discussion proving very lively and vigorous.

After the third meeting, at which the annual business was transacted, the meetings were transferred to 207, Bath-street.

The Minutes of the first Ordinary General Meeting of the Section held on Wednesday, 14th November, 1900, at 8 o'clock in the rooms, 207, Bath-street, show that the President, Lord Kelvin, was supported on the platform by the Vice-President, Bailie Maclay, Convener of the Glasgow Electricity Committee, and the paper was given by Mr. W. A. Chamen, on "Electrical Supply." This was the only meeting at which Lord Kelvin presided during his term of office. I had the honour of acting in that capacity from the 16th February, 1900, until the seventh Ordinary meeting of the Session 1901–2, held on the 13th May, 1902, when as Chairman, the title then adopted, I was succeeded by Mr. Henry Mavor. During that session 11 Members, 16 Associate Members, 20 Associates and 7 Students were added to our number. Our Section had the distinction of being the first and only one up to that date to secure an Institution Premium, awarded to Mr. A. B. Field for his paper on "A Method of Compensating Voltmeters for the Voltage Drop in Long Feeders." Another Premium was awarded to the same member in 1903 for his paper on "A Study of the Phenomena of Resonance in Electric Circuits by the Aid of Oscillograms."

The Committee Meetings at that time were mainly devoted to discussions on (1) the grants to Local Sections for expenses, and (2) the area of the Glasgow Local Section. In connection with (1) it is interesting to quote from the minutes of the 17th September, 1900. The Hon. Secretary stated that at present the funds of the Local Section were lodged in the bank in his own name only, and requested that a second name should be added. On the proposal of Mr. W. A. Chamen, seconded by Mr. Thomas Young, I was requested to act with the Hon. Secretary. From that date to the present day I have signed every cheque issued for payment of local accounts. At the same meeting of the Committee, the Hon. Secretary stated that he had received the promise

of seven papers, so that he had been able to fill the whole of the dates. Contrast that with the present method of getting all the papers from London! Last session one of these papers was actually read at 11 different places on 11 different dates. The controversy between the parent Institution and the Local Sections on the proposals that papers should be submitted to the Papers and Editing Committee in London before being put down for reading at the Local Section is now a thing of the past, so, although they are all very interesting, I shall not quote any extracts except this one from the minutes of the 9th September, 1907: "There was considerable discussion as to the action this Section should take, and it was finally decided that in view of the undoubted unworkable nature of the arrangement, this Section should take a somewhat passive attitude, and let the scheme become a dead letter by inaction." Later on we find that our Hon. Secretary was instructed to write to the parent Institution calling attention to the great inconvenience caused by the delay in dealing with papers submitted to our Section.

Early in 1901 the Committee were asked by the parent Institution to state the area that they considered should be allotted to the Local Section, and, after considerable discusssion, it was left to me to discuss the matter with Mr. McMillan in London and put forward the best proposals which he considered would be acceptable. At that time, the members of all grades resident in Glasgow were 104, and 15 outside the city had specially asked to be enrolled as members. Thus, out of 142 connected with the Institution who were resident in Scotland, 119 were members of this Centre. Now we have 676 as follows:—

Members	98
Associate Members	280
Graduates	93
Students	182
Associates	23
	676

It was in April, 1903, that Mr. F. F. Pickstone brought up the question of the possibility of having meetings in Edinburgh, and suggested that every third meeting should be held in that city. It was pointed out that the question of including Edinburgh within the Glasgow area had already been brought before the Council in London, when our Section had suggested that Edinburgh members should be represented on the Council, and that the meetings in each place should be in proportion to the total number of members in the respective areas. The Council had, however, declined to fall in with the proposal and had definitely excluded Edinburgh from the area of this Section. Mr. Pickstone was informed that the best course to adopt was to get up a memorial from the Edinburgh members, pointing out that they were not strong enough to run a separate Section, and petitioning that they be included in the Glasgow Section. The Hon. Secretary was instructed to receive the memorial (which should be as largely signed as possible) and should pass it on to London, asking the Council to reconsider the matter. Accordingly we find that the Hon. Secretary submitted a letter from Prof. Baily enclosing a draft application which the Edinburgh members proposed to present to London, asking that they should be incorporated in the Glasgow Local Section. The Committee instructed the Hon. Secretary to write to Prof. Baily and say that they quite approved of the form of application proposed. The first formal meeting in Edinburgh under the new arrangements took place on the 19th December, 1911, at the Heriot Watt College.

A reference to a proposed Students' Section occurs in November, 1905. The Secretary brought forward this subject in view of remarks made by Mr. Gray, President of the Institution, at our local Dinner. There was some discussion, after which it was left to the Hon. Secretary to consult with me as to what could be done in this direction, because anything of the kind would necessarily draw the chief support from the Technical College. A minute of the 13th March, 1906, contains a long account of a special meeting held on the 16th February, and a Report from myself as Chairman of the Students' Section giving details of another meeting held by them on the 2nd March and the draft rules adopted, a copy being submitted.

The first meeting of the Students' Section was held in October, 1906, in the Electrical Theatre of the Technical College, when I, as Chairman, gave an address upon the subject of "Electrical Wave Measurements." In the following years I gave lectures on "Testing of Transformers," "The Distribution of Electrical Energy," and "Electric Clocks." The summary of the latter, as given in the minutes, reads as follows:—

> "Electric clocks dated only from the middle of last century. Hundreds of patents were taken out during that time, and of these more than 90 per cent had been failures, owing chiefly to the faulty mechanical method in which electricity was applied. A few of the successful inventions were described in detail and classified under three heads, namely, first, independent clocks which were wound up electrically at regular intervals: second, a number of such clocks which were synchronized electrically by a master clock every hour: third, a number of clock dials which were controlled and impelled by a master clock every half-minute or minute."

For a municipal time service, with dials rented by the public, it was suggested as a feasible system one under which a single master clock, regulated to keep correct time in the usual way, would be able to synchronize every hour a few score of independent clocks situated in different parts of the city. Each of these synchronized clocks could control and impel 200 or more dials in blocks of buildings in the neighbourhood. All the circuits could be put on to the city electric mains, and the total electrical energy would be a few watt-hours per dial per annum.

As an instance of the vigour displayed in the Students' Section, the following were papers read in one evening:—"The Uses of Inductances for the purpose of limiting Short-circuit Currents in Alternators," by Mr. Archibald Page; "Is Switch Control fully taken advantage of?" by Mr. R. B. Mitchell; "Public and Private Supply,"

by Mr. H. A. Stewart; and "Petrol and Electric Vehicles," by Mr. E. G. Bowers.

The Annual General Meeting of the Students' Section for 1913-14 took place on the 3rd March, after which, owing to the war, there was no other meeting of any kind for five and a half years, the first of the ninth session being held on the 14th November, 1919.

With reference to the proposal to Lord Kelvin to take the chair for the session 1906-07, in view of the visit of foreign societies to Glasgow, the Hon. Secretary stated that he was very pleased indeed to announce that he had received a most charming and courteous reply from Lord Kelvin as follows:—

"*January* 24, 1906.

"DEAR MR. TIDD,

"I thank you very much for your most kind letter of January 19, and I beg that you will thank on my account the Glasgow Section of the Institution of Electrical Engineers for their kindness in asking me to be again their President, and to take part accordingly in the reception of the Foreign Visitors on the 2nd and 3rd July. I am afraid I could but very imperfectly fulfil the duties of President for the Ordinary Meetings, as I shall be living in London most of the time from near the end of February till midsummer or later. But I would come to Glasgow for a few days in the beginning of July gladly to be with you all, and to help in receiving our foreign friends, if, in the circumstances, I may be allowed to have the honour of being President of the Glasgow Section."

Another letter from Lord Kelvin, read on the 12th February, 1907, is of great interest now. "I have not been very well since I returned from Edinburgh. I have had a rather bad attack of my twenty-three year old trouble, No. 5 nerve, and I shall be obliged to keep very quiet for some time. I hope next session I may be able to offer a short communication to the Glasgow Section. I am very sorry not to be able to do so at present."

Lord Kelvin died that year, and the short communication offered was never given.

Discussions of the papers were eagerly taken part in during the early years of the Section, a common remark in the minutes being:—"Owing to the lateness of the hour and the interest displayed in the paper, the discussion was adjourned to the next meeting."

The minutes of September, 1903, report this pleasing social innovation:—"In view of the fact that both last session's smoking concert and the previous session's dinner were in their respective ways pronounced successes, and that some members favoured the one form of entertainment, and some the other, it was decided that an attempt should be made this time to meet the wishes of all by holding a dinner early in November to open the session, and a smoking concert later, in February."

I may be allowed here to mention the *Scottish Electrician*, a journal which fought for existence from February, 1901, to December, 1904, 44 parts in all being issued. It contained very full accounts of the proceedings at the meetings during these years, and of our first Annual Dinner, which was held in the Windsor Hotel in this city on Tuesday, the 18th February, 1902, when I had the honour to preside.

In connection with the function, an interesting novelty was introduced which caused, at the time, considerable curiosity and speculation. Attached to the lighting brackets round the room, and hidden by greenery, were arranged a number of loud-speakers, each of which was connected to a transmitter in a room of the Corporation Telephone Exchange in Renfield-street, about half a mile from the hotel, where a small band of wind instruments with a piano was stationed to render a selection of combined numbers and solos, as well as the accompaniments in connection with the loyal toasts, all of which were transmitted over the wires and heard in the dining-hall with a clearness and distinctness thought remarkable and generally commented on.

Even more memorable and interesting than the first was our fifth Annual Dinner, held in the Grosvenor on the 27th November, 1906. The Rt. Hon. Lord Kelvin, Chairman of the Section, presided. Prof. Jack, in proposing the toast of the "Glasgow Local Section," paid a high tribute to Lord Kelvin's standing in the scientific world. He imagined that the verdict of the world upon Lord Kelvin was reasonably and impartially expressed by the deputation of foreign engineers who came to Glasgow, when the Italian delegates brought Lord Kelvin two magnificent volumes containing records of the work which had been recently discovered in Milan of one of the greatest Italians, Leonardo da Vinci—a man whose genius in science was only equalled by his genius in painting and music; one of the greatest men of the world. His books are full of personal notes and drawings done by his own hand, and the Italian delegates felt that there was no place in the world where the works would be more sure of an understanding reception than by bringing them to Lord Kelvin.

Lord Kelvin, who was loudly cheered, on rising to respond to the toast, said that he had listened with intense interest to what had fallen from Prof. Jack. The latter's kind references to himself from the time he entered the University as a child, until to-day, a period of 70 years, from the time he was an inhabitant of the old College of Glasgow, living in his father's house, his father being then professor of mathematics in the University—these references had deeply interested him. He thanked Prof. Jack for the kindliness with which he had spoken of him and for the over-appreciation—he felt it to be more than he deserved—which had been expressed of his scientific work. Prof. Jack had spoken of the constitution of the universe. Electrical engineers knew that their everyday business was the practical applications of science, but they were all scientific men and would sympathize with every application of their science to extend human thought through the remotest parts of the universe, to think of every possible development of dynamic action. To speak only of dead matter—the material subject of an electrical engineer's work—he was sure they were all scientific enough to take an interest in abstract speculations, even to think of the formation of concrete matter from atomic origin. That did not sound very practical; it was not very like the daily business of an electrical engineer, but electrical

engineers were scientific men, and scientific men could not help going beyond their daily range. He was sure they had listened to what Prof. Jack had said, and he was sure they would sympathize with the endeavour of any of their number who went beyond the range of practical science—and tried to penetrate into the secrets of nature, into the works before us, the grand works of the stars and of the universe. One of our greatest electrical engineers, Sir William Siemens, showed that —he (Lord Kelvin) did not say he could lift his mind—he was elevated by his mind from his daily practical work into grand speculations far beyond anything that this world could show of the properties of matter. He (Lord Kelvin) felt that he was there not in the capacity of trying to push farther and farther into endless space the result of dynamic laws, but to represent the Glasgow branch of the Institution. In their name he thanked Prof. Jack, and he thanked all the gentlemen present for the enthusiasm with which they had drunk the toast. It was the toast of "Ourselves" to a large degree, but they had friends among them—they had Dr. Glazebrook and other members of the parent Society.

The Glasgow branch of the Institution was certainly a very large province. Dr. Glazebrook had spoken of the time when there was no Institution of Electrical Engineers, but when there was a Society of Telegraph Engineers. It was considered at that time that the word "engineer" was scarcely touched by the delicate apparatus of the electric telegraph. They had not heard watch-makers called engineers, but they had watch-makers and workers in that domain, such as Wheatstone, whose prodigious practical knowledge of dynamics led him to see in the small mechanism of a watch the means of bringing out electrical results, such as the tremendous result that he gave us of 250 words per minute of telegraphy. That and submarine telegraphy constituted the subject matter and engaged the ideas of persons connected with electric telegraphy. He thought Sir William Siemens was the first to give them the name of "engineers." Sir William Siemens was certainly the founder—he believed he was right in that—of the Society of Telegraph Engineers, which soon after became the Institution of Electrical Engineers. He remembered particularly how they first heard of very large things proceeding from telegraphic work. They first heard of things large really from Siemens. He did not say that there were not others. There was Jacobi of St. Petersburg, who had an electric boat driven by an electro-magnetic engine before the time of Sir William Siemens. That, perhaps, was the first piece of real electrical engineering in the ordinary understanding of the word "engineer"—the applying of electricity to large forces for the benefit of mankind. He still remembered Sir William Siemens bringing before the Institution—he thought it then was of Telegraph Engineers—the means of developing forces at a distance of 10, 20 and 30 miles from the coal-burning to give the forces by a steam engine. The transmission of forces was, he believed, really due—he meant practically the first inception of the idea and the first bringing of it to a practical conclusion or to an advance towards practical conclusion—to Sir William Siemens. He remembered Sir William telling him of work done in the factory of Greenwich in which they had extraordinary tantrums, if he might use the expression, performed by the dynamos that they then had. All present would know what he meant when he said that the dynamos they then had were single-series dynamos. They knew what sort of thing that was if used as a generator to charge a battery, or even to drive a motor at a distance. Sir William and those who worked with him devised the shunt dynamo, and he told them he had made one which had got over all their troubles; but his people were still so averse to it—his people at the factory—that he could not get them to make another. He did not say he could not, but there was great difficulty in getting them to look at such a new thing. He (Lord Kelvin) begged Sir William to make one for him. He did so, and during six or eight years at least it was working in a little room adjoining the physical laboratory of the University of Glasgow. It was driven by a Clerk gas engine, which did its work well. He believed that really the first thorough practical electric lighting that was done anywhere, was done by this Clerk engine and Siemens shunt-wound dynamo. He believed that the first house on this planet in which the whole lighting was done by electricity was a house in the University of Glasgow, getting the current from that Siemens dynamo and the Clerk gas engine of which he had spoken. In that house the rule given to the workers for making what began to be called an installation soon after was: "Go through the whole house, wherever there is a gas burner, put in an electric light." There were 106 gas burners and there were 106 electric lights in that house about the end of the year 1881. There had been houses lighted in London. In Mr. Spottiswoode's (then the President of the Royal Society) there were six electric lights—six Swan electric lights shown and used in one room in the house. Edison had lighted rooms in houses in America. He had never heard that any house was wholly lighted by electric light at that time. There might have been one in America. There was not in this island, he believed. Well, that was a beginning. It was quickly followed by a large spreading out of the electric light. But he felt that the University of Glasgow might look upon it with some interest that a house in the University had its whole electric lighting done in the way he explained. It was not lighted the whole 24 hours. A little before midnight every night he himself used to go across to his laboratory and stop the gas engine, and anyone that wanted light in the house must have a candle, because the gas had been cut off and soldered up. But a little later came the storage battery, and for one whole year in the house there was not an inch of candle burnt. There was no other light—there might possibly have been a cigar light—but that was the very most—that was not done by electric lamps of Swan and Edison. In closing, his Lordship briefly referred to the progress of electrical engineering. From 1875 to 1905 there had been prodigious development of activity in the applications of science for the good of mankind.

I am sure you will agree that this is a most characteristic utterance of Lord Kelvin, and well worth quoting *in extenso*. It shows the great scientist and electrical engineer thinking, on his feet, in his own peculiar style of eager delivery, giving the impression of "thoughts

that broke through language and escaped "—luminous to those who had sufficient knowledge, but deeply involved, discursive and pointless to those who had not; lighting up new fields of thought and inquiry to the more enlightened, but darkening counsel with knowledge to all the *non-parati*. That itself was a thought of wonderful import thrown off in the going-by when in speaking of Sir William Siemens he remarked: " He (that is Lord Kelvin) did not say he could *lift* his mind—he was *elevated* by his mind from his daily practical work into grand speculations beyond anything that this world could show of the properties of matter."

Then there is the marvellous picture in that short sketch of his own house on Gilmorehill, lit by electricity —the whole house—the first on this planet to be so illuminated so far as he knew. He was elevated in his mind to see this advance and how to make it an accomplished fact before anyone else had reached it. Men will go far out of their way to visit old castles and derelict ruins on the Continent, but how many of the citizens of Glasgow know, or in passing look up in wistful cogitation at, this great sequestered edifice. But lo! the scene changes. The magician shows us the same house after midnight lit only by a candle in one room. The previous rustle of a ghostly figure scuttling across the quadrangle in the silence of the night, entering the laboratory, stopping a gas engine, and soldering a pipe in a weird dim red light, calls up visions of Faust and mediaeval wizardry. The man of science by these acts had put back the clock of the ages, but all the time in his quadrangular stride he was searching in his mind for a storage battery.

" Well, that was a beginning," were his own significant words. And he felt that the University of Glasgow might look upon it with some interest. But we, too, as the Scottish Centre of the Institution of Electrical Engineers, can also claim some of the credit and kudos of this great enterprise. He was one of us.

I think it would be a most interesting thing if one of our younger members would sketch the achievements of men of our own Centre along the lines of advance in electrical engineering within the last quarter of a century, the conclusion of which we are now celebrating.

Lord Kelvin's reference at the close of his speech to the progress of electrical engineering suggests an advance since then that not even he could anticipate. " From 1875 to 1905," he said, " there had been prodigious development of activity in the applications of science for the good of mankind." But that was before the development of aeroplanes, and airships, of telephony, wireless broadcasting, heating and lighting in their latest phases. And with regard to the structure of the universe in which he was deeply interested, and to which he made reference, that was before the special and general theories of Einstein, and the new conceptions of the atom as conceived by Rutherford, Bohr, Sommerfeld, and all the rest. How the mind of our late doyen and prince of science would revel in these!

The thought of it all makes one feel that we have now more need than ever for our Local Centre. It seems to stand to us for so much, rendering, in fact, a threefold service. It stands for common social intercourse at our Meetings, and Dinners. As iron sharpeneth iron, so does the face of a man's friend.

It stands for a common interest—electrical engineering with which we are all associated. But—perhaps the most important of all in these times—it stands for a common pursuit. We come here to discuss the science and art of our profession—the rapidly unfolding applications of electricity, and to endeavour to make our knowledge as practically available as possible for the good of mankind. What the next 25 years have in store in this direction, no one can even guess. Electrical engineers may be on the roof of the world, or they may be fitting abodes and means of transport in its interior. At any rate they may be depended upon to give us light and warmth and transport with a few more of the luxuries which science continues to offer.

EAST MIDLAND SUB-CENTRE: CHAIRMAN'S ADDRESS

By B. ADAIR M. BOYCE, Associate Member.

"ENERGY."

(Address delivered at LOUGHBOROUGH, *6th October,* 1925.)

I have chosen for the subject of my address this evening "Energy." It is a very old subject and a lot has been written about it from time to time, and from various standpoints; but the point of view I wish to stress in these remarks is the comparatively inefficient use we make of energy. Whilst some of the factors affecting this inefficient use are capable of control, many—without some epoch-making discovery—are not.

Energy may be defined as the "capacity for doing work"; it is the basis of life; and without energy we cannot conceive the existence of any universe. The primary source of all our energy is the sun, but there is also the mechanical energy stored in the rotation of the earth on its axis, heat energy in the interior of the earth, and radioactive substances. Ultimately these can all be attributed to the sun.

The different forms of energy as related to these sources are:—

The Sun.
- Direct radiation. Heat and light.
- Plant life.
- Fuel. Coal, oil, gas, etc.
- Muscular energy. Man and animal.
- Flowing water.
- Wind (in part).

Earth's Rotation.
- Tides.
- Wind and waves (in part).

Internal Heat of the Earth.
- Volcanoes.
- Hot springs and geysers.

Radioactivity.
- Radium.

Before discussing these various forms of energy in detail, perhaps I should state that energy may be divided into two classes, viz.—

Potential energy, or the energy a system possesses by virtue of the position of its parts; and

Kinetic energy, or available energy possessed by a system in virtue of the motion of its parts.

The sun.—The energy received by the earth exposed perpendicularly to the sun's rays at the mean distance of the sun is 2·1 calories per minute per cm^2. This equals 1·47 kW per (metre)^2, or 1·7 horse-power per square yard.

The earth rotates at a velocity of about 17·36 miles a minute at the equator, and the energy stored up by rotation amounts to 10^{25} h.p.-hours, its orbital energy being about 10^{27} h.p.-hours. If it were possible to increase the length of the day by only 5 minutes—by decreasing the rotation of the earth—the stored energy released would amount to 1 000 million h.p. for 70 000 years. Unfortunately, from one point of view, we cannot control this.

Further classifications of energy are:—

Mechanical, Electrical, Chemical,

and also, to the extent to which the various forms are used,

Fuel, Flowing water, Winds, Tides, Ocean waves, Solar radiation, Muscular energy.

Fuel.—The most important form of energy is fuel, comprising coal, oil, gas, wood, alcohol, etc.

The heat value of an average coal may be 11 000 B.Th.U. per lb. Consider how this is used in a modern medium-sized station and let us call the heat in the coal 100 per cent.

We get only 15 per cent out as available electrical energy. We lose 20 per cent in boilers, 1·25 per cent in steam-pipe radiation, 1·15 per cent in turbine and alternator losses, and 61·6 per cent is thrown away in the condenser cooling-water.

While I am on the subject of coal as a fuel, a few figures may be of interest. In 1922 the total quantity of coal raised in Great Britain was 249·6 million tons. Of this 25·7 per cent was exported and only 2·7 per cent was used in electrical generating stations. Domestic fuel accounted for 15·2 per cent—this is probably the most inefficient way of using coal. Gas-works used 6·6 per cent; railway locomotives 5·1 per cent; collieries, for engine fuel, 6·5 per cent; and miners' coal 2·3 per cent. Coal carbonized in coke ovens, probably the most efficient way of using it known at present, accounted for 5·4 per cent of the total.

From the Report of the Electricity Commissioners for 1922–23, the average number of units generated per ton of coal was 803, which represents 2·8 lb. of coal per unit. Only 11 undertakings generated more than 1 000 units per ton, the figures being 1·8 to 2·24 lb. of coal per unit. Of the units sold, 18·9 per cent was for lighting and domestic use and 67·7 per cent for power, the average price being 5·3d. per unit for lighting and 1·3d. for power.

The number of units used per head of population is interesting:—80 per cent of the population use less than 100 units per annum; 14·7 per cent between 100 and 200 units; 5 per cent between 200 and 300 units; and only 1·1 per cent 300 units and over.

In 1920 the United States used 176 units per head,

against our 60, and in May, 1924, the figure for Chicago was 700, against Manchester's 246.

I should now like to mention, in comparison, the human energy-transformer. The figures are due to Dr. A. T. Schofield. The daily average losses of the human body are $2\frac{1}{2}$ lb. of solids and gases, and 6 lb. of water.

The daily make-up is $1\frac{1}{8}$ lb. solids (dry food), $1\frac{7}{8}$ lb. oxygen, and $5\frac{1}{2}$ lb. water. The $\frac{1}{2}$ lb. difference in water is made up by combustion. This food taken represents 3 400 ft.-tons of energy, or 2·88 kWh or units, of which 3 060 ft.-tons, or nine-tenths, are used in maintaining the heat of the body, and 340 in the active functions of life, in storing energy by physiological processes, or are expended in nervous and mechanical energy.

It will be seen that the useful efficiency is only 10 per cent, and I shall refer to this later.

Fuel oil.—The heat value ranges between 18 500 and 19 500 B.Th.U. per lb. The oil fuel used in Great Britain is under 1 per cent of the weight of coal used, whilst the average price is 80s. 6d. per ton, against the average price of 20s. 5d. for coal.

Gas.—Small producer-gas stations averaging about 500 kW maximum demand show figures comparable with the largest steam generating-stations, the best figures (taken from the report of the Electricity Commission, 1925) being :—

	Lowest aver. fuel consumption per unit generated	Maximum demand	Thermal efficiency
	lb.	kW	per cent
Steam station ..	1·51	48 870	19·85
Producer-gas station	1·54	141	14·76

A careful examination of the figures will also show that the medium-sized station, when equipped with efficient plant, can sell to the consumer cheaper energy than they could if a supply were taken in bulk from a large station some distance away, the losses in transmission being large enough to have a material effect on the efficiency.

Alcohol.—I think that we shall hear a lot more of this fuel in the future. It can be cheaply produced from a number of substances, and when the restrictions now placed on its sale are relaxed it must come into its own.

Its heat value, when 7 to 9 per cent denatured, is about 11 500 B.Th.U. per lb. If free from water the value is 12 420 B.Th.U., and with 20 per cent of water 9 936 B.Th.U.

Let us take the sugar industry now being developed in this country : 1 ton of sugar will yield 40 gallons of molasses, from which 16 gallons of first-quality alcohol can be produced. Other sources available for this country are potatoes, mangolds, and jerusalem artichokes. Cane molasses will produce 69 gallons of 95 per cent spirit per ton.

Incidentally, a company is now working in this country with tanks capable of storing 20 000 tons of molasses, which will produce 1 450 000 gallons of alcohol.

The amount produced in America for power purposes is approximately 58 000 000 gallons annually. The Commonwealth Parliament of Australia has approved of the payment of 4d. a gallon on Australian-produced power alcohol. One company is prepared to spend £50 000 for the erection of plant in Queensland, and the Queensland Government is willing to contribute £25 000.

There is a solid fuel of Continental manufacture called "meta," which has recently been introduced into this country. I have a tablet here. It has been referred to as solid alcohol ; it burns like alcohol and does not evaporate. It is at present being put forward as a portable domestic fuel in place of methylated spirit. The material is metaldehyde, and its composition is carbon, hydrogen and oxygen. The calorific value is 11 450 B.Th.U. per lb.

Water power.—The economical use of energy from water power is generally confined to areas where there is a considerable fall or head of water.

The cost of equipment for handling large volumes of water with low head will generally be so high that it will be found cheaper to buy power from steam generating-stations. This applies to the use of tidal power.

In Canada there are hydro-electric installations in operation generating 3 569 275 h.p., and 600 000 h.p. will be added in 1925.

Wind.—Wind energy can be used economically for very small plants, such as pumping and lighting plants for isolated farms, etc. The force exerted increases as the square of the velocity of the wind. A gentle breeze of 5 miles per hour exerts a force of 0·123 lb. per square foot, a brisk wind of 25 miles per hour 3 lb., whilst a storm of 50 miles per hour gives 12·3 lb.

Solar radiation.—The most economical way of using solar radiation is by means of plant life, the necessary fertilizers being produced as a by-product and returned to the soil.

We could raise the overall efficiency of our uses of energy if we could only cut out some of the transformations that we are now compelled to employ.

Take the case of a steam-driven power station. Our energy emanates from the sun and is conveyed to the earth as electromagnetic waves of the wave-length of heat and light. This is transformed by plant life to chemical energy, and in course of time coal is formed—our usual starting point.

This chemical energy is transformed to thermal energy by combustion ; the thermal energy to mechanical by expansion under heat in the turbine ; and mechanical to electrical by the alternators (which have an efficiency often reaching the high figure of 95 or 96 per cent).

We are now back at the starting point and the energy is again electromagnetic ; no wonder our efficiency is low.

If we now use this energy as light—which is also electromagnetic—we again have a low efficiency, as we have at present no efficient means of confining the wave-lengths to those parts of the spectrum which give us the sensation we call light, but we also get longer waves of heat and in some cases shorter waves of ultra-violet invisible radiation. What we want is cold light.

If we use the energy as heat we obtain the highest efficiency of all ; and if we use it as power we lose

10 to 20 per cent as heat in the motors, although, bearing in mind the magnitude of the losses which we have been considering, this represents a comparatively high efficiency.

A few remarks on the energy of electrical storms may prove interesting. Such storms have a considerable stimulating effect on the growth of plant life.

In a severe thunderstorm the approximate amount of energy stored in the electrostatic field—that is, considering the cloud and the earth as the plates of a huge condenser—is about 700 kWh. The voltage of a flash has been estimated by means of the induction on scale models as 100 million volts, and the current as approximately 78 000 amperes. This represents a tremendous horse-power, but, as it is exerted for an exceedingly short time, the energy is not of a high order, being 13 500 kW-seconds, or 3·76 kWh.

Lightning conductors and aerials when well earthed are to a certain extent a preventive of direct strokes, by lowering the electrostatic stress in their immediate neighbourhood, but people using wireless aerials should in any case take no risks during storms and should earth their aerials outside the house, as even an induced stroke from an object struck some distance away may cause considerable damage to apparatus.

We now come to human energy, or the employment of the 340 ft.-tons per day referred to earlier. This is, by the way, 0·288 kWh, or just over one-quarter of a unit (i.e. worth about 1½d. at the lighting rate in Loughborough).

It will be obvious that we consider this energy to be in a much higher and more valuable class than the energy we buy through a meter. We expend it in nervous and mechanical energy. The more we expend in mechanical, the less we have for nervous or brain energy. This is, of course, apart from the necessary mechanical work (such as the propulsion of a ball) necessary to keep the plant in order. Therefore, the only common-sense way is to buy energy through a meter and use it for every possible purpose. This means more electricity in the home, office and works, or on the farm, in fact everywhere.

More horse-power used per individual means more production all round, as it is recognized that the productivity of a country bears a direct relation to the power consumption per head. This necessarily follows from the fact that the use of more machinery gives greater leisure, and our needs will increase as the means for satisfying those needs increase.

With regard to the use of power in the home, the trouble as I see it is capital cost. If I rent a house which is not electrically wired or equipped and the landlord will not do anything, I should consider it a risky investment to have the house wired and fitted up at my own expense. It is clearly the business of the supply undertaking to make these divergent ends meet and to leave no stone unturned to convince everyone in its area that it will pay them to use power. Then, instead of, as now, only 1·1 per cent of the population using 300 or over units per annum, we might get the population to use 500 units per head and reduce the cost to a much lower figure than it is to-day.

In conclusion, I should like to acknowledge my indebtedness to articles published by Messrs. Rushmore, Peek, and others, for some of the matter included in this address.

DUNDEE SUB-CENTRE: CHAIRMAN'S ADDRESS

By J. S. THOMSON, Associate Member.

(*Address delivered at* DUNDEE, *22nd October*, 1925.)

The duties of those engaged in electrical work are varied and complex. It is therefore natural that men should find themselves gradually specializing in one branch or department, and, in fact, it would be quite impossible for the average individual, at any rate, to be an expert in every department of electrical development. We all wish, however, to be kept in touch at least with what is going on round about us, and there is no better way than by coming together at meetings such as these and by reading carefully the papers and discussions thereon printed in the *Journal*.

Electricity is rendering in a multitude of ways great service to man. This service will go on increasing, and as electrical engineers we should endeavour to develop the spirit of service. I am satisfied that the more of this spirit of service we put into the daily routine, the more will the industry we represent, and we ourselves as members of the electrical profession, prosper, and, what is also important, the more shall we individually get out of life.

We cannot cultivate the idea of service to any great extent without becoming enthusiastic in our work, and all electrical engineers should be enthusiasts. What are we to think of the engineer who does not even take advantage of electricity in his own home; or who uses it for lighting his house but only smiles when cooking by electricity is mentioned; or who shrugs his shoulders when the idea of using a battery vehicle is suggested, or who looks at us with a kind of pitying contempt when the possibility of heating water electrically is hinted at? Such men, however, do, it is to be feared, exist, but they cannot possibly help forward the electrical industry to the extent they should. What is more, they delay the coming of the time when the public will enjoy the full benefits of electricity supply—the very service they should be anxious to help in conferring on their fellow creatures.

Enthusiasm run wild may, however, be dangerous. The man who insists that electricity should be used for every cooking, transport or hot-water-supply problem without thoroughly going into the details of the case may easily do harm. There are questions to be considered, such as the capital cost of the apparatus and the cost of altering existing arrangements, etc.; and these may, for the time being, render a scheme impracticable. To get over these difficulties there is sometimes a temptation to carry the arrangement out in some half-measure fashion which is altogether unsuitable for the economical use of current. The result is failure. After a short trial the scheme is abandoned altogether and harm is done that may take a long time to live down. It is necessary, therefore, to look at every proposition with an open mind. If satisfied that electricity is the right thing in the circumstances, it should be put forward wholeheartedly. If this cannot be done and a case made for electricity strictly on its merits it is better left alone. We have such an excellent commodity that there is no need and no sense in trying to sell it on any other lines than pure merit.

The public cannot, I think, know too much about electricity, and in this connection the British Electrical Development Association is carrying on excellent educational work in bringing to the public notice the uses and advantages of electricity supply. The astonishing thing, however, is that in the past these efforts have been very greatly hampered by lack of funds. The work of the Association is of great value to both the contracting and the supply business, and one would imagine that every engineer, at any rate, must not only be in favour of but admire the educational and propaganda work that is being done. Let us hope, therefore, that the Association will increasingly receive the backing necessary for carrying on the good work.

From a return issued by the Electricity Commissioners, covering the three years 1920 to 1923, I find that the units sold for lighting and domestic purposes and for power amounted to approximately 19 per cent and 68 per cent respectively of the total sales, leaving some 13 per cent of the total for public lighting, traction and miscellaneous uses. These figures show very clearly how the output for lighting has gradually dropped to quite a small percentage of the total.

The figure of 19 per cent includes current sold for domestic purposes other than lighting. The importance of this class of load is now being more fully appreciated, and domestic use for "other than lighting purposes" will year by year demand current in increasing quantities. It will be interesting to watch future development in this direction. How long will it take for the figures of 19 per cent and 68 per cent to be reversed, or will the consumption for power purposes always exceed that for lighting and domestic uses? If the latter, will the ratio remain as at present or will it be reduced? It is probably safe to take it that less than 20 per cent of the houses in the country are wired for electricity, also that the consumption in a house making a fuller use of electricity may be anything up to, say, 30 times that for lighting only. In my own house, lighting accounts for 200 units a year, and other purposes for 4 000 units. I think it is also probably true that a large proportion of the new connections are domestic premises. In the undertaking with which I am connected about 68 per cent of the consumers added each year are "domestic." Although these consumers may, at the moment, individually make only a small demand for electricity, they nevertheless are, in the aggregate,

potential users of current to a large amount. Assume for a moment that the lighting and domestic supplies increased tenfold and that the supplies for power purposes remained stationary. The figures of 19 per cent for lighting and domestic purposes and of 68 per cent for power would then become 70 per cent and 25 per cent respectively of the total.

The demand for power purposes will of course not remain stationary, and certainly no one wishes that it should, but I want to bring out the tremendous possibilities opened up by the domestic load. There seems to be no reason why the sale of current to this class of consumer should not increase much more than tenfold. While therefore there should certainly be no slackening off in the development of the power load, the domestic and lighting loads should be cultivated as energetically as possible.

Whilst the sales for lighting and domestic uses and for power purposes represented respectively 19 per cent and 68 per cent of the total, the revenue was in each case approximately 42 per cent of the total. A tenfold increase in sales for domestic purposes would probably increase the revenue approximately threefold. This is, perhaps, the reason why some engineers seem to fight rather shy of pushing the domestic load, apparently fearing that the whole of their cable system will quickly become fully loaded and that they will soon find themselves in all sorts of difficulties. But why not load up cables? If the business is profitable it should surely be our endeavour to cultivate it to the fullest extent possible. Is the domestic load profitable? Which is the better, a factory making a power demand on the station of 100 kW, or a considerable number of houses making a combined load on the station of the same amount for purposes other than lighting? Such a factory working 44 hours per week might possibly use 4 400 units per week, or say 220 000 units per annum. This would be possible only on a load factor of 100 per cent over the whole of the working hours of the year. Even under these ideal conditions the highest possible annual load factor is only 25 per cent. A much more likely figure would be 20 per cent, giving a consumption of approximately 175 000 units.

Take now 100 houses, each using 200 units for lighting, and assume a tenfold increase in consumption due to current being used for other purposes. The increase in consumption would amount to 180 000 units, or slightly more than the factory consumption. The maximum load on the station for this output of 180 000 units for domestic purposes would, however, due to the better load factor of that class of load, be less than 100 kW and probably not more than 68 kW. Whilst the load factor of the individual domestic installation is low, the diversity factor comes to the rescue to such an extent that the load factor on the station in respect of supplies for domestic purposes other than lighting is considerably higher than that from supplies to factories and other concerns working the ordinary day-hours only. This is easily appreciated when it is remembered that the ordinary day in the home covers about 16 hours for 7 days each week, making a total of 112 hours per week, as against 44 to 50 hours for the factory. Thus, for a given maximum demand on the station, approximately three units will be sold for domestic purposes for every two units taken by factories.

So far then as the cost of generation, transmission to substations, and transformation is concerned, current for domestic supplies can be delivered at the low-pressure terminals of the substation transformers more cheaply than for factory supplies.

This brings us down to the low-pressure distribution mains and service cables. The size of a service cable, to an ordinary house, is generally much larger than would be required for the lighting load only. In certain cases it might be necessary to lay a larger cable, but even then the extra cost is small and, generally speaking, there would be very little, if any, additional outlay on the actual service cables. The same applies largely to meters, and no extra cost would be incurred in the meter-reading and accounts departments, although the consumption of every domestic consumer increased much more than tenfold.

Any possible difficulty in providing current for domestic purposes therefore can only be in connection with the low-pressure distribution mains. These mains, however, must in any case be provided for giving supplies for lighting. The only additional cost, therefore, of supplying current for domestic purposes from the low-pressure distribution mains, compared with supplying current to a factory from a substation in the factory, is that in respect of the outlay in providing additional copper in the distribution mains. The interest and other charges on such additional outlay is certainly more than provided for by the revenue received from the sale of 50 per cent more current than would be taken by the factory for the same loading on the station plant, high-tension transmission cables and transformers.

The problem may be considerably simplified by having transforming substations placed at frequent intervals. This allows a fuller use to be made of the copper in the low-pressure mains without undue voltage-drop. For purely residential districts and thinly populated areas it would seem desirable to adopt a higher pressure, say 3 000 volts, for the distribution mains, using transformers for each house or for groups of houses as required, and in this way ultimately to limit the low-pressure distribution cables fed from each transformer to, say, not more than a few hundred yards in length. It would seem unnecessary to provide any switch- or fuse-gear on the 3 000-volt side of these transformers, and the transformers would simply form part of the cable system. The space taken up by, say, a 100-kW transformer arranged in this way is very small and should easily be provided.

In the foregoing I have been thinking of alternating-current supplies only. It may be weakness on my part, but I find it difficult to do otherwise. In the case of direct-current networks it would appear desirable to consider the question of installing a.c. generating plant in conjunction with rotary converters in the power station and the laying down of new cable extensions beyond a certain distance from the power station on the a.c. system. It is difficult to see how otherwise the ordinary town or city undertaking is to develop the outlaying areas economically. In my opinion the

domestic load is very desirable and profitable and should be cultivated to the fullest extent. I believe that in time it will very largely form the backbone of the electricity supply industry.

I do not know to what extent the wiring and contracting branch of the industry is represented at our Institution meetings generally, but I should like to see a better representation at the Dundee Sub-Centre. Supply engineers are apt sometimes to look upon installation work as a job that any fool can tackle. That is not my view and I think that there is a large scope for good engineers in the contracting business. Certainly examples of shop and house wiring are to be seen that are anything but a credit to the contractor or to the profession. This condition of things is, for the most part, probably due to very keen competition and consequent price-cutting—a feature which we should all wish to see the industry rid of.

Now, unless premises are wired, the supply undertakings cannot sell current, and it is the business of contractors to wire premises. Supply undertakings should therefore welcome every application brought in by contractors and should give contractors, especially the smaller firms just starting business, all the assistance possible. On the other hand, contractors should see to it that only sound jobs are carried out, as otherwise they bring discredit, not only on themselves but on the whole industry, and retard the rate of development.

There is no doubt that, but for the high cost of wiring, new consumers of electricity would be secured at a very rapid rate. To reduce the cost of wiring by using inferior material and rough workmanship will not help matters. Is there no other way of reducing installation costs? I have counted the number of circuits in an ordinary house, not by any means a large one, and find that there are no fewer than 12 circuits—12 pipes and 24 wires—starting from behind the back door to carry current to a few lamps, an occasional radiator or two, and in the kitchen a cooking outfit. According to the tables in the I.E.E. Wiring Regulations these 12 circuits are capable of dealing with 188 amperes, or a load of approximately 41 kW. The lighting circuits alone are sufficient for 6½ kW. The total loading of the lamps installed, at an average of 40 watts per lamp, is under 1¼ kW, and the actual load probably never exceeds ½ kW. The service cable from the street is 7/16 S.W.G., and on the same basis is therefore sufficient for a load of approximately 10 kW. The house referred to is, I take it, quite typical of many others and, if so, it seems to me that there is something very wrong here and that a considerable saving might be brought about simply by reducing the number of circuits. The introduction of the two-part tariff should help in this direction, but it is doubtful to what extent the advantages of this tariff are understood or appreciated by contractors. By unnecessarily keeping up the cost of installation work by putting in a lot of needless material, contractors are, of course, simply standing in their own light. To my mind the ideal system, modified to suit conditions, would be one main circuit controlled by a switch and fuses, each individual piece of apparatus connected to such circuit being fused at the point of connection. In the case of portable apparatus the fuse should be embodied in the plug. Groups of lamps would also be connected through fuses to the main circuit.

This is, after all, the arrangement generally followed in the wiring for motors in works. What should we think if a supply undertaking fixed a large fuse distribution-box at the end of a street and from this ran a twin cable for each consumer in that street? The arrangement would, however, be just about as sensible as the usual method employed in wiring a house. It may be going too far to say that the existing methods of house wiring should be revolutionized, but I am quite sure that it is not beyond the skill of the industry to devise methods for, at the same time, both improving and cheapening installations. I should greatly welcome some good papers on this very important subject.

Any method of providing satisfactory installations at less cost would undoubtedly secure increased business both for contractors and for supply undertakings. There would still remain, however, the difficulty of the tenant occupier; and some system of assisted hire-purchase, or free wiring, seems necessary in order to secure a very large proportion of the present unwired premises. Even now the supply undertaking takes the risk of putting down power stations, transmission cables, substations, distribution mains, service lines and meters. Why not proceed a stage further and wire to the actual lamp or other current-consuming device, thereby securing more consumers per unit length of distribution main?

This would seem a very sound method of reducing the cost of distribution. We all appreciate that systems of assisted wiring are not altogether free from difficulties. A considerable number of such schemes are, however, in operation, and for the most part with apparently satisfactory results. I think that this is a matter to which all supply engineers will sooner or later have to give their serious attention.

I do not wish to discuss the different designs of cooking apparatus. I have already said enough to show the importance which I attach to electric cooking. Apparatus has now reached such a stage of development that no one need be afraid to recommend his best friend to buy it, if the latter can afford the outlay and is unable to obtain the articles he requires on hire.

There is really nothing wrong with the apparatus or with the cost of using it. The initial cost is, however, a difficulty, and not every one is in a position to purchase a cooker, however great may be the desire to enjoy food cooked in the best way. Sooner or later I am satisfied that all supply undertakings will appreciate the necessity of giving their consumers facilities, on easy terms, for cooking by electricity.

The use of electricity for heating has increased very rapidly during recent years, and electric fires are now available in almost endless variety. As one unit of electricity contains a fixed number of heat units, all such fires have, in one sense, an equal efficiency, viz. 100 per cent. What may, however, be called the effective efficiency varies very considerably, and it is always necessary when advising on the use of electric heating to try to ascertain exactly what is the duty required of the heater; otherwise the best results cannot be expected. In this connection it is well to remember

that the best condition for working is to have warm feet and a cool head. For example, a small amount of heat applied under a desk or table from, say, a 250-watt fire will frequently give, at one-eighth of the cost, better results than a 2 000-watt fire placed in the wrong corner of a room.

The heating of water offers some very interesting problems, and while it may be difficult to see how electricity can compete on cost with coal or coke for heating large quantities of water, there are many cases where the matter is not nearly so hopeless as may at first sight appear. The very high efficiency of the apparatus, the ease with which the water may be heated at the points of use, and the absence of all labour, fumes, dust, etc., are frequently sufficient to turn the scale entirely in favour of electricity. Water-heating also opens up possibilities of securing a considerable and steady 24-hour load.

In premises making a sufficient use of electricity for general purposes, to cover all standing charges it would seem that an additional unmetered supply taken continuously over the 24 hours could be given at a low, but at the same time remunerative, fixed charge. A properly lagged tank fitted with a 250-watt heater should provide over 18 gallons of water per day at a temperature of about 140° F. A charge for this service of 7s. 6d. per month would give the supply undertaking a revenue of £18 per kilowatt of demand. Are there many undertakings likely to refuse such an additional revenue from existing consumers? Would many not gladly accept less?

The battery vehicle does not seem to make in this country the progress one would have expected. We all know the dislike many engineers have for storage batteries, a dislike brought about in many cases, I believe, due to the installing of a battery for a certain purpose and using it for duties for which it was never intended. We should, however, be just, and in such cases it is hardly fair to blame the battery. Several large firms in London and elsewhere are using battery vehicles in increasing numbers, and I take it that they are doing so because they find it pays. For city and town work the advantages of the battery vehicle are really well known, if not always readily admitted. Are we engineers encouraging the use of such vehicles to the extent we might? At Townhill power station we have a 3½-ton battery vehicle and a battery locomotive, and I can safely say that very few parts of the station equipment perform their duties as regularly and with as little fuss as do these two battery vehicles. There are two other vehicles on our system each using about 14 000 units a year, and from the revenue point of view such vehicles are therefore worthy of consideration. The surface of our roadways generally is being steadily improved, and I really think that we should give the use of battery vehicles in transport problems more attention than we have perhaps done in the past. I hope that we shall soon become more familiar with the appearance of such vehicles on our streets.

I am glad to notice that the supply of electricity to farms is receiving increasing attention. The farmer requires a supply in his home for lighting, cooking and heating, just as much as other people do. He also requires light in all the farmstead buildings, in addition to a supply of power for an almost endless variety of purposes in connection with the working of his farm. Where 6 600-volt or 11 000-volt lines or cables exist there is no difficulty in giving a supply from such. In my own area a supply is at present given to some 50 farms and I know how greatly the advantages are appreciated by the farmers. I look forward to a steady increase both in the number of farms connected and also in the number of units used per acre. There is no doubt about the advantages arising from a supply of power being always available at a farm, and it is, I think, for us to see that electricity is brought within reach of as many farms as possible. In the interests of the country we cannot do this too soon.

We still hear a good deal about "cheap and abundant supplies of electricity"—a rather unfortunate phrase, I think, and one that is apt to do more harm than good. The price of electricity in this country is not unduly high, and is certainly not responsible for trade depression. It is questionable whether many industries which are now finding it difficult to make ends meet would be appreciably better if supplied with free electricity.

The price of electricity for various uses should very largely be regulated by the cost of the alternative methods of obtaining the power, light or heat required. In practically every case electricity offers advantages which are not available by the other methods, and such advantages are always worth something.

The way to cheapen electricity is to develop and push its use for all purposes and carefully to grade the price to suit the different purposes for which it is used.

We require foresight and, above all, an implicit belief in the commodity we have to sell. If only everyone connected with the manufacture of electrical plant and the generation of electricity, and especially those engaged in the sale of current, completely possessed these qualities, the country would be satisfied with the price of electricity and the sufficiency of the supply.

A GENERAL SURVEY OF THE HIGH-TENSION SWITCHGEAR FIELD.

By S. FERGUSON, Member.

(*Paper* received 19th January, 1925; read before the* EAST MIDLAND SUB-CENTRE *10th February*, 1925.)

SUMMARY.

The object of the paper is to aid the operating engineer in laying out high-tension switchgear schemes. It deals with the evolution of switchgear, giving the contributing factors in its development. The present-day types are scheduled and the principal features compared in the light of the requirements of good switchgear. The most suitable type to meet modern conditions is indicated as being a form of metal-clad, compound- or oil-filled, interlocked, draw-out unit for pressures up to 66 kV. A plea is made for the standardization of this type as the best course to adopt for effecting a reduction in switchgear prices.

Various schemes of connections for central stations and substations are considered, and the advantages and disadvantages of different arrangements recorded. A number of typical installations are shown for super-power stations, and particularly super-tension layouts for indoor and outdoor service. The working principles of oil circuit breakers are considered, together with the various factors which affect breaking capacity.

Section 1.

PRESENT-DAY TYPES AND THEIR EVOLUTION.

SCHEDULE OF TYPES.

The following is a brief schedule of present-day types of high-tension switchgear :—

(1) Open floor mounting.
(2) Panel mounting.
(3) Cellular (brick or concrete).
  (*a*) Non-interlocked.
  (*b*) Interlocked.
(4) Metal-enclosed, stationary, air-insulated.
  (*a*) Non-interlocked.
  (*b*) Interlocked.
(5) Metal-enclosed, truck, air-insulated, interlocked.
(6) Metal-clad, draw-out, compound-insulated.
  (*a*) Truck type, completely interlocked, horizontal isolation.
  (*b*) Carriage type, completely interlocked, horizontal isolation.
  (*c*) Slung type, completely interlocked, vertical isolation.
(7) Metal-clad, draw-out, oil-insulated, interlocked.
(8) Outdoor type.
  (*a*) Open floor mounting.
  (*b*) Cubicle floor mounting.
  (*c*) Pole mounting.

* The original paper consisted of eight Sections, of which five are here published. The Sections omitted were entitled "Introduction," "Protective Gear," and "Circuit Equipments" respectively.

EVOLUTION OF HIGH-TENSION SWITCHGEAR.

It would appear to a casual observer that the numerous present-day types of high-tension switchgear have been dictated by fashion. Such is not the case, however, as there are many reasons for the continual changes which have taken place during the past 20 years. Environment has had a profound effect on the evolution of switchgear. In England, with its dense, industrial areas, switchgear has taken a condensed form and a relatively small amount of outdoor gear is in service. In America, with its large stretches of open space, outdoor switchgear has been developed to a much greater extent in order to avoid high building costs as transmission voltages have increased.

Concentration of power due to the rapid growth of power schemes has made it all the more imperative that switchgear should not be a source of weakness to the system which it is intended to protect. The open cellular principle was introduced by Dr. Ferranti in 1894, the ideas underlying the design being the entire elimination of earthed metal work in the vicinity of high-tension conductors, and the provision of a cellular housing with a view to the localization of damage. This type of switchgear proved dangerous to the attendant, was non-fireproof, and was only suitable for the control of small amounts of power.

In order to protect the operator the panel-mounting type was evolved. All high-tension gear was mounted behind flat-back control panels which protected the attendant during switching operations but did not protect him sufficiently when cleaning or repairing the oil circuit breaker. A more satisfactory arrangement was the use of concrete or brick cells, closed in with steel doors, for the switchgear housing. As a result of the rapid increase in plant capacities, cellular gear had to be correspondingly increased in size until several floors of the central station were needed for its accommodation, with a consequent increase in building costs. This type of construction was also used initially for substations, but it was too costly, lacked portability, and took too long to erect. Consequently, the steel cubicle type was adopted because it was factory-built, portable, and could be erected with ease and rapidity.

Experience showed that with the ever-increasing size of apparatus the cubicle construction was not altogether the best as regards accessibility of gear. This was specially so where it was desired to erect cubicles against a wall and to obtain access from the front only. In consequence a demand developed for the truck type of cubicle in which all the parts required to be accessible could easily be withdrawn from the live portion of the equipment. The draw-out idea, as

applied to built-up sheet-steel cubicles, was introduced in this country as early as 1903. The demand for this class of gear was also prompted by the desire for increased safety to the operator. It was not an uncommon occurrence for one of the connecting rods on a set of mechanically-operated isolators to break, thus giving the operator a false sense of security. Compared with the totally-interlocked steel cubicle, the truck had a great advantage in its increased safety of operation and accessibility, but it did not come into its own for a considerable time, due to the fear that the plug-and-socket portion might not give satisfactory service. Subsequent experience proved the gear to be sound, and the demand became considerable.

The development of larger power stations along with underground cable systems brought in its train many factors which reacted on switchgear design. The interruption of heavy short-circuit power produced excessive surges, and under these conditions the air clearances, which had hitherto been considered adequate, were broken down. The solution of this problem was either to increase the air clearances and thus make the switchgear more bulky, or to replace the air by a more stable dielectric such as compound or oil. In order to meet these conditions the metal-clad compound-filled draw-out type was developed contemporary with the truck cubicle. The commercial design of this apparatus was first undertaken by a British maker in 1905, when it was installed by the electrical companies operating on the North-East Coast.

Reviewing the evolution of switchgear, the following factors have contributed largely to the result :—

(1) Space considerations. These were brought into prominence by high building costs for central stations and substations in built-up areas. The difficulty in getting consumers to allow sufficient space for substations and the desire to increase the capacity of generating units in existing stations have led to condensed forms of switchgear.
(2) Stability. The dependence of large industries on the public supplies has increased the demand for reliability and continuity. This factor has contributed to the introduction of dielectrics having a greater stability than air.
(3) Protection to life. This has been increased by the Home Office Regulations and "safety first" propaganda, resulting in the encouragement of draw-out switchgear.
(4) Low cost. The demand for cheap electric supplies, which has been the main factor in the development of factory-built control units.

Deciding Factors in the Selection of a Suitable Type.

In making a fair comparison of different types the following factors have to be considered, and the relative importance to be attached to each will vary according to the conditions to be met. Each factor can only be applied relatively to the various types from which a choice is to be made.

Schedule of factors.

(1) Immunity from breakdown due to the following causes :—
   (a) Surges.
   (b) Instability of the dielectric.
   (c) Vermin.
   (d) Dust, dirt and moisture.
   (e) Electromagnetic forces on short-circuit.
   (f) Thermal effects on short-circuit.
   (g) Explosions.
(2) Protection to life of operator.
(3) Localization of damage and reduction of fire risk.
(4) Ease of control for normal switching operations.
(5) Facilities for inspection and repairs to circuit breaker.
(6) Space occupied.
(7) Time taken to install.
(8) Portability.
(9) Cost.
   (a) Capital.
   (b) Depreciation.
   (c) Maintenance and cleaning.
(10) Facilities for carrying out extensions and modifications.
(11) Facilities for installation of a spare circuit breaker.

Comparison of Features.

The numerous present-day types of high-tension switchgear are well known and therefore no attempt has been made to describe them. Metal-clad oil-insulated draw-out switchgear is an exception. This type is an entirely new development and has only recently been put into commercial use. An illustration is given in Fig. 6. Oil insulation is used in place of compound insulation, but with slight variations the same unit can be used for either.

Each type derives its individuality by virtue of a particular combination of the seven fundamental features given in Table 1, and these will be discussed separately.

Insulation.

The connections between individual pieces of apparatus may be insulated by air, compound or oil, and it is the relative merits of these dielectrics which will be considered. In the following remarks, air-insulated gear will be referred to as "open gear," and compound- or oil-insulated gear as "filled gear."

Space occupied.—The space occupied by switchgear is almost entirely dependent on the clearances between phases and to earth through the surrounding insulation.

Fig. 1 shows three curves, A, B and C, giving the breakdown voltages for various thicknesses of air, compound and oil respectively. It is clearly demonstrated that the dielectric strength of air is very much inferior to that of compound or oil. In consequence, the space required for the accommodation of filled gear is very much less than that needed for open gear. This advantage is reflected in the reduced building costs of the switch house.

The relative space occupied by cellular and filled

gear of comparable breaking capacity is illustrated by Figs. 2 and 3, which are drawn to the same scale.

As an example of the large dimensions which metal-enclosed air-insulated gear assumes at the higher voltages, Fig. 4 is an illustration of a 33-kV substation cubicle with bushing-type transformers. Further space would be required for the accommodation of metering transformers.

Surges and instability of dielectric.—A comparison of air, compound and oil dielectrics brings out the difference in behaviour of a gas, liquid and semi-solid under the action of an electrostatic field. Air, in common

TABLE 1.

Feature	Methods adopted
Insulation	Air Compound Oil
Isolation	Stationary Draw-out
Enclosure	Open Metal Masonry
Interlocks	None Complete
Location	Indoor Outdoor
Control	Direct Remote mechanical Remote electrical
Busbar selection	Isolating switches Change-over of plugs Oil isolators Double circuit breakers

with all other gases, is a very unstable insulator and its dielectric strength is affected, to a certain extent, by temperature, pressure and humidity. The most serious disability of air as an insulator lies in the fact that its dielectric strength is reduced considerably by ionization, which is generally caused by local breakdown at points of excessive potential gradient or by the leakage of ionized gas and semi-conducting oil vapours from breakers.

The ejection of gas synchronizes with the voltage surge caused by the interruption of short-circuit power. In the case of totally-enclosed air-insulated gear the ionized gases accumulate owing to bad ventilation and, in consequence, flash-over may take place as a result of a voltage surge on the system. The effect is cumulative, because a number of sparks may quickly follow at a much lower voltage due to the increased ionization produced by the preceding flash-over. Nearly 50 per cent of failures are due to breakdown in air after the fault has been successfully cleared. Flash-overs of 6-in. have even occurred across the open blades of isolating switches on 6 500-volt systems.

In the case of filled gear the dielectric is stable, has a greater spark-lag than that of air and has a sufficiently high dielectric strength to withstand voltage surges on the system. The rupture of insulation requires not only a sufficiently high voltage but also a definite minimum amount of energy. This accounts for the time-lag between the application of voltage and the breakdown of the material. The rupturing energy required for oil and compound is much greater than that for

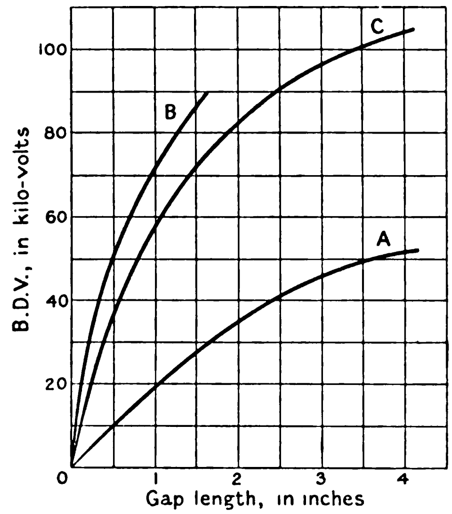

FIG. 1.—(Breakdown voltage)/(thickness) curves for air, compound and oil insulation.

air. If similar oil-, compound- and air-gaps are set for breakdown at the same low-frequency voltage, a much higher transient voltage will be required to rupture the oil and compound gaps than that necessary for the air-gaps, thus demonstrating the greater spark-lag of oil and compound.

Fig. 5 illustrates the difference in spark-lag for air and oil sphere-gaps set for breakdown at the same continuously-applied low-frequency voltage. Curve " A " is for air, and curve " B " for oil.*

Compound, in common with other solid dielectrics, has a greater spark-lag than oil.

Oil is self-healing after a breakdown, and with commercial oil the voltage required for a second breakdown is increased due to drying of the oil.

Vermin.—Vermin, always a menace to electric supply, can often bridge the clearances employed in air and so cause short-circuits. Even if the connections are completely taped, as is common practice in important breaker cells, there are always exposed parts, such as

* The curves have been prepared from data presented by Hayden and Steinmetz in a paper entitled "Disruptive Strength with Transient Voltages," *Transactions of the American Institute of Electrical Engineers*, 1910, vol. 29, p. 1125.

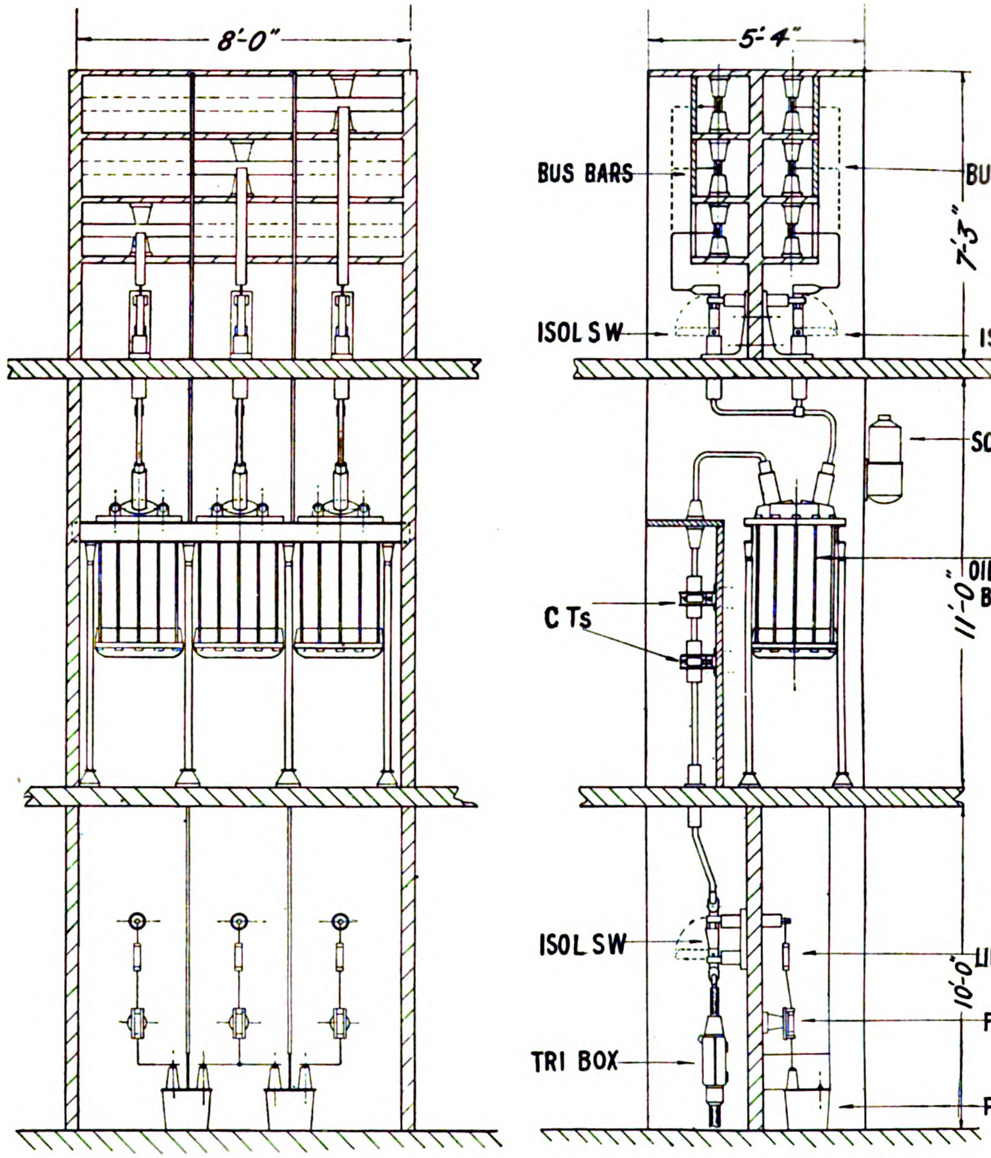

FIG. 2.—Typical cellular switchgear.

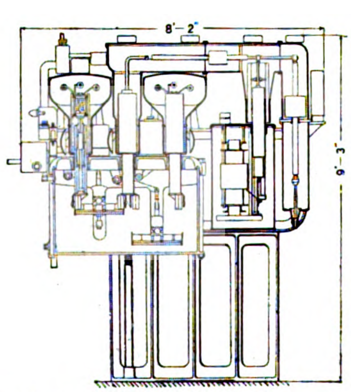

FIG. 3.—Metal-clad switchgear unit of comparable breaking capacity to the cellular gear shown in Fig. 2.

isolating switches, which have been known to be bridged by rats. In large central stations employing air insulation, switchgear occupies several floors, with many exposed points of possible breakdown. Such is not the case with filled gear and consequently there is no risk of shut-down due to this cause.

Dust, dirt and moisture.—Dust, dirt and moisture can collect on open gear, necessitating periodical interruptions of supply for cleaning and maintenance. Filled gear is dirt- and dust-proof on account of the close "metal cladding" of the external insulation. The dielectric strength of oil is reduced considerably by the absorption of a small percentage of moisture, but this is so high and the factor of safety is such that in practice no serious difficulties are introduced on this score.

Electromagnetic forces on short-circuit.—The value of

the electromagnetic forces varies inversely with the distance between conductors, so that with the smaller spacings employed on filled gear the forces are greater than those on open gear. The possible maximum

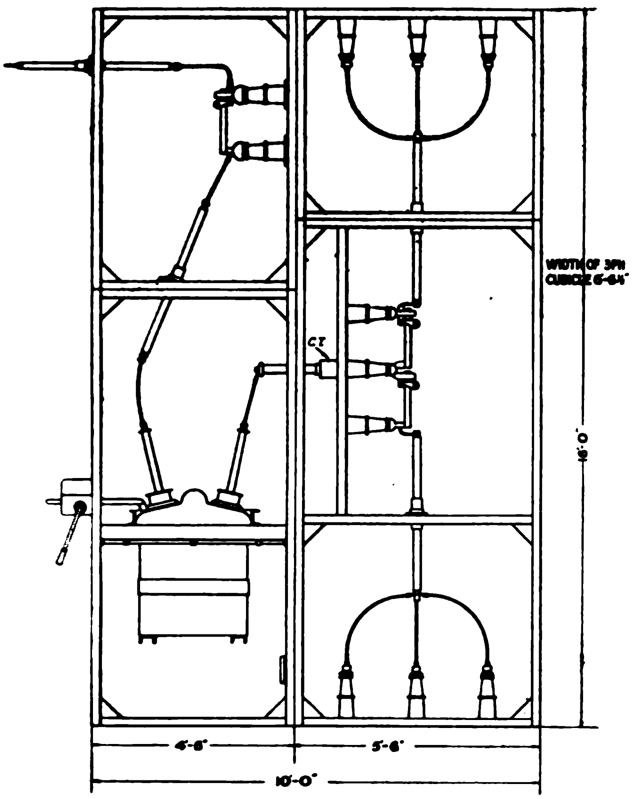

FIG. 4.—33-kV air-insulated substation cubicle.

forces can, however, be calculated to a reasonable degree of accuracy and the conductors supported accordingly. In the case of compound-filled gear the conductors are supported throughout their entire length.

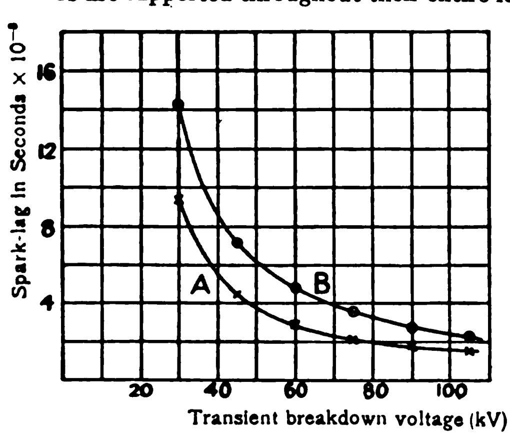

FIG. 5.—(Transient breakdown voltage)/(time) curves.

Explosions.—With open gear there is always the danger of an accumulation of explosive gases in the air, which may be exploded, with consequent danger to the equipment. A case is on record where a sub-station building was demolished through this cause, 8 tons of concrete, etc., being hurled a distance of 20 ft. The spaces where such gases can accumulate in filled gear are eliminated. The danger in the breaker is common to all types, and the tanks, top plates, etc., are usually designed to withstand any possible explosive forces developed in the breaker structure.

Protection to life of operator.—In the case of filled gear, accidental contact with live metal is impossible on account of the complete earthing shield. Even when the breaker is removed for inspection there still remains a completely earthed envelope over all the live contacts. Filled gear does not require any cleaning for the purpose of maintaining high insulation. It is in

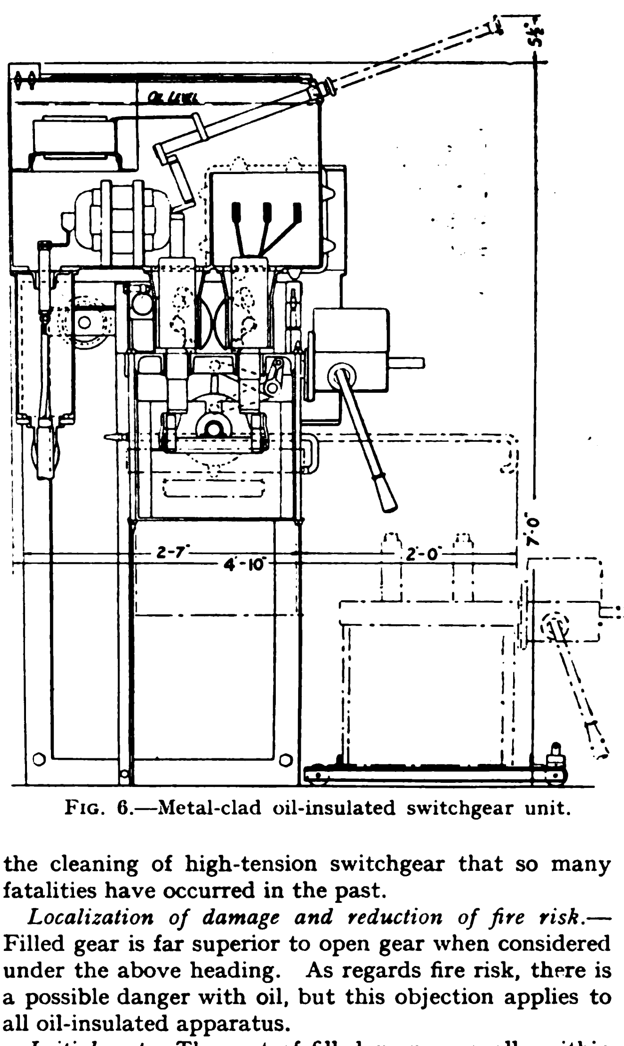

FIG. 6.—Metal-clad oil-insulated switchgear unit.

the cleaning of high-tension switchgear that so many fatalities have occurred in the past.

Localization of damage and reduction of fire risk.—Filled gear is far superior to open gear when considered under the above heading. As regards fire risk, there is a possible danger with oil, but this objection applies to all oil-insulated apparatus.

Initial cost.—The cost of filled gear is usually within 10 per cent of that of open gear. In special cases where the latter is spread over several floors and complete interlocks are required, the former has the lower initial cost.

Depreciation.—There is more deterioration of contacts and current-carrying parts with air than with oil or compound insulation.

Facilities for modification.—One of the main objections urged against compound-filled gear is the lack of

accessibility of the current-carrying parts for modifications. This applies to instrument transformers, particularly when it is desired to alter ratios. In order to overcome this objection some of the later designs embody oil-insulated transformers, whilst the busbars, etc., are embedded in compound, thus making a compromise.

Facilities for carrying out extensions without interrupting the supply.—Compound-filled gear is not so convenient for carrying out extensions as air- or oil-insulated gear, but where duplicate busbars are provided it is always possible to work on one set whilst normal running is maintained on the other set. With oil filling it is more convenient to carry out extensions to the busbars than is the case with compound. Furthermore, there is no possibility of air pockets being formed. In the case of compound, this is a possible danger, due to the difficulty of preheating the busbar connecting chambers when filling on site. A metal-clad oil-insulated switchgear unit is shown in Fig. 6.

Cooling conditions.—The different cooling capacities of oil, air and compound affect the maximum current densities permissible with the three types of insulation. In the order stated, the approximate ratio of densities is 1·4, 1·0 and 0·6.

ISOLATION.

Whatever type of gear be employed, it is necessary to provide means for isolation in order to carry out inspection, cleaning and repairs to the breakers. From an analysis of the Factory Inspector's Report, covering a period of four years, 1911–1914, before truck gear became so popular, it was found that the average number of accidents occurring on switchboards, due either to faulty design, or to cleaning, repairing and handling apparatus supposed to be dead, represented 72 per cent of the total.

The two methods of isolation are :—

(1) Stationary method by means of isolating switches, the breaker when isolated remaining in its normal position.

(2) Draw-out method, the breaker being withdrawn from the live parts.

(1) *Stationary method.*—Air- or oil-insulated switches may be employed, and it is necessary to provide these on both sides of the breaker. Cellular switchgear employing this method is shown in Fig. 2. A unit employing oil-immersed isolating switches is illustrated in Fig. 26.

(2) *Draw-out method.*—The breaker is withdrawn bodily from the live parts, this being made possible by the provision of plugs and sockets. Two variations in the draw-out method are in use, i.e. the breaker may be withdrawn either horizontally or vertically. In the case of the latter, large breakers are withdrawn by a lowering motor. The vertical method requires less floor space, and inspection can be carried out without encroaching on the passage way. A further advantage of this method is that it provides a more direct run of connections between the breaker and busbars.

A unit having vertical isolation is shown in Fig. 3, and one of the horizontal type in Fig. 7.

Draw-out gear is very popular at the present time and is gaining favour not only in this country but in America, where it was introduced only a few years ago. The initial objection raised was the necessity for plug-and-socket connections, but entirely satisfactory results have been obtained by the incorporation of self-aligning features. The main advantage lies in the fact that, when the breaker is withdrawn, one can see definitely that the gear about to be handled is dead. There is never the same certainty with the stationary method.

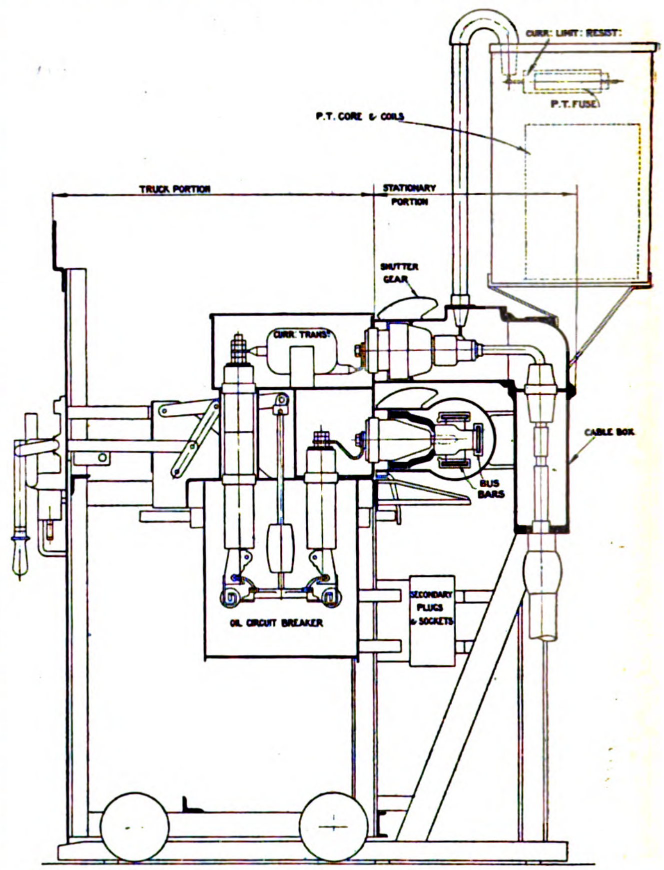

FIG. 7.—Metal-clad compound-filled horizontal draw-out truck-type switchgear unit.

The draw-out feature gives more facilities and greater accessibility for inspection and repairs to the breaker. A spare can be run into position in a much shorter time than is necessary in the case of stationary gear. This enables a change in the circuit equipment to be carried out whilst the spare breaker maintains the supply.

It is comparatively simple to provide complete interlocks on draw-out gear, and these are invariably embodied. On the withdrawal of the breaker the live portions are automatically shielded by safety shutters so that persons cannot make accidental contact. With stationary gear, reliance has to be placed on the human element and there always remains the possibility of doors being left open.

The draw-out feature adds 7 to 10 per cent to the cost, but is usually no more expensive than the completely-interlocked stationary type, over which it has many advantages.

On rare occasions very light trucks have been blown out of their housing due to explosion in the cubicles. This has doubtless occurred after the breaker has operated, as the truck is locked in when the breaker is closed. The author is not aware, however, of any case where this has happened to a heavy truck. It is comparatively easy to safeguard against this trouble by the provision of a positive locking-in arrangement. Fig. 8 shows a heavy-duty truck cubicle in which the horizontal

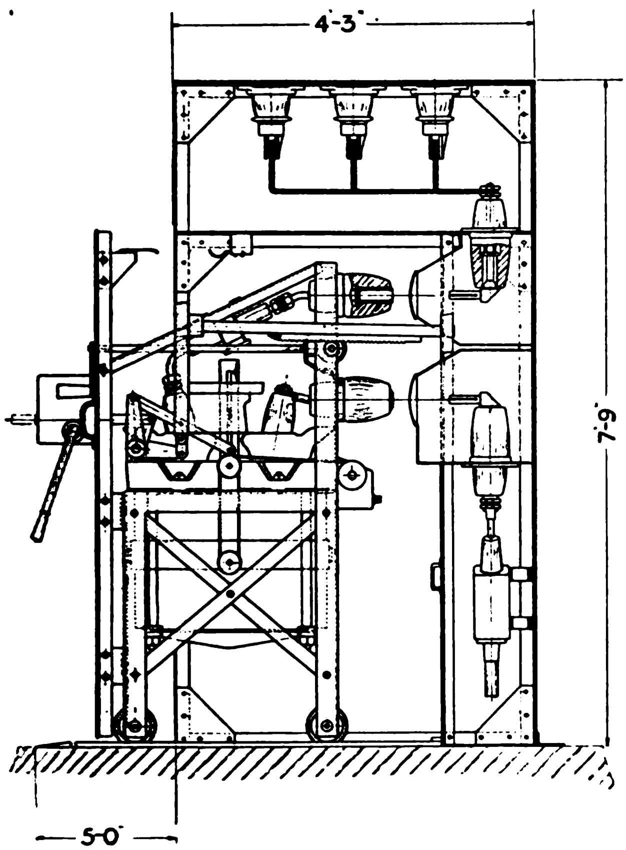

FIG. 8.—Heavy-duty air-insulated draw-out truck cubicle.

method of isolation is used. The truck is withdrawn by means of a manually-operated rack and pinion.

ENCLOSURE.

In this respect, switchgear may be classified under three headings :—

(1) Non-enclosed	Indoor, Outdoor
(2) Metal-enclosed	Cubicle, Metal-clad
(3) Masonry-enclosed.	Cellular

In comparing the above variations of enclosure, the first affords no protection to life, the second affords definite protection in that the metal enclosure can be readily earthed, whilst the third, being in the nature of a semi-insulator, is not quite so safe to handle as the metal-enclosed. If a flash-over to earth occurs on metal-enclosed gear, it will be a dead earth and will be maintained until the fault is cleared by the protective gear, whereas with masonry the arc will in all probability be extinguished after the pressure-rise has subsided, unless the arc strikes to earthed metal. In the former case there would be no danger in touching the enclosure, but in the latter there is a risk to the attendant. The majority of engineers would prefer a fault to show up definitely and be rectified.

The open type of gear is prohibited in this country by the Home Office Regulations, unless the live conductors are above 8 ft. from the ground or made absolutely dead from without before handling. This 8 ft. must be measured from the bottom sheds of the porcelain insulators, in view of the fact that such sheds will have a potential above earth. In America the open construction is used extensively for 22 kV and upwards, whilst on the Continent masonry enclosures without phase separators are employed.

The reasons put forward by American engineers for their preference for open gear are as follows :—

(a) Masonry structures must be considered to be conductors for voltages in excess of 11 kV, and consequently this construction takes up more space than open gear.
(b) Masonry structure entails more expensive building and construction.
(c) Inspection and repairs are easier with open gear, and incipient trouble is more readily detected.
(d) At higher voltages the destructive effect of an arc is less, owing to the small currents dealt with, and fireproof structures are not so essential.
(e) There is less danger of mistakes on the part of an attendant when operating open-type gear, as he can see the whole of the connections and the position of isolating switches.

Whilst there is much force in the above contentions, separate compartments for oil breakers are practically essential in this country to meet the Home Office Regulations, as shown in Fig. 36.

Space occupied.—Some engineers are prepared to allow clearances to masonry 20 per cent less than those required to earthed metal, but generally the safer course is adopted and full clearances are allowed, on the assumption that masonry is a conductor. This increases the size of masonry-enclosed gear when compared with equivalent metal-enclosed gear. With the larger sizes of the former it is frequently necessary to occupy two or three floors, with consequent possibilities of operating mistakes. A masonry structure is illustrated in Fig. 2.

Localization of damage and reduction of fire risk.—Masonry structures are more fireproof than sheet-steel cubicles, and arcing which is not cleared promptly will burn holes through the latter and spread to adjacent cubicles.

Factory-built units.—One of the chief points of advantage of metal-enclosed gear is that it can be built up as self-contained units in the factory. Factory-built units are illustrated in Figs. 3, 4, 6 and 7.

It is generally conceded that erection work on site costs about three times the amount for identical work done in the factory, and it is not carried out under the same degree of supervision. Metal-enclosed gear has a strong claim not only as regards cost but also on the score of soundness of construction. Self-contained units are portable, quickly installed, and easily removed foı modifications. This is a distinct advantage where the system outgrows the breaking capacity of the breakers in a particular location, in so much that they can be readily removed to a less important part of the system.

Interlocks.

It is desirable that the human element should be eliminated as far as possible in the manipulation of switchgear, especially in view of the large proportion of accidents which occur thereon and the necessity for prompt action with full self-control in cases of emergency. Interlocks are now generally called for, but some engineers object to them on the grounds that they do not allow temporary connections to be made. This is really an advantage, in that it avoids risks that would be taken if such work were attempted.

Complete interlocks are very cumbersome on masonry-enclosed gear occupying several floors, but it is under these conditions that they are most needed. The cost is also very great because interlocks have to be specially designed for each job.

All modern types of draw-out gear can be easily fitted with complete interlocks and are generally so supplied.

A complete system of interlocks should fulfil the following conditions :—

(*a*) It should not be possible to break or make the circuit on the isolating device until the breaker is in the "open" position, but it must be possible to check the operation of the latter when in the completely isolated position.

(*b*) No part of the gear should be capable of being exposed when alive.

(*c*) Where the isolated apparatus is earthed before being handled, it must be impossible to reclose the isolating device until this earth has been removed.

The most prevalent operating mistake is the opening of isolating devices while current is passing, and many people protect against this contingency only by the provision of an interlock between the breaker and the isolating device so that the latter cannot be opened until the former is in the "open" position. This interlock is usually simple and cheap, but it is questionable whether half-measures are satisfactory. In reckoning the cost of complete interlocks it should be borne in mind that the cost of attendance, maintenance and cleaning is reduced because a less skilled grade of labour can be employed.

Location.

Outdoor gear has had a very limited application in this country and on the Continent, but it is used extensively in America. There is no doubt whatever that for super-tension gear this form of construction is coming into favour, due to an overall saving of from 15 to 20 per cent for voltages of 44 kV and upwards. No buildings are required except for the control panels. A 135-kV outdoor oil circuit breaker is shown in Fig. 44. The cost of outdoor switchgear itself is 10 to 15 per cent more than that of corresponding indoor gear, the overall saving being due to the difference in cost between the structural steelwork and the buildings. The space occupied by super-tension gear is very considerable, and the building costs represent an appreciable portion of the total costs.

Many engineers question the wisdom of installing outdoor gear, in view of the difficulties experienced when carrying out routine testing and cleaning. Furthermore, when urgent erection or repair work has to be undertaken regardless of weather conditions, outdoor gear is at a serious disadvantage. It is a very difficult job to exclude rain from the oil tanks when a breaker is opened up during a storm. The difficulty is overcome in the cubicle type of gear illustrated in Fig. 9. It consists of indoor apparatus mounted in weatherproof cubicles. This arrangement affords some protection against driving rain when the oil tank is lowered. The cubicle type of gear is being employed in America on a number of schemes for voltages up to 22 kV.

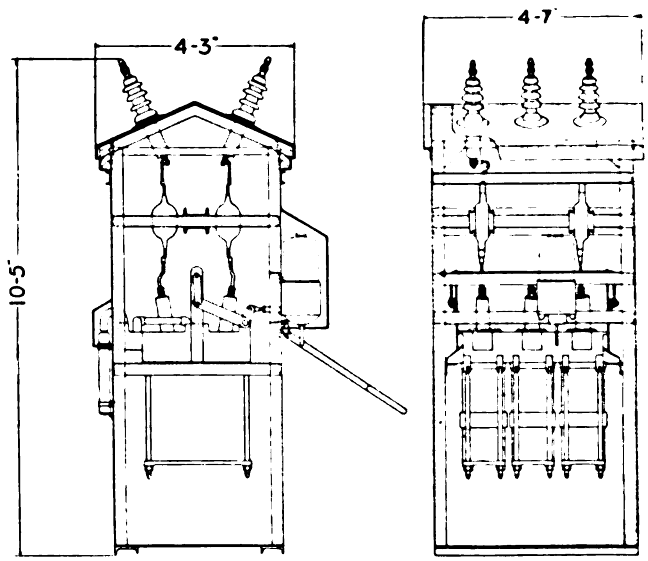

Fig. 9.—Cubicle floor-mounting type of outdoor switchgear.

Outdoor gear obviously takes less time to erect, as it is merely necessary to provide foundations for the supporting structure.

Control.

Direct control is only employed in central stations for plants of very small capacity, say up to 5 000 kVA. It is not desirable to exceed this limit, for the following reasons :—

(*a*) The attendant must have full self-control if he is to act promptly in cases of emergency. This is best attained by removing the high-tension gear from the point of control.

(*b*) With larger sizes of plant there is more likelihood of explosions and other dangers, and hence remote control increases the safety of the operator.

(*c*) With remote control the switchgear can be located in a fireproof building in any convenient position, and at the same time the control panels can be so situated that the operator has sight of the generating plant.

(*d*) The instruments may require attention while the plant is running, and this is much more conveniently done when they are mounted on a separate control board.

Remote control.—Two methods are in common use :—

(1) Mechanical.
(2) Electrical.

(1) *Remote mechanical control.*—Where the breakers are not too large and the control board can be located in close proximity, mechanical control may be quite suitable. On the other hand, where heavy breakers have to be operated, or the distance is considerable, it is advisable to adopt remote electrical control. If the automatic trip coils are not fitted on the breaker itself, the inertia of the bell crank levers and connecting rods will reduce the opening speed of the breaker. Backlash in the mechanical driving system will reduce the final pressure on the contacts of the breaker when in the closed position. This is a serious matter in the case of laminated-brush contacts, as their current-carrying capacity depends on the contact pressure employed.

(2) *Remote electrical control.*—The methods commonly employed are either solenoid or motor operation. The former is cheaper and generally preferable if a d.c. supply is available. If not, it is necessary to adopt motor operation or install a battery and motor-generator.

Electrical operation enables the control gear to be condensed to a minimum so that centralization of control is carried out to its highest degree. It is common practice to energize each solenoid from its own contactor, which is operated from the control board. This removes heavy control wiring from the latter and also the interruption of inductive circuits at the point of control. With electrical control the breaker is free to trip without any external mechanical load, as is the case with the other method.

On one or two recent American installations a combination of electrical and mechanical operation has been employed. The three phases are segregated into separate fireproof compartments and, although remote electrical group operation is employed, the three poles of the breakers, isolators, etc., are coupled mechanically over long distances. The solenoid is mounted above the middle pole of the three so that only the two outer poles are operated by long connecting rods. Necessary precautions are taken to counterbalance the weight and inertia of the mechanical system.

Where remote operation is employed, it is customary to embody an automatic dummy diagram and indicating lamps on the control board in order that the position of all breakers and isolating switches may be seen at a glance.

Busbar Selection.

One of the following four methods is generally adopted for the selection of duplicate busbars :—

(1) Air-break isolating switches for each set of bars or change-over switches—applicable to stationary gear.
(2) Change-over of plugs—applicable to draw-out gear.
(3) Oil isolators—applicable to all types.
(4) Double circuit breakers—applicable to all types.

Air-break isolating switches.—A separate set of isolators for each set of busbars is used in conjunction with a busbar coupler if the circuit has to be transferred from one set of bars to the other without breaking load.

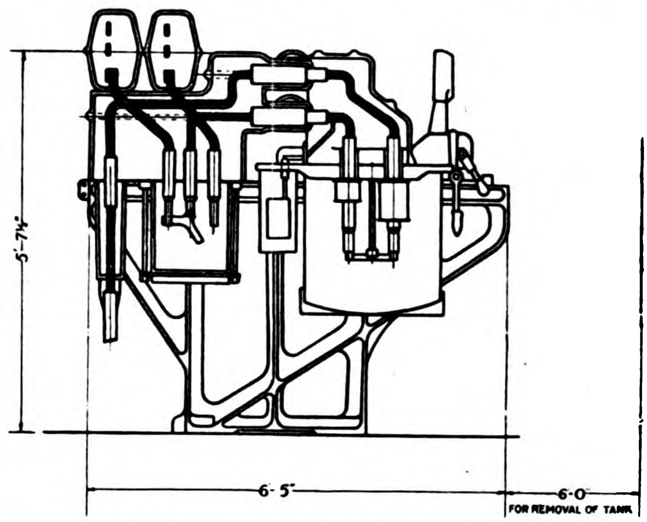

Fig. 10.—Metal-clad compound-filled switchgear unit with oil-immersed selector switches.

This can only be done with change-over switches if they are provided with double blades. Air-break isolating switches are almost universally employed on stationary gear, and in many cases the operator has to enter the switch room and expose high-tension conductors in order to operate them. This is a serious disadvantage. For convenience of connections, the two sets of isolating switches are often mounted back-to-back on opposite sides of a dividing wall, but this arrangement introduces a risk due to the possibility of incorrect operation.

Change-over of plugs.—The transfer of a circuit by this method necessitates withdrawal of the breaker, change-over of the busbar isolating plugs, of which only one set is provided, and re-insertion of the breaker. A serious objection can be raised, as an operator may change two plugs out of the three, and also a considerable time is required for transfer. It is easy to imagine how serious the inconvenience would be in the case where one set of busbars is made dead for repairs or extensions. The whole of the circuits concerned would have to be isolated and transferred one by one to the other set of bars and re-synchronized if necessary. This

scheme prevents the quick transfer of circuits in cases of emergency, and thus the main advantage of the duplicate busbar system is lost. In addition, the operator may fail to tighten the plugs in his hurry to meet an emergency.

Oil isolators.—Oil-immersed selector switches have been introduced principally for the improvement of metal-clad compound-filled gear, in order to overcome the objections already cited. The selector switches can be operated externally and are easily interlocked. Duplicate blades can be provided to allow transfer of a circuit without breaking load when used in conjunction with a busbar coupler. A unit of this type is shown in Fig. 10.

Double circuit breakers.—Although more expensive, this method is undoubtedly the best. It is almost invariably used in America on heavy power systems and is finding favour in this country on important installations.

The main advantages are:—

(*a*) All normal switching operations can be performed from the control board, giving unified control.

(*b*) Except for inspection of a circuit breaker, it is not necessary to enter the high-tension room.

(*c*) Full advantage can be taken of the facilities which duplicate busbars provide.

(*d*) One breaker is virtually a stand-by for the other, and if one is operated on a heavy fault it is possible to bring the other into service until there is an opportunity for inspection.

(*e*) It is not necessary to employ a separate busbar coupler.

(*f*) It has been suggested that with double oil circuit breakers it might be possible to transfer immediately all circuits from a faulty set of bars to the other set. Although the author is not aware that this has been done, it seems to be quite a feasible proposition.

A metal-clad switchgear unit having a double breaker in one tank is illustrated in Fig. 3. Nine terminals are provided, the middle set of three being common to both breakers.

Conclusions.

From an analysis of the fundamental features of the various types of high-tension switchgear the following conclusions can be drawn:—

Insulation.—Both compound and oil show a distinct advantage over air. The difference between compound and oil is not so marked, but the latter has advantages over the former. Oil can be used for all voltages, whereas the use of compound will probably have an upper voltage limit of 66 kV.

Isolation.—Within its range of application, the draw-out method is preferable to the stationary method. Owing to the enormous size of the apparatus and difficulty in the design of satisfactory plug-and-socket bushings, the limit of the draw-out method will probably be in the neighbourhood of 66 kV.

Enclosure.—Metal enclosure is preferable to either masonry or the open type.

Interlocks.—Complete interlocks are demanded by modern conditions and are essential both for safety and for continuity of supply.

Location.—Indoor gear is preferable for all voltages, but for 44 kV and upwards outdoor gear has an application where cost is of prime importance.

Control.—Remote electrical control is the most flexible system and for all large schemes is essential. Remote mechanical and direct control have a limited application.

Busbar selection.—Double breakers are preferable to all other methods. In the order of efficiency the remaining methods may be placed as follows: Oil isolators, air-break isolating switches and change-over of plugs.

Present-day types of high-tension switchgear combine the above features in various ways, and from the conclusions drawn it will be evident that in the author's opinion the following types are considered to be the most suitable:—

Metal-clad, draw-out, compound- or oil-insulated gear for voltages up to 66 kV.

Open floor-mounted indoor gear with separate compartments for oil breakers, for voltages of 44 kV and upwards, but outdoor gear is recommended where cost is of prime importance.

For a period, metal-enclosed air-insulated truck gear will have an application up to 22 kV, but the author believes that it will be eventually superseded by filled gear.

Section 2.

STANDARDIZATION.

Advantages and Disadvantages of Standardization.

It is unnecessary and costly to perpetuate such a large number of switchgear types as at present exist. Generating plant, transformers, motors, etc., have reached more or less standard forms, and switchgear is the only part of the equipment which can be varied to suit the individual tastes of engineers. Many take full advantage of this and, in consequence, a large number of superseded types are still specified. In addition to the types already scheduled, various supply undertakings insist on their own special variety of a particular type. Very frequently, instead of buildings being designed to suit the switchgear, the reverse is the case.

Simplification and cheapening of switchgear can be effected by standardization of the best types. Manufacturers would then be in a position to produce in bulk at a reduced cost. The price of standard types would be no more than that now paid for inferior types. In short, standardization would mean mass production, low cost, minimum of spares, and quick delivery. An objection raised to standardization is that progress would be impeded. There is little ground for this objection, because a stage has been reached where the rate of change is likely to be very much less than it has been in the past.

The creation of new designs has been prolific and it is now necessary to consolidate the position so that the perfection of the best types may lead to their general adoption and production in such quantities as to reduce the cost and benefit the whole industry.

Relation of Cost to Standardization and Quantity Production.

The cost of central station switchgear varies from about 3 per cent of the overall capital cost in the case of stations round 20 000 kVA, to about 6 per cent in the case of super-power stations. Central station switchgear is a vital part of the system, and it is unwise to adopt a "cheese-paring" policy in relation to it.

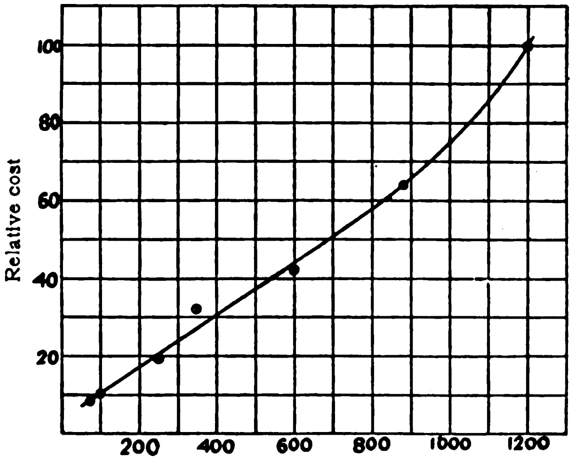

Fig. 11.—Relation of cost to breaking capacity.

It is an inherent disadvantage of the a.c. method of distribution that the cost of switchgear increases rapidly with the size of the system, and hence switchgear accounts for an appreciable portion of distribution costs.

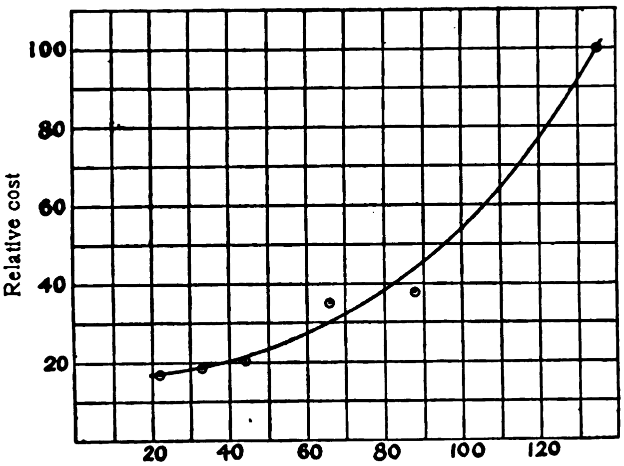

Fig. 12.—Relation of cost to rated voltage.

This fact has led many engineers to reduce considerably the factor of safety as regards the breaking capacity of substation switchgear, and it has been suggested that, when cables and transformers, etc., are more immune from breakdown, it may be possible to cut down switchgear equipments by the solid connection of apparatus. In the author's opinion, a much more fruitful course to pursue would be the reduction of cost by standardization, without any sacrifice of flexibility of control and continuity of supply.

The cost of switchgear for high-tension generating voltages is a function of its breaking capacity, as indicated by the curve shown in Fig. 11.

For pressures up to 1 000 volts the cost usually varies with the normal current rating, whereas for extra-high voltages the predominant factor is the rated voltage, as illustrated in Fig. 12.

The manufacture of switchgear demands a proportionately larger staff than any other manufacturing branch of the electrical industry. Purchasers will accept standard machines or transformers, but by reason of special requirements and conditions they make switchgear more expensive than it need be. In British switchboard factories the annual cost of the drawing office is 70 to 80 per cent of the productive labour costs for the assembly of switchboards. This is not surprising, since there are scarcely two switchboards alike. The advent of standardization would reduce overhead charges and labour costs. This tendency is illustrated in Fig. 13, which relates to a special variety of a certain type of switchgear standardized by a supply authority. Curves A and B show how the overhead charges and labour costs decreased as more orders for this particular gear were executed. The predominant factors were the reduction in drawing office expenditure and the increased familiarity of workmen with the standardized product. Curve A gives the relative total

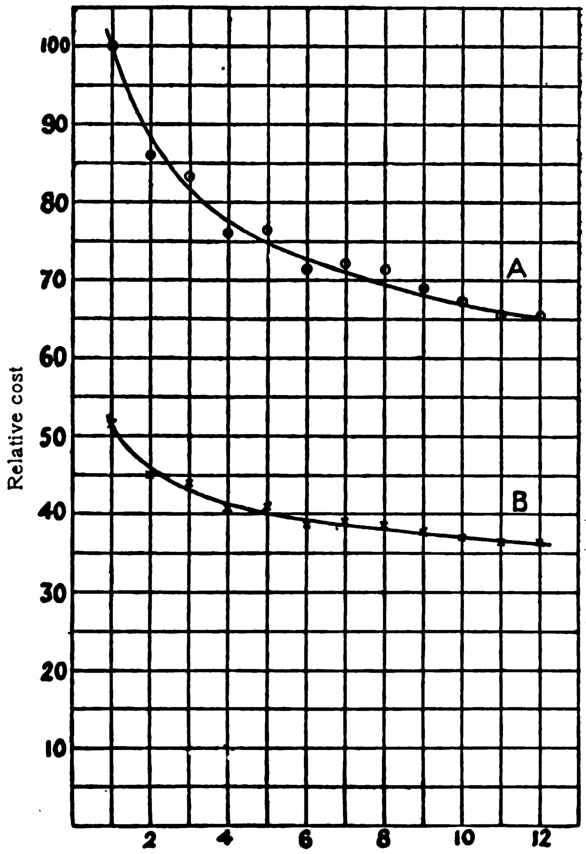

Fig. 13.—Reduction of cost by standardization.

factory cost, and curve B indicates the relative cost of material plus labour. The cost of material may be taken as being approximately constant.

Jigs and tools for production at low cost, provision of interchangeability, and elimination of the human element are only warranted if there is a sufficient demand for the product. As is well known, it is the quantity produced which determines the price of a standard product.

It is the standardization of type which is most important, because variations in circuit equipments, protective gear, etc., can be made without materially increasing the cost. At the present, mass production cannot be applied to switchgear owing to the multiplicity of types and the consequent limited demand for each.

Types Recommended for Standardization.

If suitable types are to be standardized it is essential that they shall consist of factory-built units in order that mass production may be possible. The vital question as to which types shall be chosen can only be answered by the pooling of experience gained by supply undertakings in the operation of existing types. It would certainly be dangerous to standardize prematurely, but the author feels confident that the demand is in the ascendancy for those types embodying the draw-out feature and filled insulation. Both features have been tried out during the past 20 years with increasing satisfaction to the users. Several of the leading manufacturers in this country have recently put such types on the market, necessitating a heavy outlay in patterns, jigs and tools, which in itself indicates that the demand is likely to increase. American and Continental engineers also have recently taken a keen interest in this distinctively British development and have been exploring the possibilities of taking up manufacture in their own countries.

It is certain that the factors which brought this form of gear into existence, namely, space considerations, demand for stability of insulation, protection to life and low cost, will continue to operate, and the best types should ultimately prevail.

Since mass production and cost are inseparably bound up with each other, low cost will not be attained until the gear is standardized and made the prevailing type. It is a common fallacy to associate metal-clad draw-out gear with high initial cost. Even with its limited application to-day the cost is usually not more than 10 per cent above that of other types.

The author confidently believes that, within their range of application, the types which will ultimately be standardized will be in the form of metal-clad, fully interlocked, draw-out, compound- or oil-filled gear.

Section 3.

SCHEMES OF CONNECTIONS.

In planning a scheme of connections for any large power system it is possible to get numerous combinations, and this section deals with the many variables which enter into the problem.

Arrangements of Main Busbars.

The main busbars of a central station may be arranged according to the different systems enumerated :—

(*a*) Single.
(*b*) Single ring.
(*c*) Duplicate.
(*d*) Duplicate ring.
(*e*) Sectionalized.

(*a*) *Single busbar system.*—A single set of busbars is now rarely employed in central stations, because work on the bars or connections thereto cannot be carried out without interruption of the supply. They are, however, frequently used in substations where the bars can be occasionally made dead.

(*b*) *Single-ring busbar system.*—A single-ring busbar arrangement is indicated in Fig. 14. The ring formation renders it possible to disconnect any section for alterations and repairs.

Single-ring busbars have an obvious disadvantage in that the generators and feeders on the disconnected section need to be made dead. This is rarely possible under modern conditions unless the feeders are inter-

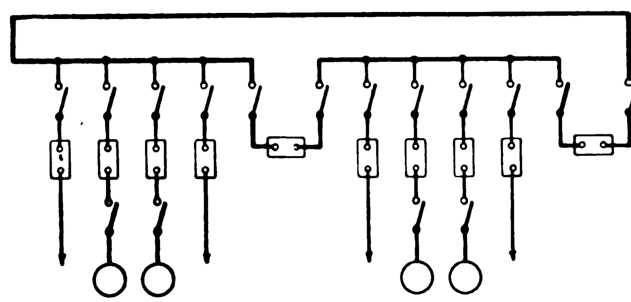

Fig. 14.—Single-ring busbar system.

connected outside the generating station in such a way that they can be fed by an alternative route. The advantage of single-ring busbars lies in the fact that one set of isolators only is required for each circuit.

(*c*) *Duplicate busbar system.*—It is now almost universal practice to provide a duplicate set of busbars in central stations, as it enables a supply to be maintained even if there should be a fault on one section of the bars. Fig. 15 shows a duplicate busbar system.

Spare plant is usually provided in any generating station, and it is obviously necessary to provide spare busbars if continuity of supply is to be maintained. Not only do the spare bars serve as a stand-by but they are used frequently to facilitate control of the system. The main advantages are scheduled below :—

(i) Cleaning, repairs or extensions to busbars are possible without interruption of the supply.
(ii) Certain feeders can be worked under conditions differing from the remainder, e.g. voltage boost at times of heavy load.
(iii) A supply from an interconnected generating station can be received and distributed without running in parallel.

(iv) A feeder which has been under repair can be tried out separately with a spare machine before paralleling with the rest of the system.

(v) Non-adjacent busbar sections which are lightly loaded can be paralleled through the spare bars and run as one section.

(vi) A feeder supplying a faulty overhead line can be put on the spare bars and connected to an alternator, which is isolated from the rest of the system. The faulty phase would be earthed at the station and the supply maintained until an opportunity occurred to repair the line.

In order to take full advantage of the duplicate busbar system, it is necessary to provide means for synchronizing and paralleling the two sets of bars so as to enable circuits to be transferred without breaking load. Where control is by single breakers it is necessary to provide a separate busbar coupler for each section, as shown at Y (Fig. 15). Where duplicate breakers are used, this coupler is unnecessary.

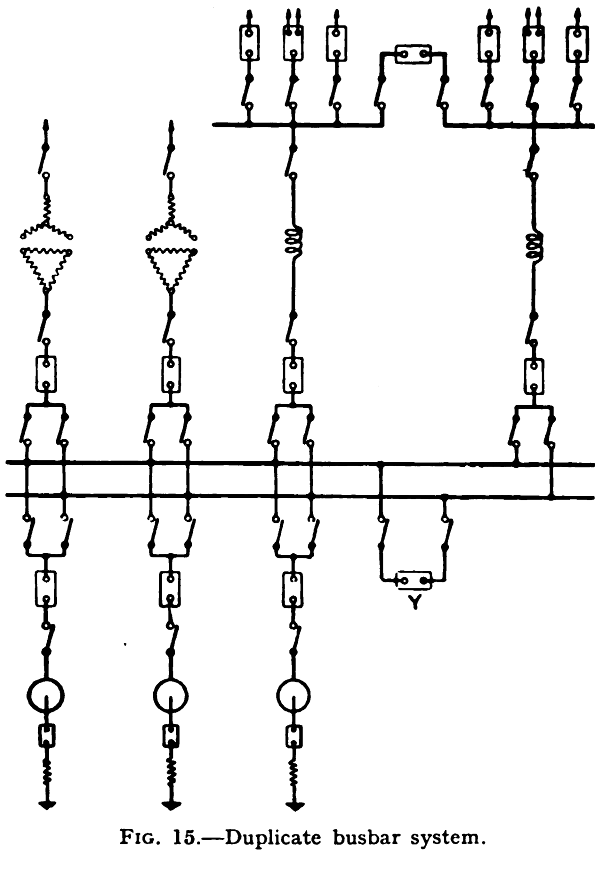

FIG. 15.—Duplicate busbar system.

(*d*) *Duplicate-ring busbar system.*—This system consists of duplicate busbars in ring formation. Supply can be maintained even though a section of the main bars as well as a section of the spare bars is disabled, provided the two faults are on different busbar sections. The duplicate-ring arrangement is shown in Fig. 16.

(*e*) *Sectionalized busbar system.*—For super-power stations the busbars are almost invariably divided into sections, each controlling 20 000 to 40 000 kVA of plant. With this arrangement the generating plant can be sectionalized at times of full load; the short-circuit current which may flow into any fault is reduced and the effects of a disturbance are limited. Sectionalization also provides suitable points for the insertion of reactors, when required. It is necessary to watch that interconnected feeders outside the generating station are fed from the same busbar section.

Facilities for synchronizing and coupling any two busbar sections should be arranged. For adjacent sections a busbar section switch is provided, as shown at X (Fig. 20); other sections can be coupled together through the busbar couplers and spare bars.

Methods of Busbar Selection.

This question has been dealt with in Section 1. Single breakers and selector switches are shown in Fig. 15.

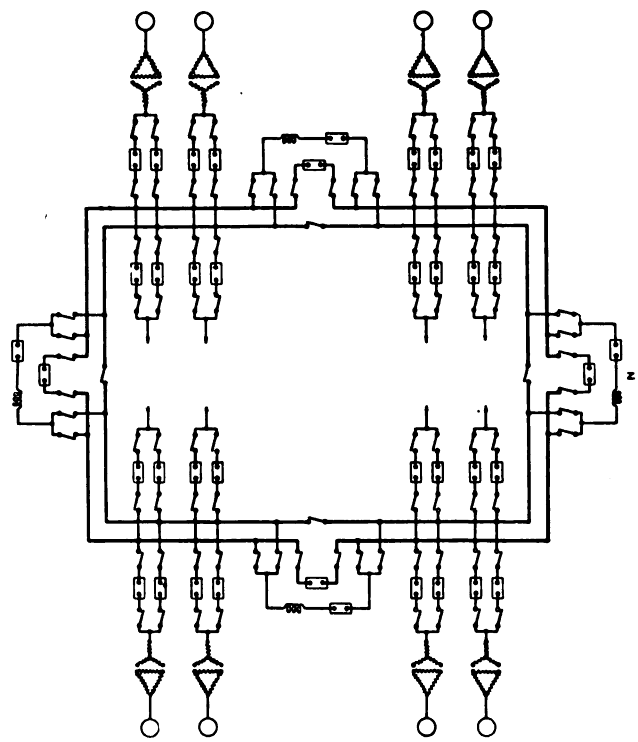

FIG. 16.—Duplicate-ring busbar system.

Where double breakers are used they are so interlocked that normally both cannot be closed at the same time. The interlock can be removed if it be desired to parallel the duplicate bars. Selection by means of double breakers is illustrated in Fig. 16.

Busbar Reactors.

Some form of reactance is essential in modern super-power stations, where the peak short-circuit currents may exceed 100 000 amperes. The electromagnetic forces and heating vary as the square of the current, with disastrous effects if the short-circuit power is not limited.

Reactance may be inserted in generator, feeder or

busbar circuits, and in America all three methods are used, whereas the most usual British practice is to employ busbar reactance only. The latter is installed at points where there is little transfer of energy under normal load conditions, but where, unless limited by reactance, large amounts of power would flow under fault conditions. The voltage-drop across the reactor under normal conditions is thus reduced, and consequently a higher value of reactance can be employed.

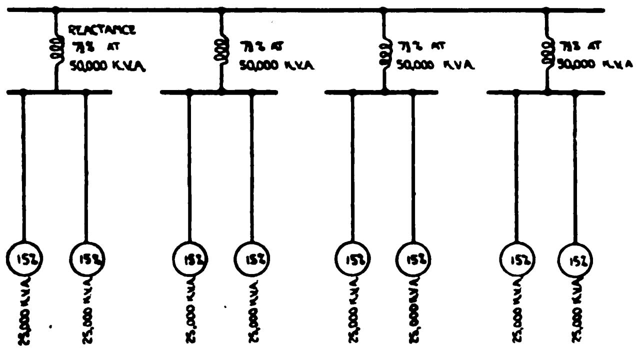

FIG. 17.—Star-connected busbar reactors.

In the case of feeder and transformer circuits it is preferable so to arrange them that the maximum amount of inherent impedance is obtained. This may be done by sectionalizing parallel feeders, with a consequent reduction in the short-circuit current. Reactors are necessary, quite apart from the reduction in breaking capacity of switchgear. Oil circuit breakers can be built to interrupt practically any value of short-circuit power, but it is preferable to limit the latter because,

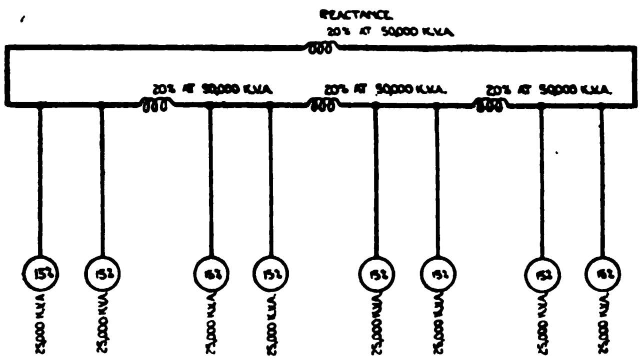

FIG. 18.—Ring-connected busbar reactors.

before the breaker can operate, severe stresses are imposed on the system although the breaker itself may be undamaged.

Two arrangements of busbar reactance are in common use, namely :—

(1) Star system (see Fig. 17).
(2) Ring system (see Fig. 18).

The advantages and disadvantages of these alternative methods have been dealt with by E. B. Wedmore.*

Feeders which are interconnected outside the generating station must be fed from the same busbar section, or otherwise they will short-circuit the busbar reactor. It is possible to provide means for automatically short-circuiting the reactor on each side of a busbar section if the alternators are disconnected or transferred.

The use of busbar reactance enables the short-circuit power of large stations having 200 000 kVA plant capacity to be limited to 750 000 kVA, with satisfactory voltage regulation. Fig. 17 shows a scheme for a station of this size with star-connected busbar reactors. The maximum short-circuit power is limited to approximately 650 000 kVA, and the voltage difference between sections need not exceed 2 per cent at 0·8 power factor.

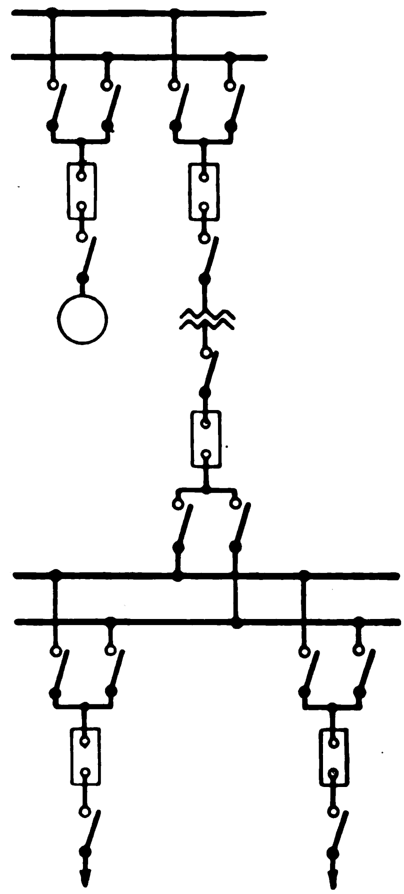

FIG. 19.

A similar scheme with ring-connected busbar reactors is shown in Fig. 18, and in this case the maximum short-circuit power is again limited to approximately 650 000 kVA.

The cost of reactors is usually less than the cost of switchgear of higher breaking capacity, where there is a large number of circuits. It is sometimes urged that the addition of reactance increases the duty on the breakers, but it should be borne in mind that the most severe faults are those near the generating station and the power factor is very low, so that the addition of reactance reduces the fault current with little alteration

* "Control of Large Amounts of Power," *Journal I.E.E.*, 1918, vol. 56, p. 269.

to power factor, the duty on the breaker being consequently reduced by a considerable amount.

Ring-connected busbar reactors should each be provided with a breaker connected in series for interrupting the load when the reactor is in circuit, and one connected in parallel for short-circuiting the reactor. The necessary isolators should be included as shown at Z (Fig. 16). For star-connected reactors it is necessary to provide one series breaker together with isolators, as shown at W (Fig. 20).

Methods of Control.

In many modern stations the voltage has to be stepped up for transmission, and in some cases power is also distributed at the generating voltage.

The following are alternative methods of control:—

(*a*) Alternator, transformer and feeder controlled separately.
(*b*) Alternator and transformer switched as one unit.
(*c*) Transformer and feeder switched as one unit.
(*d*) Alternator, transformer and feeder switched as one unit.

(*a*) *Alternator, transformer and feeder controlled separately.*—This arrangement is shown in Fig. 19, and the following are its advantages and disadvantages.

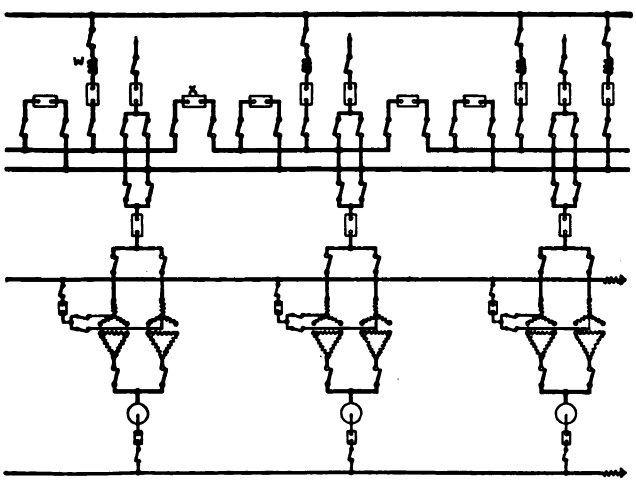

Fig. 20.

Advantages :—

(i) Plant can be operated at its maximum efficiency, because any unit can be disconnected when not required.
(ii) Breakdown on any one unit does not affect the remainder.
(iii) Discriminative protective gear can be provided on the transformers and alternators separately.
(iv) All transformers can be made the same size, so that a minimum number of spares are necessary.
(v) Where transmission is at two or more voltages this method enables all generators to supply any feeder if required.
(vi) The capacities of the alternator, transformer and feeder need not be definitely related.

Disadvantages :—

(i) High cost.
(ii) Heavy transients are possible when switching-in transformers and feeders.
(iii) The grouping of generators gives higher short-circuit current than would obtain if they were connected in series with the transformers.

(*b*) *Alternator and transformer switched as one unit.*—Fig. 20 indicates this scheme, which has the following advantages and disadvantages.

Advantages :—

(i) Low cost, as heavy-current switching is eliminated.
(ii) The magnitude of short-circuit currents is reduced due to the transformer impedance.
(iii) The transformer is magnetized gradually, thus eliminating heavy transient currents, which ordinarily occur with separate switching.
(iv) Separate breakers are retained on feeder circuits, as these are most liable to be called upon to operate frequently.

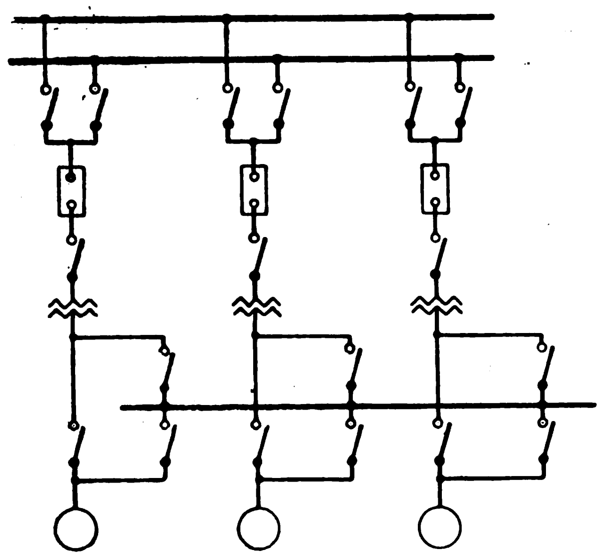

Fig. 21.

Disadvantages :—

(i) The transformer and alternator must be of equal capacity.
(ii) A faulty alternator on one set and a faulty transformer on another set may put two equipments out of action unless a transfer bar, as shown in Fig. 21, is provided.

With this scheme, three-phase power transformers corresponding to the generator capacity would be very large, and occasionally they are connected in parallel, as indicated in Fig. 20. The neutral points of the machines may be coupled together under normal running conditions and earthed, with consequent simplification of neutral switching equipments. This differs

from the usual practice of only earthing the neutral poiht of one machine at a time, as in this case the machines are not interconnected electrically except at the neutral point.

(*c*) *Transformer and feeder switched as one unit.*—Common control of transformers and feeders is illustrated by Fig. 15. The advantages and disadvantages are :—

Advantages :—

(i) Switching surges on the high-tension side of the transformer are reduced to a minimum.
(ii) The transformer introduces reactance between the busbars and feeder so that a fault on the latter has the minimum effect on the system voltage.
(iii) No super-tension breakers are required.

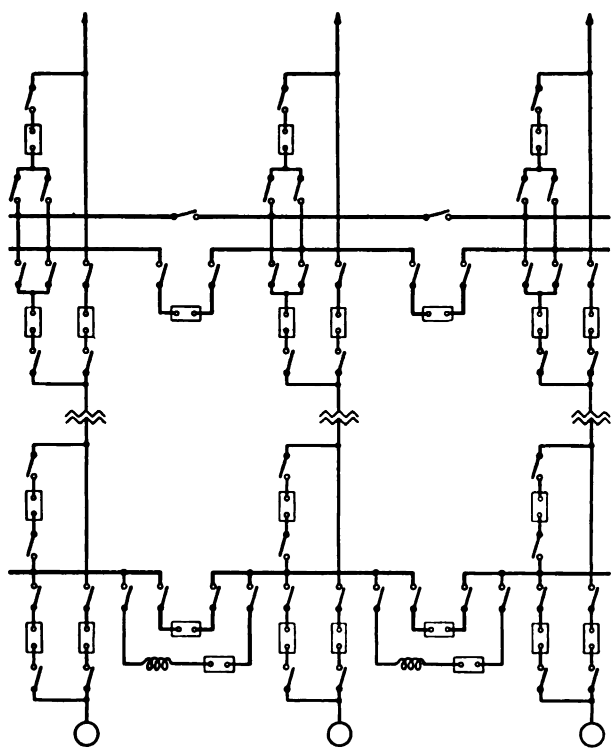

FIG. 22.

Disadvantages :—

(i) The transformers have to be of varying capacities to suit different feeders.
(ii) The failure of a transformer puts its feeder out of commission until repairs can be effected. Transfer bars would overcome the difficulty.
(iii) In the case of feeders paralleled at the receiving end, the opening of one transformer breaker causes a larger voltage-drop on the other feeders than would be the case with other methods of connection.
(iv) The overload capacity of an overhead feeder is very much greater than that of a transformer, but this advantage cannot be utilized if transformer and feeder have equal capacities.

(*d*) *Alternator, transformer and feeder switched as one unit.*—Where heavy blocks of power have to be transmitted at very high voltages it is often necessary to switch the alternator, transformer and feeder as one unit. Such a scheme is indicated in Fig. 22.

The advantages and disadvantage are :—

Advantages :—

(i) Switching surges are reduced to a minimum because the voltage is gradually applied to the transformer and line.
(ii) The system is independent of busbars for normal running.
(iii) The short-circuit power is reduced to a minimum.

Disadvantage :—

(i) The failure of one unit renders a group inoperative unless main busbars or transfer bars are provided, as shown in the figure.

Group switching.—Where there are a large number of outgoing feeders, it becomes very expensive to provide circuit breakers each capable of dealing with the maximum short-circuit power, and group feeder control is often adopted in order to reduce the cost. A scheme embodying this method is shown in Fig. 15; sometimes a reactance is connected in series with each group breaker, as is the case in the scheme illustrated. Each group breaker has sufficient breaking capacity to deal with the maximum short-circuit power, whereas the individual feeder breakers are arranged to deal with only a proportion thereof. The former is usually set at a high value for instantaneous tripping and clears short-circuits, whilst the latter are usually provided with a lower setting having a fixed time-lag and deal with ordinary overloads. A failing of this scheme is that a dead short-circuit on one feeder will cause the whole group to be disconnected. An alternative arrangement sometimes adopted is shown in Fig. 23.

The opening of the group breaker introduces a reactance of such a value that the short-circuit power is reduced to an amount within the capacity of the feeder breakers, and the former is set to operate at a predetermined value of short-circuit current approaching the safe limit of the smaller breakers. A value of reactance is chosen such that considerably more than half the breaking duty is imposed on the group breaker. Obviously, this modification enables a fault on one feeder to be cleared without interference with the rest, and the group breaker does not disconnect the circuit but merely removes the short-circuit from the reactance.

SUBSTATION SCHEMES.

The scheme of connections for a substation is usually much simpler than that for a central station, and flexibility of control is frequently sacrificed in order to reduce the initial cost.

Where the busbars can be occasionally made dead, the single-busbar system is adopted. In order to keep one half in commission whilst the other half is made dead, the busbars are often split into two sections by an isolating switch or non-automatic breaker. Duplicate bars are resorted to in important substations.

It should be remembered that, with the ring-main system of feeders, the substation busbars form part of the ring, and a fault on these may involve the supply to other substations. The scheme of connections to be adopted in any particular case will vary according to the type of feeders used and also whether discriminative protective gear is employed. Supply engineers are constantly in search of methods for the reduction of substation switchgear costs by the elimination of automatic control on certain units of the plant or by controlling two units by one breaker, e.g. a dead-ended substation supplied by a radial feeder and equipped with one transformer may be controlled by one breaker; a similar substation supplied by duplicate radial feeders may be controlled by two breakers. In such cases, however, flexibility is sacrificed because difficulties would arise if a second transformer had to be installed or the supply fed into the substation from two directions.

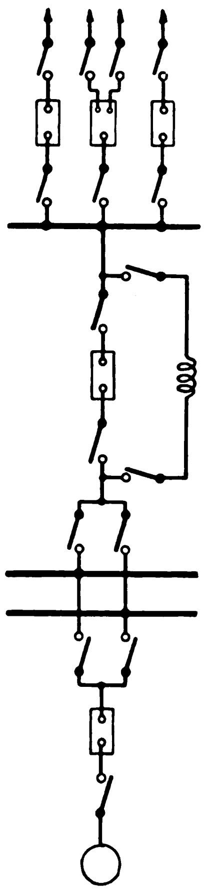

Fig. 23.

On some schemes the complete plant is divided into two sections both at the central station and at the substation, each large substation being fed by duplicate feeders, one on each section. The feeders and transformers are controlled by two automatic breakers in the substation, so arranged that only one can be closed at any one time; thus the consumer has two alternative supplies.

If discriminative protective gear is not used on the feeders, they are occasionally coupled solid and protected at the generating station only, and this is occasionally adopted on underground cables working at generating voltages, where a high degree of reliability has been attained. In this scheme a fault on the cable would affect all consumers fed from the ring main.

It will be evident that any departure from separate automatic control of each unit introduces disadvantages which might be more costly to the supply authority during the life of the switchgear than the initial outlay on the full equipment.

Substation fed by ring mains.—One of the most frequent problems encountered by supply engineers is how to deal with switchgear in substations where an incoming and outgoing cable form part of a ring main and a consumer's transformer has to be controlled. Fig. 24 gives four alternative arrangements.

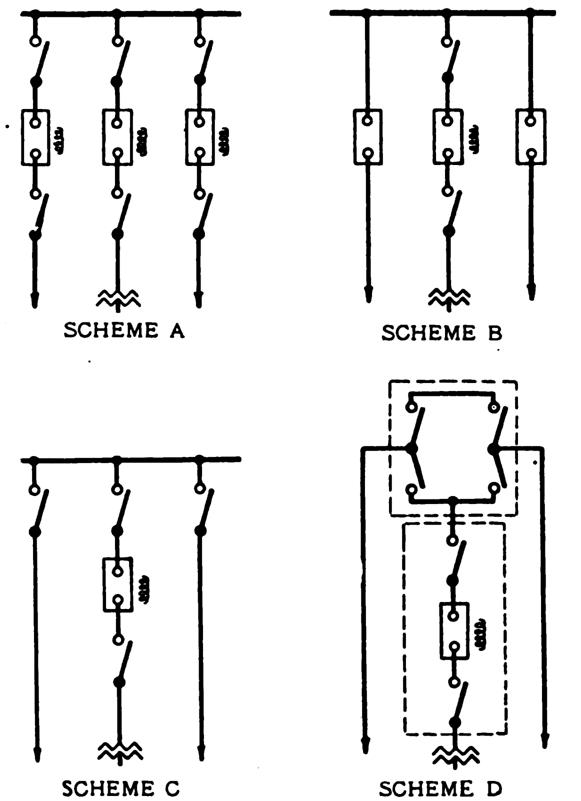

Fig. 24.

The best and most generally adopted arrangement is shown at A, in which separate automatic control is provided for each unit. Where the feeders are not fitted with discriminative protective gear the feeder breakers may be replaced by non-automatic breakers, as indicated at B. A further reduction in cost can be effected by the provision of isolators only on the ring-main feeder, as illustrated at C. An arrangement which allows the ring main to be kept closed while the substation bars are made dead is given at D.

It is important that the ring main should be kept closed under all conditions, and from arrangement D it

will be seen that the isolators have double blades which enable the substation board to be disconnected without opening the ring. Schemes C and D require very careful manipulation and only skilled attendants can be employed. For scheme C, before the isolators are opened it is necessary to ascertain whether the ring is broken at any other place, either at the generating station or at any of the substations. If a break should exist and the isolators were operated, then the latter would break load current at full voltage; whereas, with a closed ring, current would only be broken at a voltage represented by the potential difference at both ends of the ring where opened, say, a maximum of 200 to 300 volts. Skilled attendants operating the isolators quickly under these conditions have been able to avoid trouble, but the risk is always present.

The provision of voltage indicators on feeders is helpful in determining whether the ring is closed or otherwise. It will be evident that the ring may be opened automatically at the same instant that an attendant is opening the isolators, so that danger cannot be entirely eliminated. During these operations the out-of-balance relays must be rendered inoperative on the ring main because the isolators are not opened simultaneously.

without interfering with the supply to any consumer. Such an arrangement is not practicable with the remaining three schemes, and a fault on any section will

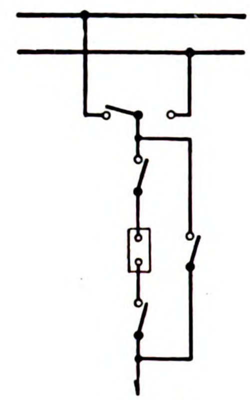

FIG. 25.

interrupt the supply to the whole of the consumers on the ring.

(2) *Continuity of supply.*—Any section can be opened up for inspection or repair without interfering with the

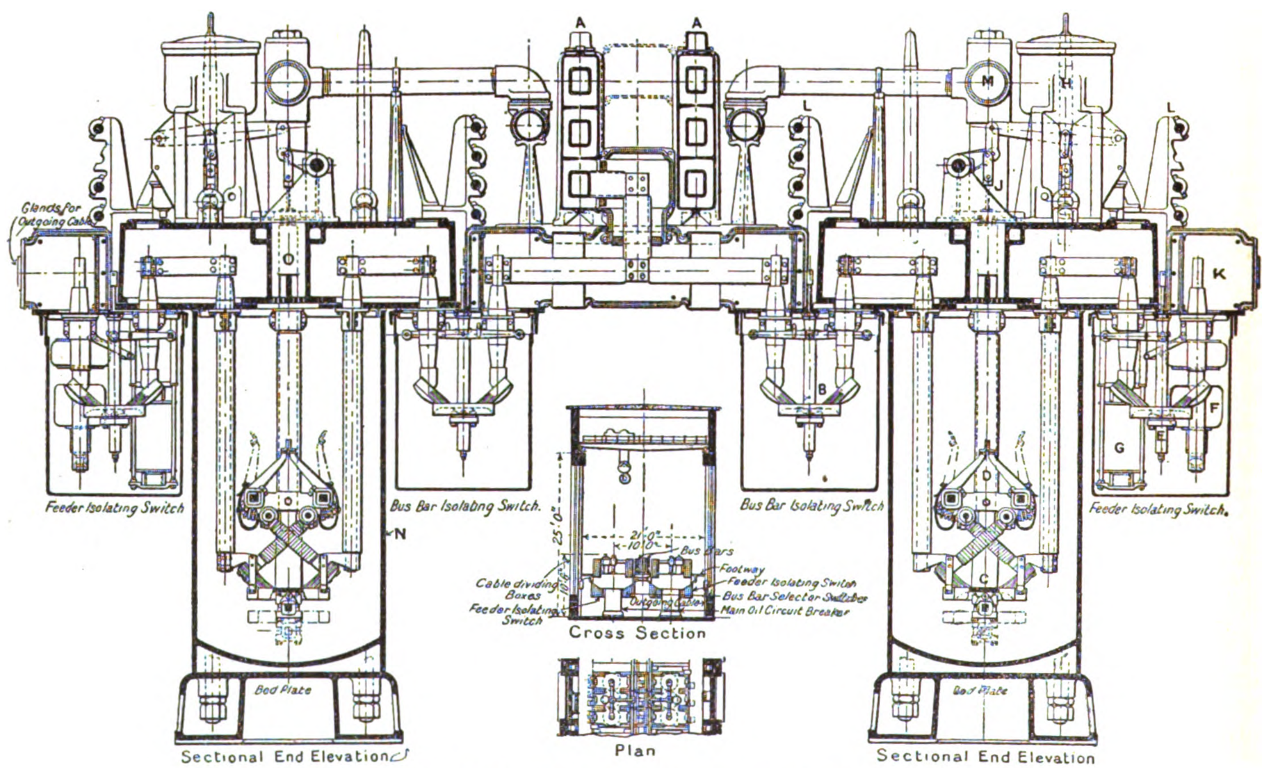

FIG. 26.—Heavy-duty metal-clad compound-filled switchgear unit.

ADVANTAGES OF SCHEME "A" OVER SCHEMES "B," "C" AND "D."

(1) *Protection.*—It is possible to provide discriminative protective gear for each section of the ring main so as automatically to isolate any faulty section at both ends

supply to the consumers. This is also possible with scheme "B," but is more difficult with schemes "C" and "D."

(3) *Maintenance.*—The minimum amount of time is required for the isolation of a faulty section and the

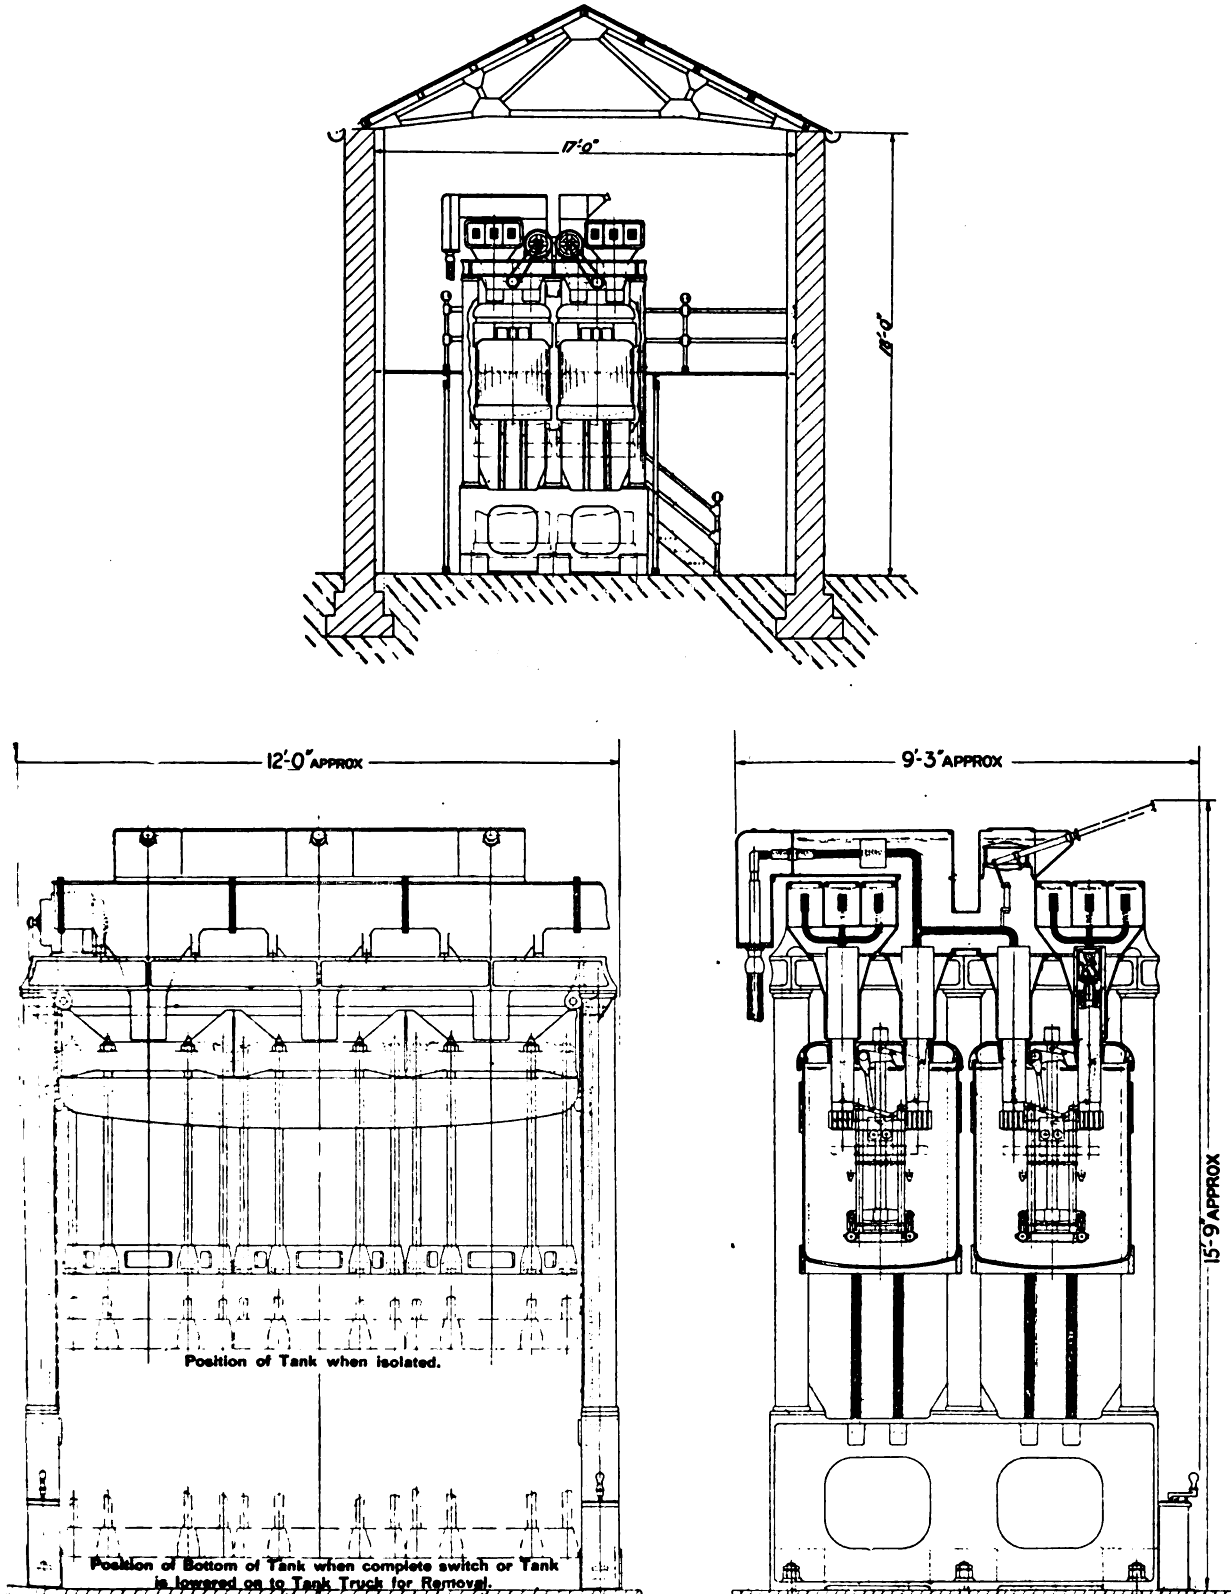

Fig. 27.—Heavy-duty metal-clad compound- or oil-filled switchgear unit, with double breakers.

localization of the trouble, i.e. there is the least period of interruption of the supply. If the ring has been opened automatically by a fault, the supply can be quickly resumed by telephoning to the substation concerned. This is possible with arrangement "B," but it is not so with arrangements "C" and "D," because it is necessary for the mains engineer to visit the substation in order to localize and isolate the faulty section.

(4) *Reliability*.—Several breakers are provided on the ring main, and thus there is less dependence on the generating station breakers. In the case of schemes "B," "C" and "D" there is no second line of defence.

Advantages of Scheme "D" over Scheme "C."

(1) *Isolation of substation busbars*.—The supply to other substations is not jeopardized, because the busbars can be made dead without breaking the ring. With scheme "C" not only is the ring opened but before the busbars can be made dead it is necessary to ascertain whether the ring is opened or not at any other place, and to render any balanced relays inoperative.

shut-down. There is not the same facility and security with scheme "C."

It will be evident that scheme "A" affords con-

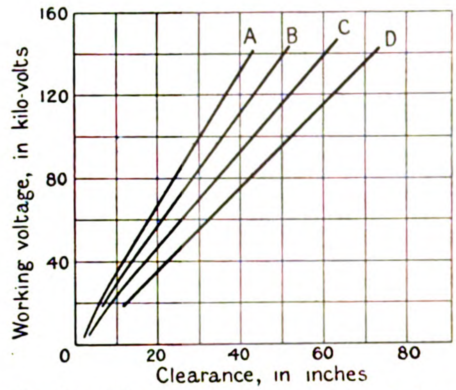

FIG. 28.—Clearances for conductors, indoor and outdoor.

siderable advantage over the others, but where capital cost is the first consideration it is possible to employ

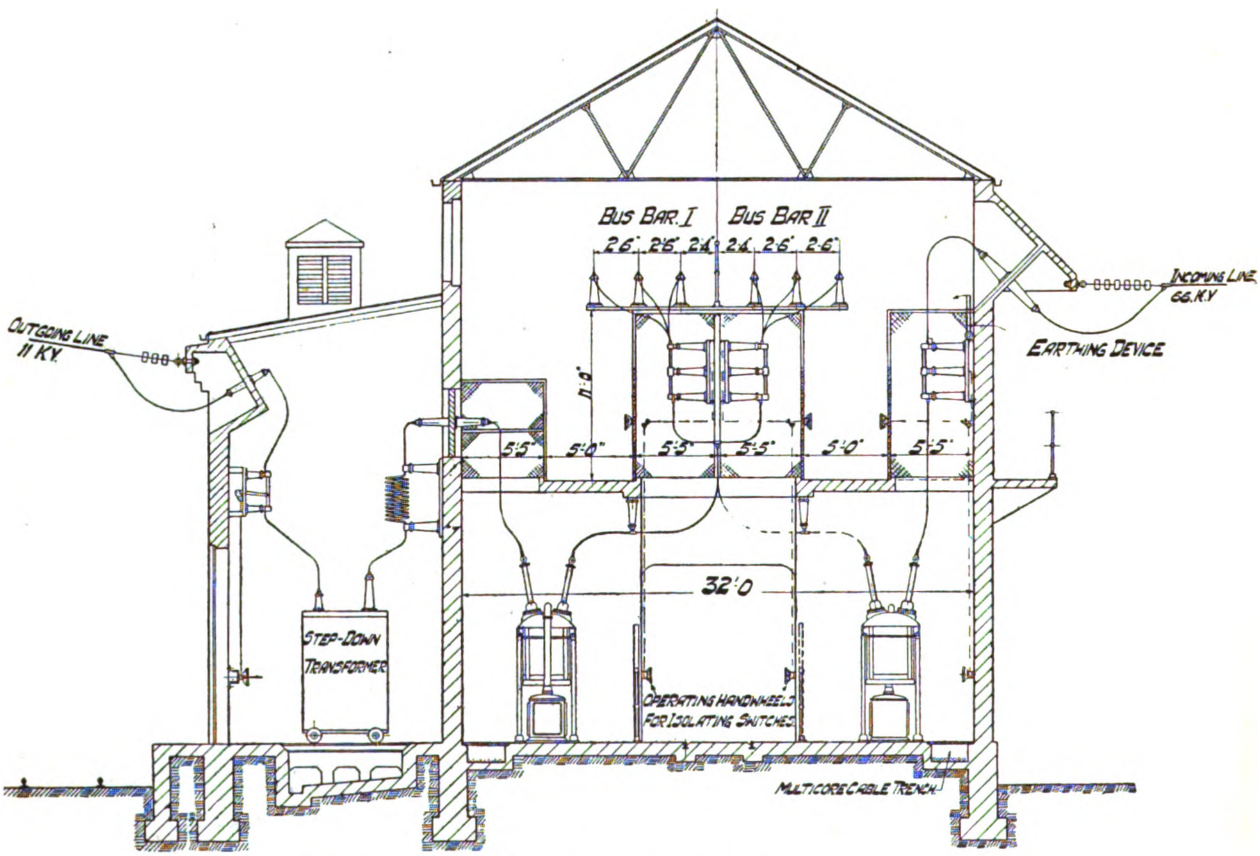

FIG. 29.—Layout of 66-kV indoor station. Sectional elevation.

(2) *Isolation of section of ring main*.—When it is desired to isolate sections of the ring main, a consumer can be transferred from one section to another without

scheme "A" at the important substations and one of the other schemes at the less important substations on the same ring main. Schemes "B" and "C" may be

incorporated in a single metal-clad draw-out type unit having oil-immersed isolators, as illustrated in Fig. 10.

General Considerations.

Isolators.—Isolators should be provided on each side of oil circuit breakers. In some cases they are omitted from the side of the breaker remote from the busbars, but it is very dangerous practice and fatal accidents have occurred on account of this omission. It is imperative that there should be no fear of the breaker being made alive from the other end, and the attendant should be able to see for himself that the breaker is isolated on both sides.

Single-pole isolating switches cannot be relied upon to break any current but, where the poles are coupled and remotely operated, the magnetizing current of small transformers or the charging current of short transmission lines may be broken.

Difficulty occasionally arises with protective gear when pole-operated isolators are operated consecutively, on account of the unbalanced capacity currents which affect core-balance protection, and hence mechanically-operated isolators are now frequently used.

Potential transformers.—It is highly desirable to avoid the connection of potential transformers to the busbars, because the former are a very weak link in the system. It is better to connect them to the individual circuits on the side of the breaker remote from the busbars, and all ordinary synchronizing operations can still be carried out. The synchronizing of busbar sections or main and spare bars can be carried out by the use of potential transformers on the machines connected to the individual sections or sets of bars. Difficulties arise if summation wattmeters are required, and if potential transformers must be connected to the busbars they should preferably be protected by an oil circuit breaker.

Synchronizing.—Interlocks are occasionally provided to prevent generators being connected to the busbars before the synchronizing instruments have been energized. This is accomplished by the provision of auxiliary contacts on the synchronizing plug. These complete the control circuit of the electrically-operated breaker, so that the latter cannot be closed until the synchronizing instruments are in circuit.

By-pass switches.—On super-tension systems, where a considerable time would be required to carry out the inspection of a breaker, a by-pass switch is often used, as shown in Fig. 25. Its function is to short-circuit the breaker so that the latter can be taken out of the circuit without opening the line connections.

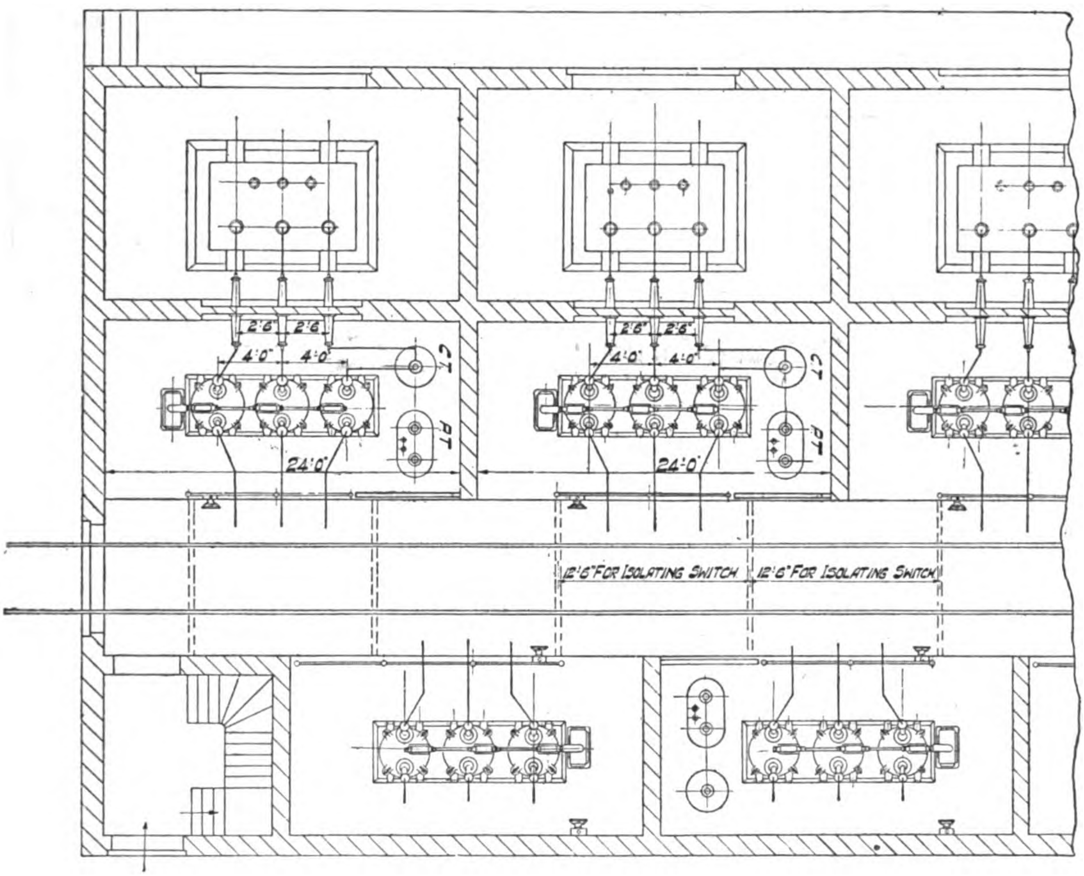

Fig. 30.—Layout of 66-kV indoor station. Plan.

Section 4.

TYPICAL INSTALLATIONS.

Installations operating at high-tension generating voltages are generally well known, but, as an example of modern super-power station switchgear, two illustrations of the metal-clad type are included.

overhead crane, thus exposing the internal portions of the breaker.

A metal-clad compound or oil-filled switchgear unit of the vertical draw-out pattern is illustrated in Fig. 27. Double breakers are provided for busbar selection, and each set is raised and lowered separately by means of a motor-operated mechanism.

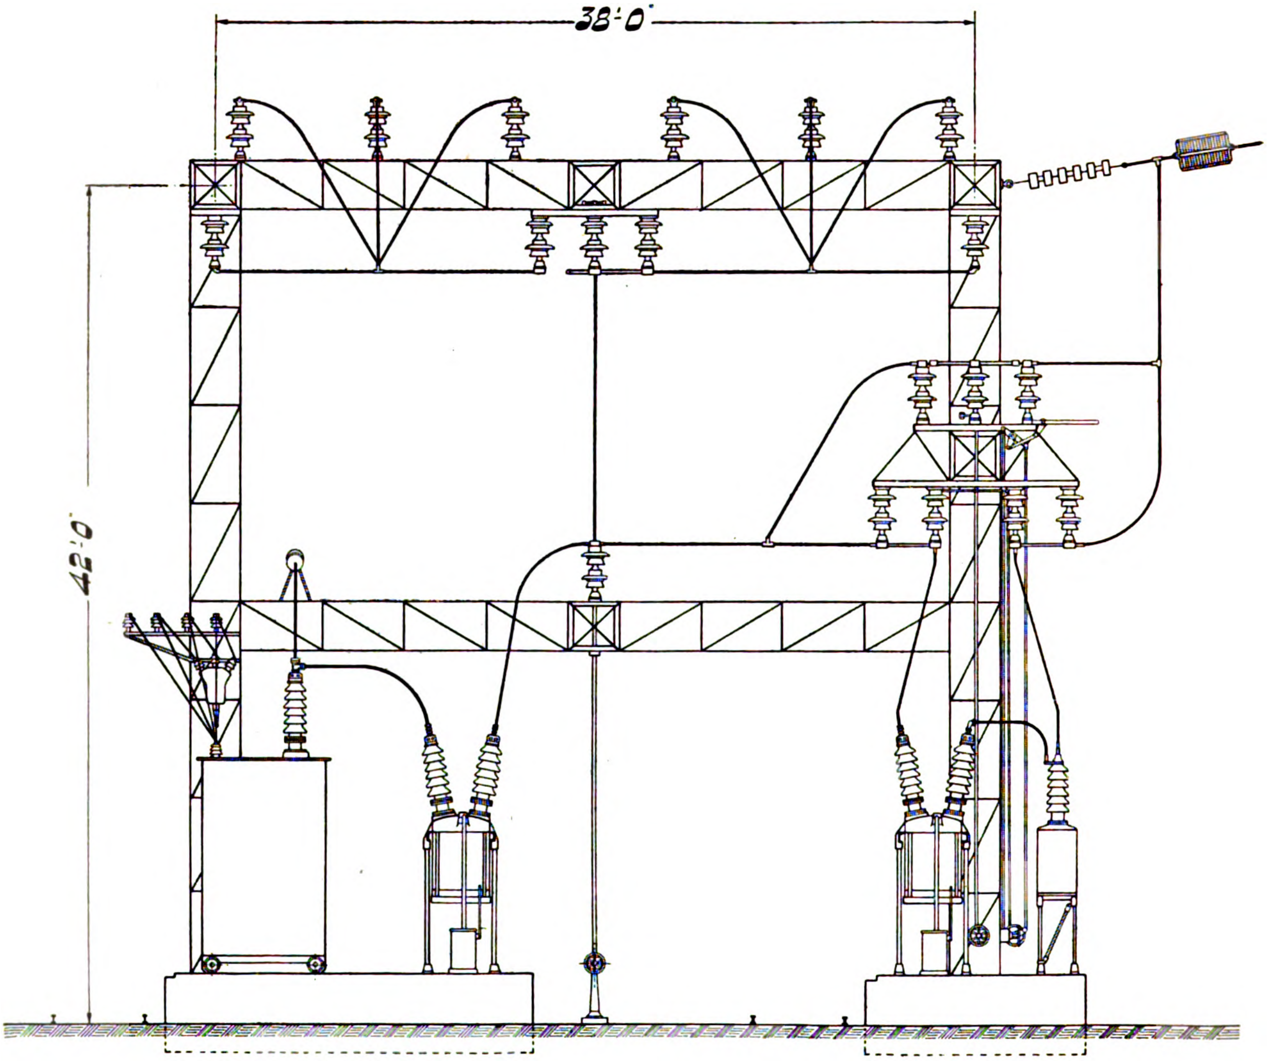

Fig. 31.—Layout of 66-kV outdoor station. Sectional elevation.

Super-tension schemes are not so generally well known, and accordingly a number of typical indoor and outdoor layouts are given.

Super-Power Station Switchgear.

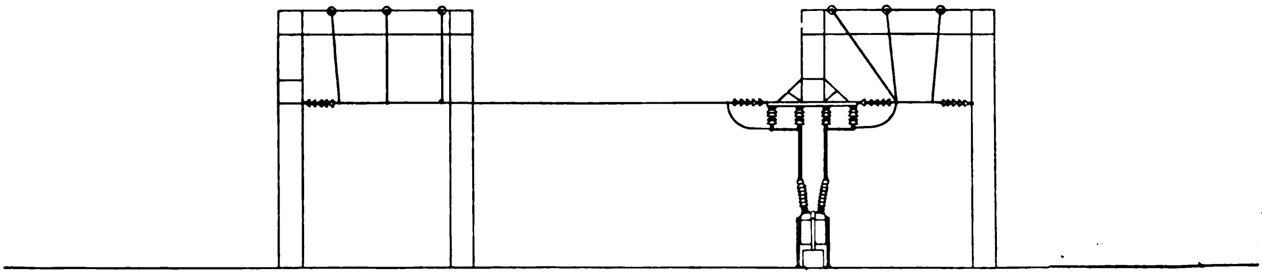
A metal-clad compound-filled switchgear unit is shown in Fig. 26. It should be noted that oil-immersed isolating and busbar selecting switches are employed and the complete three-phase breaker can be withdrawn vertically from the fixed framework by means of an

Clearances for Air-Insulated Conductors.

The minimum space required for super-tension installations depends on the minimum clearances allowable. Recommended values for rigid conductors are given in Fig. 28. Curves A and B indicate clearances to earth for indoor and outdoor gear respectively, whilst clearances between phases are given by curves C and D.

Super-Tension Indoor and Outdoor Installations.

66-kV indoor station.—The busbars and isolators are supported on an open-type steel framework. Expensive



Alternative arrangement of busbar sectionalizing equipment.

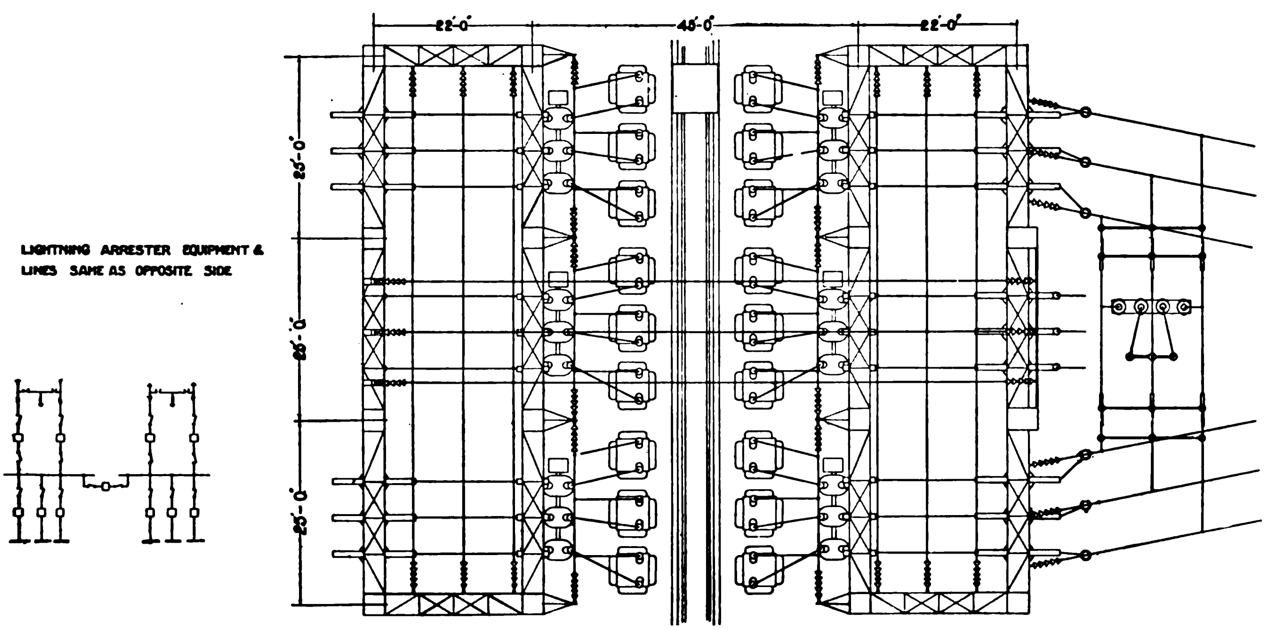

FIG. 33.—Layout of 88-kV outdoor station. Plan.

bushings are avoided, where possible, by the use of large holes in the divisions. All isolating switches are mechanically operated and can be controlled and observed from the ground floor. A sectional elevation and plan are given in Figs. 29 and 30.

88-*kV outdoor station*.—The station is in two halves arranged back to back in order to reduce the length, one set of busbars only being provided, together with a busbar section switch. An alternative arrangement for busbar sectionalizing is shown in the sectional elevation, Fig. 32. A plan of the layout is given in Fig. 33.

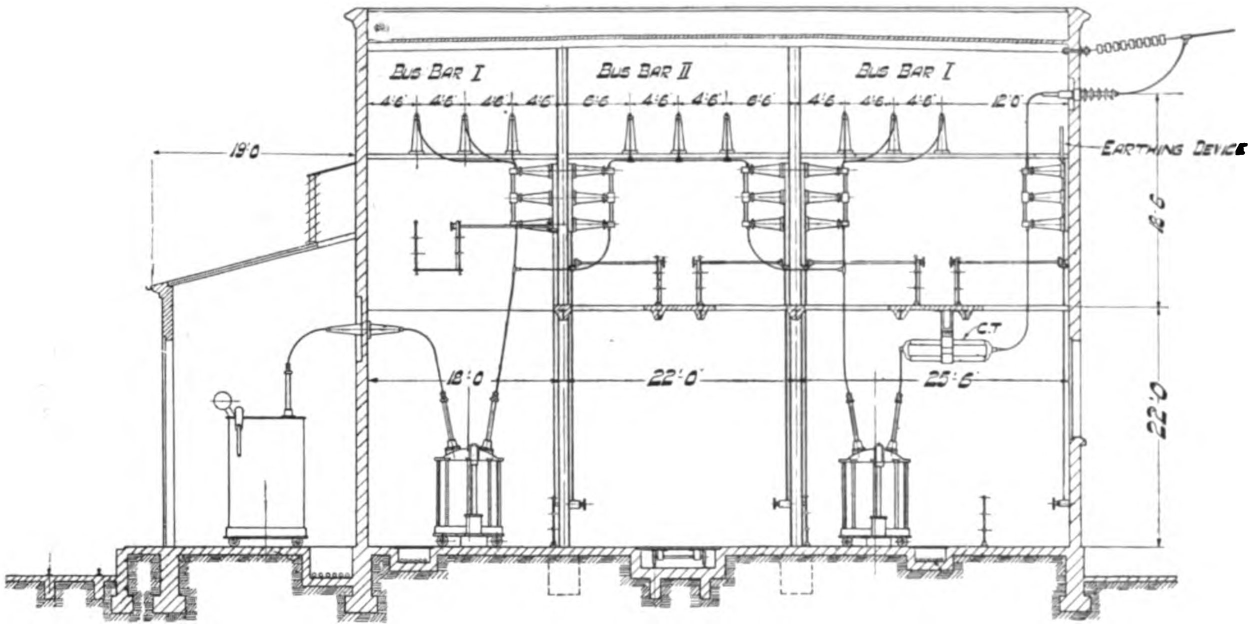

FIG. 34.—Layout of 110-kV indoor station. Sectional elevation.

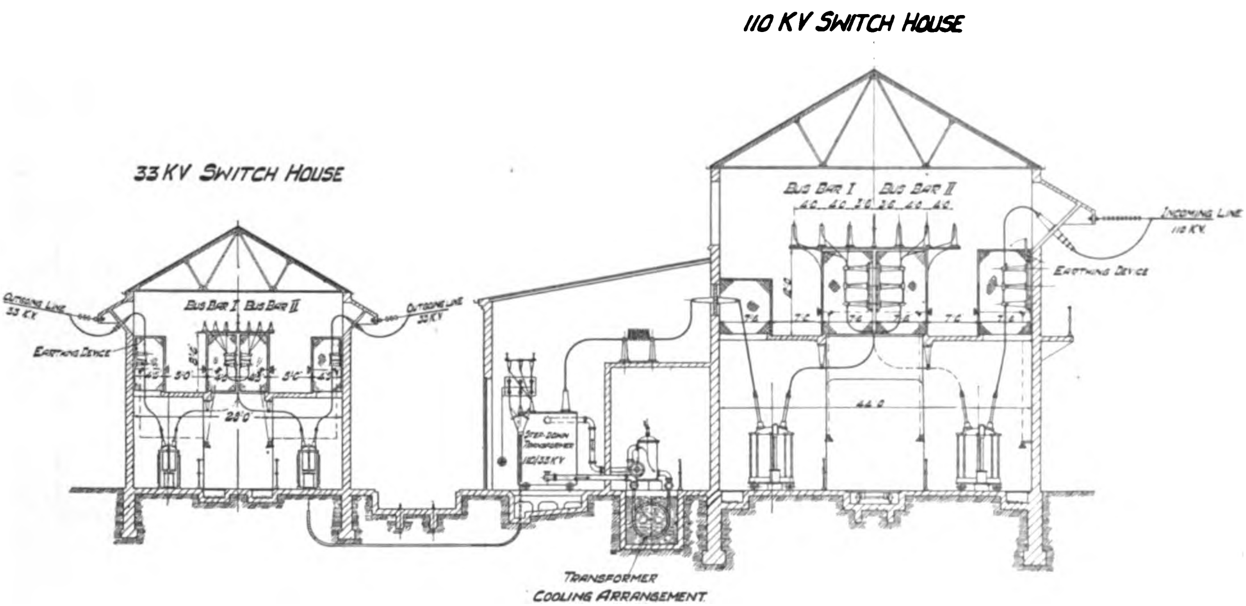

FIG. 35.—Layout of 110/33-kV indoor station. Sectional elevation.

66-*kV outdoor station*.—A sectional elevation of the layout is shown in Fig. 31. Busbar selection is effected by change-over switches. By-pass switches are provided in order that a breaker may be disconnected for repairs without interruption of supply. All insulators are built up from standard units, thus facilitating repairs.

110-*kV indoor station*.—A sectional elevation is shown in Fig. 34. The length of building is reduced by the horseshoe arrangement of one set of busbars. The other set is arranged in a straight run down the centre,

and the breakers are arranged directly opposite to one another in two rows.

110/33-*kV indoor station.*—Separate 110-kV and 33-kV switch rooms are shown in sectional elevation and plan in Figs. 35 and 36 respectively. Duplicate busbars arranged in the usual manner are employed. The breakers are mounted in two rows in zigzag formation. This arrangement makes the breaker cell twice the width of the isolating switch cell, but the extra space may be used for the accommodation of instrument transformers.

A gallery is provided for the inspection of the 110-kV wall-type bushings. All isolating switches can be operated and observed from the ground floor. Both switch rooms are constructed on the same principle.

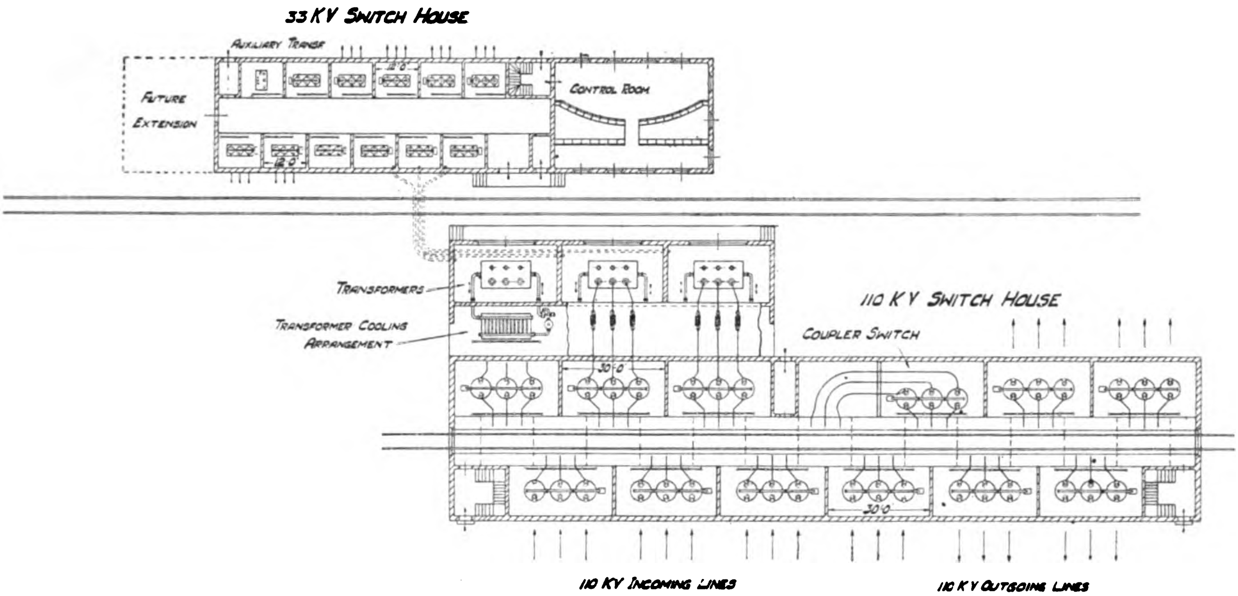

FIG. 36.—Layout of 110/33-kV indoor station. Plan.

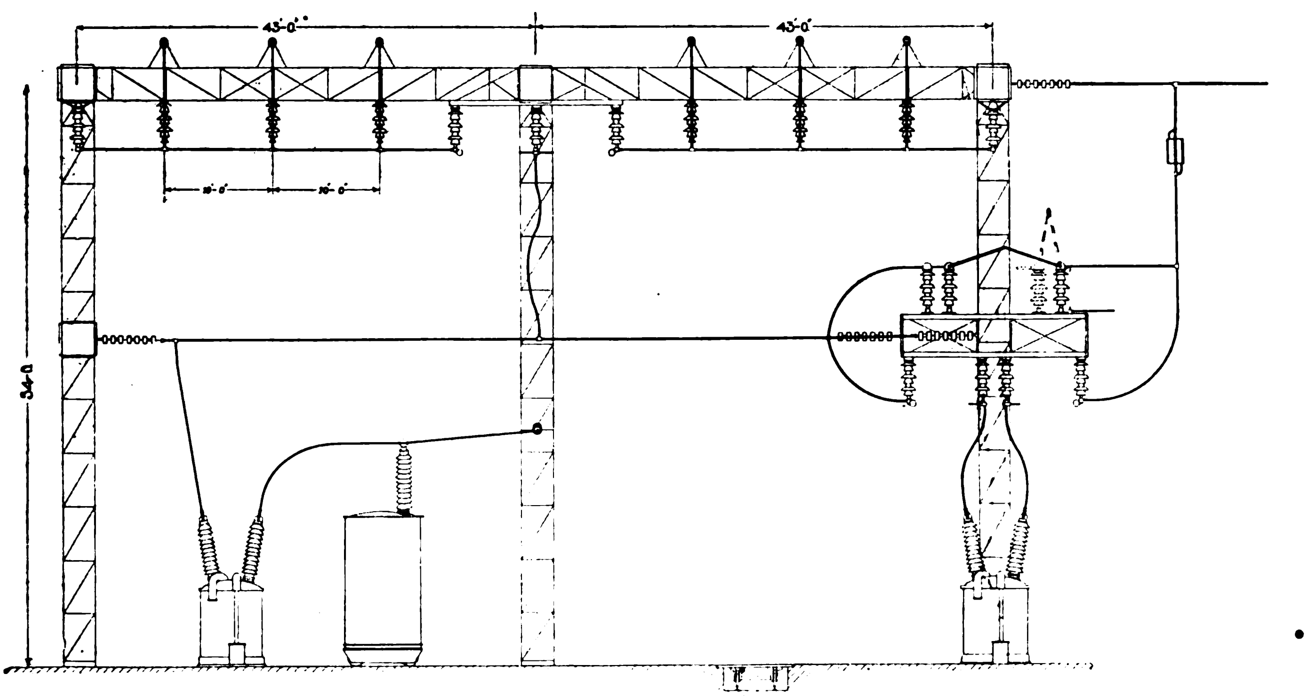

FIG. 37.—Layout of 135-kV outdoor station. Sectional elevation.

135-kV outdoor station.—A duplicate set of strained busbars is employed and selection effected by mechanically-operated, carriage-type change-over switches, as shown in the sectional elevation in Fig. 37. By-pass switches are provided for each line breaker. The layout is shown in plan in Fig. 38.

On the above indoor installations, protection is afforded by expanded-metal screens placed at operating positions on the second floor. All breakers are provided with masonry enclosures for protection while carrying out repairs.

RATINGS.

Oil circuit breakers have two distinct ratings:—

(1) Normal rating.

Voltage.
Current.
Frequency.

(2) Short-circuit rating.

(*a*) Breaking capacity.
(*b*) 5-sec. current capacity.

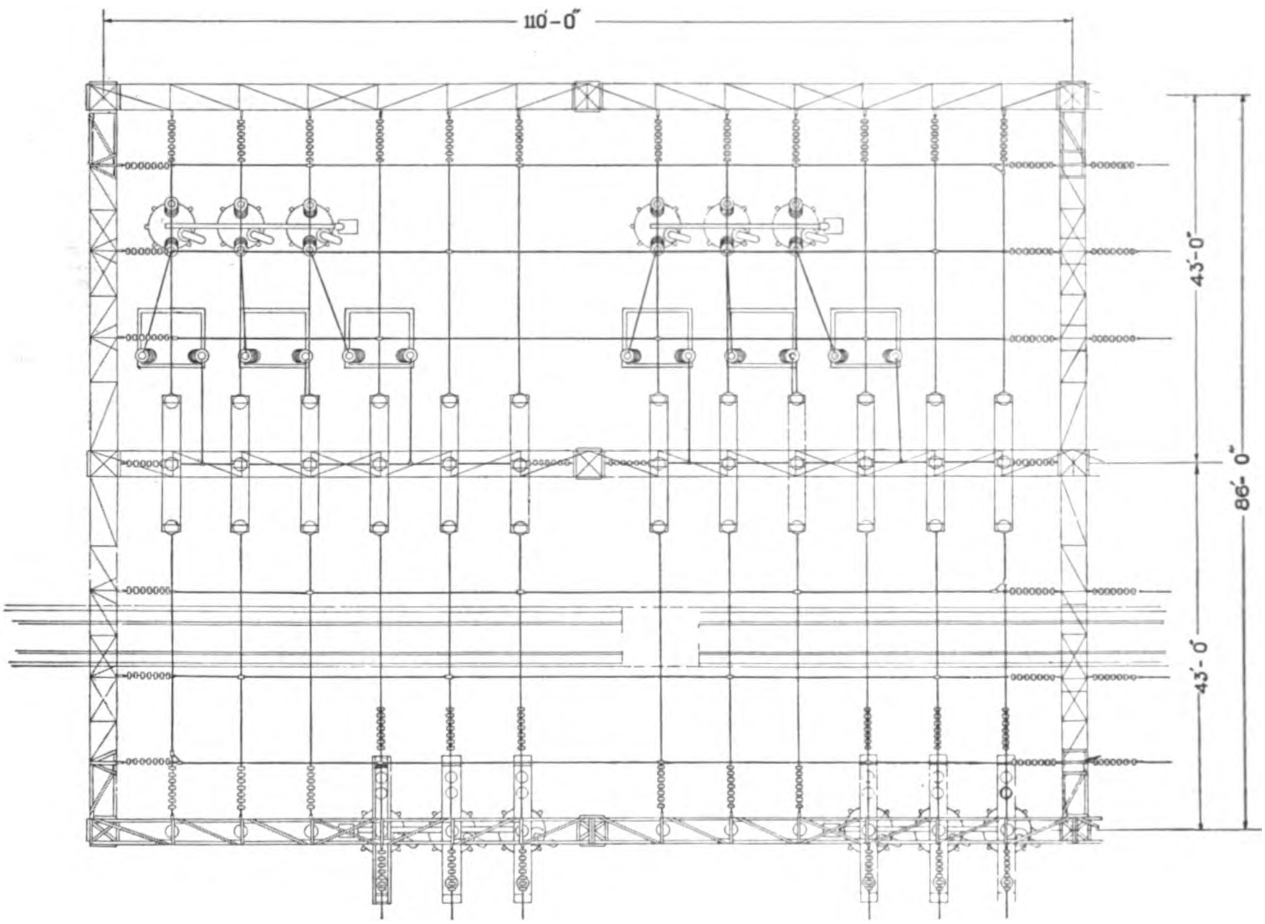

FIG. 38.—Layout of 135-kV outdoor station. Plan.

Section 5.

OIL-IMMERSED CIRCUIT BREAKERS.

Air-break fuses and breakers are satisfactory on small-capacity low-tension a.c. systems, but oil breakers are essential for breaking high-tension a.c. circuits, the principal reason being that an oil breaker breaks the current at or near the zero point of the wave, whereas a fuse or breaker operating in air generally breaks the current at or near the maximum point, thus creating excessive surges.

(1) *Normal rating.*—The British Standard Specification, No. 116, 1923, deals with the breaking capacity and normal rating of oil-immersed circuit breakers. The design of a breaker to fulfil its normal rating presents very little difficulty.

(2) *Short-circuit rating.*

(*a*) *Breaking capacity.*—Research on this subject has been conducted in nearly every country, and the British Electrical and Allied Industries Research Association have urgent need of plant, with a short-circuit capacity up to, say, 750 000 kVA, being placed at their disposal.

Co-operative action in this direction would be of mutual benefit to supply undertakings and manufacturers. Up to the present an increase in the breaking capacity of oil breakers has been obtained very largely by increasing their physical dimensions, whereas it is reasonable to believe that when a scientific basis of design has been evolved the size and cost will be reduced appreciably. Many tests have been carried out in other countries on running systems, without serious interruptions of supply.

The breaking-capacity rating is most important at generating voltages, and is defined as the maximum kVA which the circuit breaker will break on a definite operating duty. The kVA is based on the arc current and the system voltage, presupposing that the normal voltage will be re-established on the opening of the breaker. A better indication of the duty imposed would be obtained by using the recovery voltage instead of the system voltage. The recovery voltage, however, depends on the power factor, the stored energy in the system, the connected shunt load and whether the neutral is earthed or not, and it cannot be easily calculated. The system voltage is therefore taken to represent the average recovery voltage. This point becomes of considerable importance when a relatively small breaker is connected to a large system in such a way that it may afford the only outlet for the stored energy. It is generally conceded that the worst duty imposed on a breaker is operation on a short-circuit at the generator terminals with neutral insulated and no connected shunt load.

Operating duty.—The standard operating duty, both in this country and in America, is for the breaker to interrupt its rated kVA twice at a two-minute interval and then to be in a condition to be closed and carry its rated current until it is practicable to inspect it and make necessary adjustments. This operating duty may not suit the practice of supply undertakings, and in America agreement has been reached as to the percentage of interrupting rating applicable to the following modified duties :—

	Per cent
(1) Two unit-operating cycles separated by a two-minute interval (standard operating duty)	100
(2) Four unit-operating cycles separated by two-minute intervals	70
(3) Four unit-operating cycles separated by half-minute intervals	60
(4) Four unit-operating cycles with no time delay between full open position and start of closing position	30

For the above purpose, each unit-operating cycle consists of closing the breaker on a fault followed immediately by the opening of the breaker, that is, without time-lag. The operating duty therefore begins and ends with the breaker in the open position.

It is evident from the above figures that an attendant can ruin a breaker by closing too frequently on a fault or at too short an interval between unit-operating cycles. The failure of oil breakers after repeatedly opening short-circuits is due, principally, to the ignition of explosive mixtures, which are formed by the combination of the arc gases with the air in the top of the oil vessel. The gases cannot be vented quickly enough to relieve the danger.

Fig. 39 illustrates the operation of a breaker under fault conditions. The short-circuit characteristic for a typical turbo-generator is shown by curve A, which is the B.E.S.A. assumed curve and does not allow for possible doubling effect. Curve B is a breaker-opening characteristic, and both curves are on a common time basis in order to correlate them. It is assumed that the arcing contacts of an average breaker, set for instantaneous tripping, do not separate until 0·2 sec.

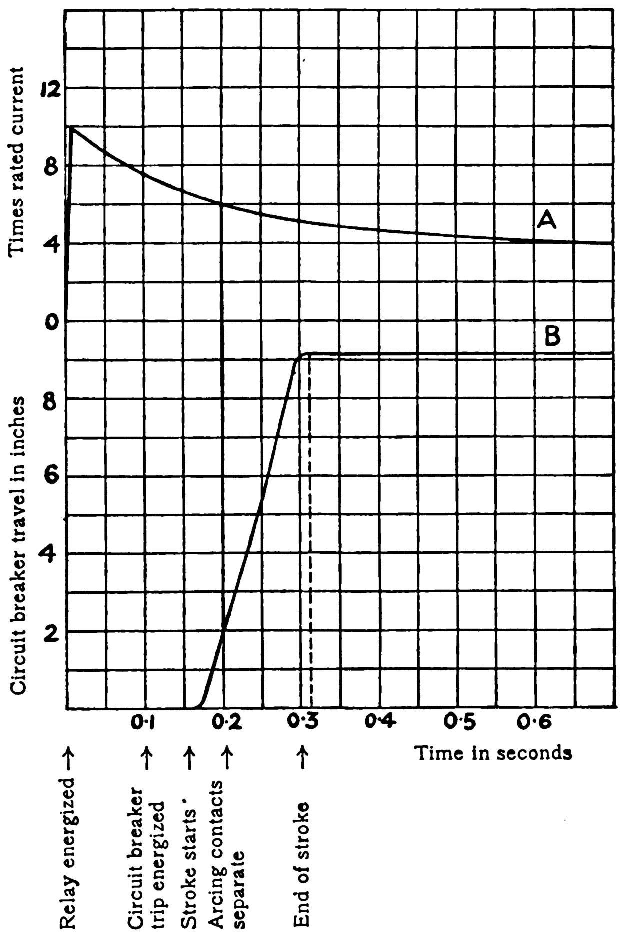

FIG. 39.—Operation of breaker on short-circuit.

has elapsed, and the current to be broken will be that corresponding to six times the aggregate plant capacity. In the case of cable systems a fault may not develop instantaneously, and it is possible for the peak value of the short-circuit to occur at the instant the arcing contacts separate. On this account, important main breakers are often selected with a capacity equal to the peak value of the short-circuit kVA.

Short-circuit rating.

(*b*) *5-sec. current capacity.*—The 5-sec. current capacity is defined as the maximum current that the breaker contacts can pass for five seconds without danger of

welding the contacts or causing mechanical distortion due to electromagnetic forces. This rating should be determined experimentally and is frequently about 50 times the normal current capacity.

Working Principles.

The function of an oil breaker is to break the current in the shortest possible time after the contacts start to separate. The energy of the arc appears as heat, which decomposes a certain amount of oil around the contacts so that a gas stream is formed. At or near each zero value of the current wave the circuit is interrupted and there is an instantaneous voltage-rise, tending to re-establish the arc. This may be termed the recovery voltage and is affected by the conditions of the external circuit, as will be indicated later.

Final interruption of the circuit occurs when the recovery voltage is insufficient to re-establish the arc, and in order to accomplish this in the shortest possible time the opening speed of the breaker must be sufficiently high. Operation at the normal rating presents no difficulty. It is the short-circuit rating which demands the greater attention, and which at generating voltages determines the size and cost.

Factors Affecting Breaking Capacity.

The fundamental laws governing the breaking of heavy power arcs under oil have not yet been discovered, and when a systematic investigation of an oil breaker is attempted its erratic behaviour under short-circuit conditions soon becomes evident. The severity of a short-circuit depends upon the point of the voltage wave at which it occurs, and even if a large number of tests be carried out under constant and controlled conditions the amount of gas generated may vary several hundred per cent. Since the final measure of the efficiency of a given breaker is the amount of gas generated and the rate of generation, it follows that a single test is inconclusive, and the only safe breaking capacity that can be ascribed to the breaker is that obtained from many tests made at all capacities under the worst conditions.

The factors which influence the breaking capacity of an oil breaker are :—

(1) Opening speed; that is, speed at instant of contact separation.
(2) Number of breaks per phase.
(3) Length of break.
(4) Head of oil above point of break.
(5) Volume of air cushion.
(6) Type and size of vents.
(7) Shape and strength of top plate, oil tank and fastenings.
(8) Clearances in air and under oil.
(9) Characteristics of the oil.
(10) Volume of oil.

(1) *Opening speed*.—The initial acceleration of a breaker should be high in order to get sufficient speed at the instant the arcing contacts separate. It is the speed at this point that is of most importance. A high opening speed is usually obtained by means of accelerating springs and a reduction of the weight of the moving parts to a minimum. In the case of heavy-current breakers, where the acceleration of heavy moving parts becomes difficult, the necessary speed at the instant of contact separation is usually obtained by means of spring-operated arcing contacts or by the use of an external snap switch, in which the arc is ruptured.

Ideal conditions require that the arc shall not re-establish itself after passing the first zero value of current following the separation of the arcing contacts, and this emphasizes the value of a high opening speed. A slow breaker may allow the current to persist for several half-cycles after the contacts have separated, and would thus have to dissipate much more energy.

From tests carried out at generating voltages by various observers it appears that no advantage is gained by an increase in the opening speed beyond a certain figure. Various values ranging between 3·5 and 7 ft. per sec. have been given. Tests have shown that opening speeds in excess of the best value result in a longer arc, increased gas generation and increased internal pressures, except in the case of the explosion-pot breaker.

The speed of a breaker when breaking heavy short-circuit currents at generating voltages tends to exceed its no-load speed due to the electromagnetic throw-off force exerted on the moving contact bar, as illustrated in Fig. 41.

In cases where the contact-bar lifting-rods pass through the top plate, the internal pressure developed may exert sufficient force on the former to reduce the opening speed. In such designs it is essential to reduce the diameter of the rods to a minimum.

(2) *Number of breaks per phase*.—In the majority of cases oil breakers are designed with two breaks per phase, but on the Continent as many as ten breaks per phase are occasionally used. The advantages of the increased number of breaks are not so great as were anticipated, and tests carried out on the Continent gave the following results for an increase from four to fourteen breaks per phase. The duration of the arc was reduced by about 50 per cent, whilst the aggregate length of the different portions of the arc was increased by 25 per cent. The impulse pressures were more pronounced by about 50 per cent, and the arc energy was only reduced by about 23 per cent. On Continental breakers, which are handwheel-operated, the use of multiple breaks enables a suitable length of break to be obtained on high-voltage gear, but where the mode of operation permits of a longer travel it is doubtful whether the small advantage due to multiple breaks warrants the necessary complication.

The above conclusion may have to be modified in view of a recent patent taken out by the British Electrical and Allied Industries Research Association in connection with multiple breaks. The outstanding feature of the invention is that the breaks are not simultaneous in operation, but are so arranged that they open successively during a cycle or a part thereof. It is claimed that the arc energy is substantially reduced by the timing of the breaks, because at least one pair of contacts will open near the zero value of the wave.

(3) *Length of break*.—The length of break must be

ample in order that the arc may be interrupted, under the worst conditions, without permanent gas generation, otherwise the breaker will quickly be destroyed. At one time it was thought that the breaking capacity was a direct function of the length of break. This assumption has been disproved and it is now known that the main factor which determines the minimum length of break is the rated voltage. Tests carried out at generating voltages have shown that well-designed breakers can break the arc at the end of one-half cycle after the arcing contacts separate. Assuming the above figure for the period of arc duration, then with an opening speed of 5 ft. per sec. the length of arc per break would be 1·2 in. at 25 cycles, and 0·6 in. at 50 cycles. Very big factors of safety have, however, to be allowed, because the throw-off force on the moving contact bar may increase the speed materially and thus lengthen the arc. Furthermore, the recovery voltage has an effect on the minimum length of break that can be employed. The author has never met a case where a breaker has failed due to the length of break being insufficient.

(4) *Head of oil above point of break.*—If the head of oil be insufficient, the amount of gas generated may cause a continuous stream of gas from the contacts to the oil surface. This has been termed "chimney" effect, and under these conditions it is almost certain that an explosive mixture will be formed and fired by the arc, with possible fracture of the top plate. For generating voltages the minimum head of oil that can be used is that necessary to avoid "chimney" effect, whereas on higher voltages the creepage distance over the terminal bushing becomes the deciding factor. Oil throw, gas ignition, and the impulse pressures developed above and below oil level are influenced by the head of oil. A good head of oil gives increased cooling to the rising gases, but tests have shown that too much oil in the tank is as bad as too little. The most suitable head of oil depends on the form of the breaker and must be considered in conjunction with the volume of air cushion.

(5) *Volume of air cushion.*—The volume of air cushion affects the tank pressures, oil throw, arc stabilizing, secondary explosions and gas ignition. The diffusion of the arc gases into the air cushion may form an explosive mixture which may be fired by compression or by a hot bubble of gas on a second fault, for by this time the mixture will be well diffused and easily fired. The volume of the air cushion required will depend on the size and efficiency of the breaker. An air cushion having a volume equal to about one-third that of the tank gives satisfactory results.

(6) *Type and size of vents.*—The problem of breaking heavy power arcs under oil presents the most difficulty at generating voltages, and in order to get the maximum breaking capacity in a given space it is necessary to provide means for freely venting large amounts of gases without oil-throwing. With short vent pipes, baffles are needed to prevent the ejection of oil, but it is essential to avoid over-baffling, or otherwise free venting will not be effected. The greatest risk of explosion occurs on repeated operations, because in this case the gases generated on the first opening have time to diffuse into the air cushion and so produce a mixture, which is readily ignited and through which flame can travel with explosive violence. A vent pipe does not relieve the maximum instantaneous internal pressure. It is desirable to keep the vent pipes for each breaker separate from the rest, and to carry them well away from the breaker terminals, preferably to the exterior of the building, to avoid breakdown between the terminals, due to the presence of hot, ionized gases. If a common exhaust pipe be used there is a danger of explosion in the piping due to trapped gases being fired from an explosion in a breaker.

(7) *Shape and strength of top plate, oil tank and fastenings.*—The explosive pressures produced in a breaker may be considered under three separate headings :—

(*a*) The impulse pressures due to the sudden generation of a comparatively large volume of gas in a confined space.
(*b*) The pressure developed in the air cushion due to the increase in volume and temperature of the resulting mixture of air and arc gases.
(*c*) The pressure generated by possible ignition of the explosive mixture present above the oil surface.

The maximum pressure developed will depend probably upon the extent to which the tank gives, and the pressure exerted. A rectangular tank gives at the sides more readily than a circular one, and the energy is thus absorbed without excessive pressure developing. On the other hand, circular tanks are built to withstand the high pressures without distortion, and either shape of tank may be used providing it has sufficient strength.

Actual tests on heavy breakers have recorded tank pressures of 200 to 300 lb. per square inch.

(8) *Clearances in air and under oil.*—The safe clearances depend on the voltage, circuit conditions, and amount of current interrupted, and no earthed metal should be below oil level in any position where bubbles of gas may be expected. Tank linings and phase barriers are occasionally omitted on Continental breakers, and greater clearances to earth and between phases are necessary. Minimum air clearances and test pressures are specified in British Standard Specification No. 116, 1923.

(9) *Characteristics of the oil.*—The breaking capacity of an oil breaker is influenced by the characteristics of the oil more than is generally understood. The most suitable oil is one which :—

(*a*) Produces the least quantity of gas for a given interruption.
(*b*) Has the least carbon production.
(*c*) Has the most suitable viscosity.
(*d*) Has the highest electric strength for a given interruption.
(*e*) Vaporizes the least.
(*f*) Has the greatest percentage carbon precipitation.
(*g*) Absorbs the least quantity of moisture.
(*h*) Has the highest flash point.

Standard transformer oil is frequently used at ordinary operating temperatures, but where breakers have to work in cold climates an oil which remains fluid must

be used. Alternatively, immersion heaters may be employed.

(10) *Volume of oil.*—Strictly speaking, this factor cannot be separated from head of oil. A sufficient quantity must be provided to ensure ample cooling of the arc and the gases generated. Fig. 40 gives a set of curves (B), (A) and (C), showing the relation between rated breaking capacity and volume of oil for typical British, American and Continental breakers respectively.

Continental breakers have larger clearances, giving a greater volume of oil, but the tanks are weaker than those of British and American design.

From the attempt to segregate the main factors which influence the breaking capacity of an oil circuit breaker, it will be evident that all the variables are

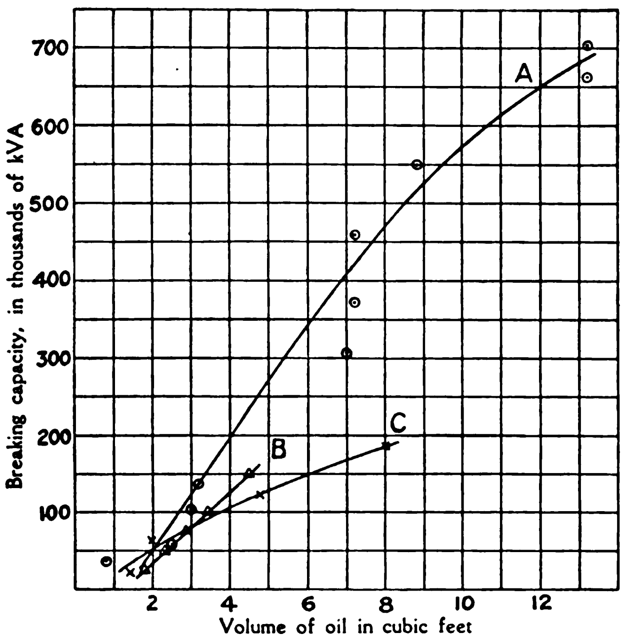

FIG. 40.—Relation of breaking capacity to volume of oil.

interdependent and some of them cannot be controlled by the designer.

CONDITIONS OF THE EXTERNAL CIRCUIT.

The duty imposed on a breaker is affected by the conditions of the external circuit as regards the following characteristics :—

(*a*) Earthed or unearthed system.
(*b*) Power factor under short-circuit conditions.
(*c*) Periodicity.
(*d*) Connected shunt load.

The recovery voltage which is produced at every circuit interruption is affected by the above four factors. It is considerably greater on unearthed systems and short-circuits of low power factor. Connected shunt load reduces the recovery voltage, and hence for a given periodicity of supply the worst circuit conditions are when the fault occurs at the generator terminals on an unearthed system without connected shunt load.

Tests have shown that the breaking capacity of a given breaker on a 60-cycle system is greater than that on a 25-cycle system. At the former frequency the arc energy per half-cycle is only two-fifths that on the latter frequency, and the opportunity for breaking the current occurs more frequently.

THERMAL AND ELECTROMAGNETIC EFFECTS.

The effects produced by short-circuit current are :—

(1) Electromagnetic stresses.
(2) Rapid heating of conductors.

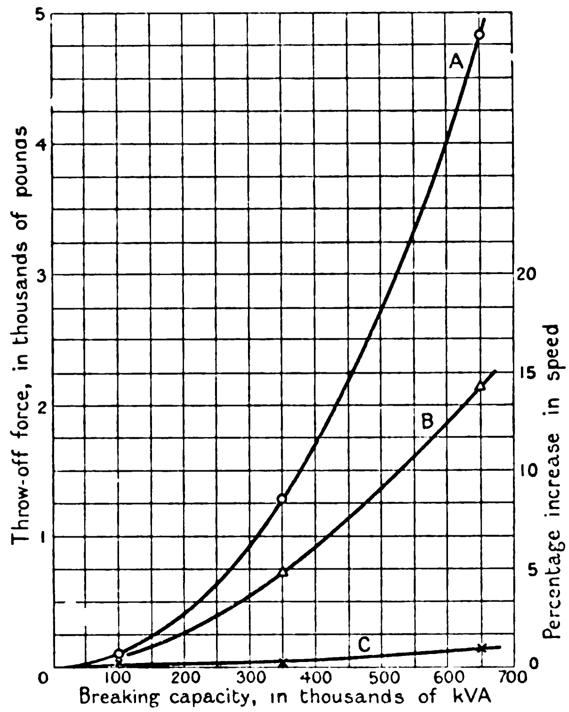

FIG. 41.—Relation of throw-off force and speed increment to breaking capacity.

ELECTROMAGNETIC STRESSES.

There are two forces to be considered :—

(*a*) Throw-off force on the moving contact bar.
(*b*) Repulsive force on the breaker terminals.

(*a*) *Throw-off force.*—The moving contact bar and the breaker terminals form a loop, and in consequence short-circuit currents produce a throw-off force on the former. Fig. 41 gives curves showing the calculated throw-off forces and their effects on the opening speeds of breakers of various breaking capacities. Curve A gives the highest peak value of throw-off force per phase before the arcing contacts separate. The values shown on curve C are the mean values of throw-off force per phase during the first half-cycle of the arc. The percentage increase in opening speed is given by curve B. The curves are based on a line of breakers rated up to 650 000 kVA, and all figures are calculated for the full rating of each breaker.

The breaker mechanism must be strong enough to resist the throw-off force without excessive deflection

of the various mechanical parts, otherwise the main contacts will separate at each instant when the current attains its peak value. In such a case, arcing would occur at the main contacts, with possible welding, before the trip coil released the breaker.

(*b*) ***Repulsive force on breaker terminals.***—The terminal studs experience a mutual repulsive force due to the flow of short-circuit current along parallel conductors in opposite directions. Each stud may be considered to be a uniformly-loaded cantilever, and the fixed contact blocks will be deflected due to the loading caused by the short-circuit currents. Where porcelain insulators are used they will relieve the stud of the repulsive load up to the breaking limit of the former, but where bakelized paper insulation is employed it will accommodate itself up to the elastic limit of the copper.

The curves shown in Fig. 42 give the calculated repulsive forces and consequent deflection of the contact

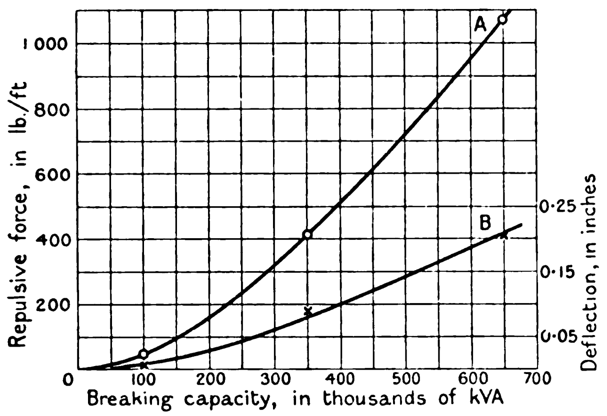

FIG. 42.—Repulsive force and deflection in relation to breaking capacity.

blocks at the ends of the terminals, on the assumption that the insulators do not offer any resistance. Figures are given for breaking capacity ratings up to 650 000 kVA. Curve A gives the highest peak value of repulsive force in lb. per foot run of the terminal before the breaker opens, whilst curve B gives the deflection of the contact blocks in inches.

Repulsive and throw-off forces should be calculated for a current equal to five times the rated arc amperes, in order to allow for possible doubling effect, and Figs. 41 and 42 are based on this value. In view of the serious forces which may be experienced at the instant of closing a breaker on an existing fault, it is necessary that a quick-closing action be obtained in order to relieve the auxiliary contacts as soon as possible and get the breaker home against the heavy forces, as otherwise a reduced opening speed will be the consequence.

RAPID HEATING OF CONDUCTORS.

On large plants it is necessary to limit the minimum section of conductor allowable near to the source of power on account of high current densities which may be obtained at the moment of short-circuit. At a density of 100 000 amperes per square inch, the initial rate of temperature-rise would be 120 deg. C. per second. Fig. 43 illustrates the rapid heating of the terminals of a typical breaker rated at 650 000 kVA. Curve A is an unsymmetrical short-circuit characteristic for a generator having 10 per cent inherent reactance. Curve B gives the temperature-rise of the breaker terminals where tripping does not occur until 5 seconds have elapsed. The equivalent steady current, which would produce the same temperature-rise at the end of 5 seconds, is shown in curve C. The curves are calculated for a short-circuit current such that with tripping at the end of 0·2 sec. the breaker would be rupturing its rated kVA.

The preheating of arcing contacts is minimized by liberal design, and in many cases there is more copper

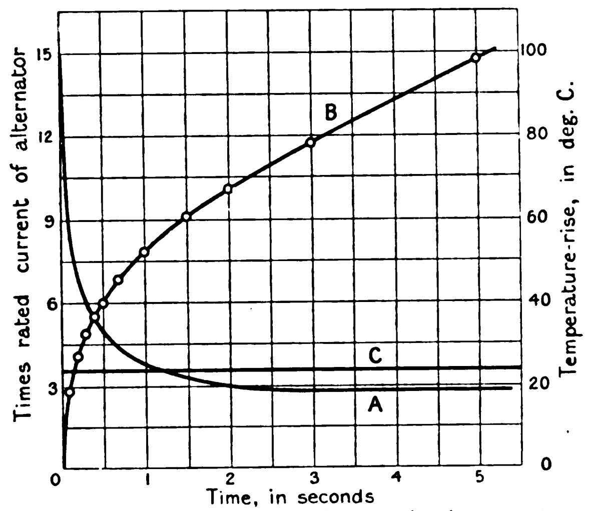

FIG. 43.—Thermal effect of short-circuit current.

necessary in the arcing contacts than in the main contacts.

CONSTRUCTIONAL FEATURES.

The modern oil breaker is characterized by its strength of tank and top plate, absence of external mechanism, improved venting, and substantial main and arcing contacts.

TERMINAL BUSHINGS.

For breakers up to 33 kV, plain insulators of porcelain or bakelized paper are satisfactory. For higher voltages a composite construction becomes necessary, and two types have been evolved, namely, the condenser type and the oil or compound-filled type. At 110 kV the cost of the terminal bushings may easily be 50 per cent of the total cost of the breaker.

MAIN CONTACTS.

The following forms of main contacts are to be found on modern breakers :—

(*a*) Wedge type.
(*b*) Laminated brush.
(*c*) Wound brush.
(*d*) Reverse brush.
(*e*) Butt type.

(*a*) *Wedge contacts.*—The fixed contacts consist of pairs of fingers between which moves the wedge-shaped moving contact bar. They are easily adjusted and are self-aligning. The variation of contact pressure is very small for a wide range of wedge position. The pressure used is of the order of 8 lb. per square inch, with a contact current density of 100–150 amperes per square inch.

Several pairs of fingers are used for heavy currents, and on short-circuit the current divides equally between the contacts of each pair, consequently the fingers are attracted to each other, giving an increased contact pressure. This form of contact is eminently suitable for heavy duty, because each finger is reinforced with a steel backing spring, and a constant pressure is maintained. A first-class wiping action is obtained, and the contact surface is divided into a number of unit areas, each of which can be readily renewed without affecting the rest. Further, a greater deflection of the mechanism is permissible under the action of the initial short-circuit current without fear of welding of the contacts before the trip coil has released the breaker.

(*b*) *Laminated brush.*—The fixed contacts consist of plain copper blocks on the under surface of which a laminated brush makes contact. A finer setting and more accurate workmanship is required than for the wedge type, and the conductivity is seriously affected by a very small variation in the relative position of contact block and brush holder. This type is generally worked at a current density of 250 amperes per square inch, with a pressure of 15–50 lb. per square inch. The elasticity of the brush deteriorates with time and proves faulty under the action of the throw-off force set up on short-circuit.

(*c*) *Wound brush.*—This is an improved form of laminated brush of broad **U** shape, with the ends or the laminations bedding almost normal to the under face of the fixed contacts. Flexure in the brush is taken at the back of the **U**, and, consequently, variations in the relative position of the brush holder and contact block do not affect the contacts of individual laminations to the same extent as the ordinary form. With the wound brush, a current density of 500 amperes per square inch can be used at a pressure of 100 lb., or more, per square inch. Under the action of the throw-off force this brush may prove faulty.

(*d*) *Reverse brush.*—This type of contact is an improvement on the wound brush in so much that any deflection of the brush under the action of the throw-off force tends to increase the contact pressure. A laminated brush is fitted on each terminal and each is similar to half of a wound brush but is mounted the reverse way so that the ends of the laminations bed almost normally to the upper face of a straight moving contact bar. This construction increases the number of joints per phase.

(*e*) *Butt type.*—This form of contact is only practicable for handling small currents, on account of the low current density permissible.

ARCING CONTACTS.

In order that the current may be transferred cleanly from the main to the arcing contacts, it is necessary that the contact resistance of the latter should be reduced to a minimum. The arcing contacts should not separate until the main contacts are well clear. The life of a breaker between the periods of inspection and repair is principally a function of the amount of copper in the arcing contacts, and they should be given the maximum amount of care as regards cleaning and replacements if the breaking capacity is to be maintained at its rated value. The most common forms of arcing contacts are :—

(*a*) Controller finger type.
(*b*) Flat finger type.
(*c*) Butt type.
(*d*) Latched plug type.

(*a*) *Controller finger contact.*—This takes the form of a semi-cylindrical block of copper carried on a flat spring riveted to the under side of the moving contact bar. The block makes a line contact with a flat plate carried by the fixed contact block. The semi-cylindrical block has a slight rolling action as the breaker opens, thus shifting the position of the contact. This form is only suitable for light duty.

(*b*) *Flat finger contact.*—This type is similar to the wedge main contact except that the two main faces of the wedge are parallel and vertical. The fingers are fitted with very strong backing springs and have only a limited play in a horizontal direction to avoid damage in case of a bad entrance of the moving arcing contact, which consists of a heavy block of copper having parallel vertical sides. The top of this block has a blunted **V** shape to give good entrance between the fingers and to take the arcing. It is necessary to have a sufficiently high opening speed with this type of contact, due to the danger of welding as the moving contact slides off the fingers.

(*c*) *Butt contact.*—This form consists of two cylinders of copper, their flat faces butting together. One contact is held to the other by means of a spring so that they do not separate until the main contacts are well clear. The spring contact may be fitted on either the fixed or movable element of the breaker. The current density is not decreased before separation of the contacts as is the case with the flat finger type.

(*d*) *Latched plug contact.*—The contact is obtained by a plug and socket, the plug definitely latching with the socket. The former is carried on a spring-loaded telescope attached to the fixed main contact block, and both arcing contacts are carried down together until the telescope is extended. When the springs are almost fully compressed, a fixed stop arrests the travel of the plug and the contacts are disengaged, separating at a high speed due to the combined effect of the opening of the breaker and the action of the compressed spring. This form of contact is generally applied to super-tension breakers having a considerable length of break, and it is essential to avoid corners or edges on the contacts to eliminate brush discharges. Generally all contacts are enclosed in electrostatic shields having rounded contours.

At high current ratings, where it is difficult to accelerate the heavy moving parts, a separate spring-operated snap breaker is frequently used for final

rupture of the current and is connected in parallel with the main breaker. The snap breaker is timed to close before, and open after, the main contacts.

OPERATING MECHANISM.

It is essential that the operating mechanism should be robust, especially on heavy-duty breakers, in order

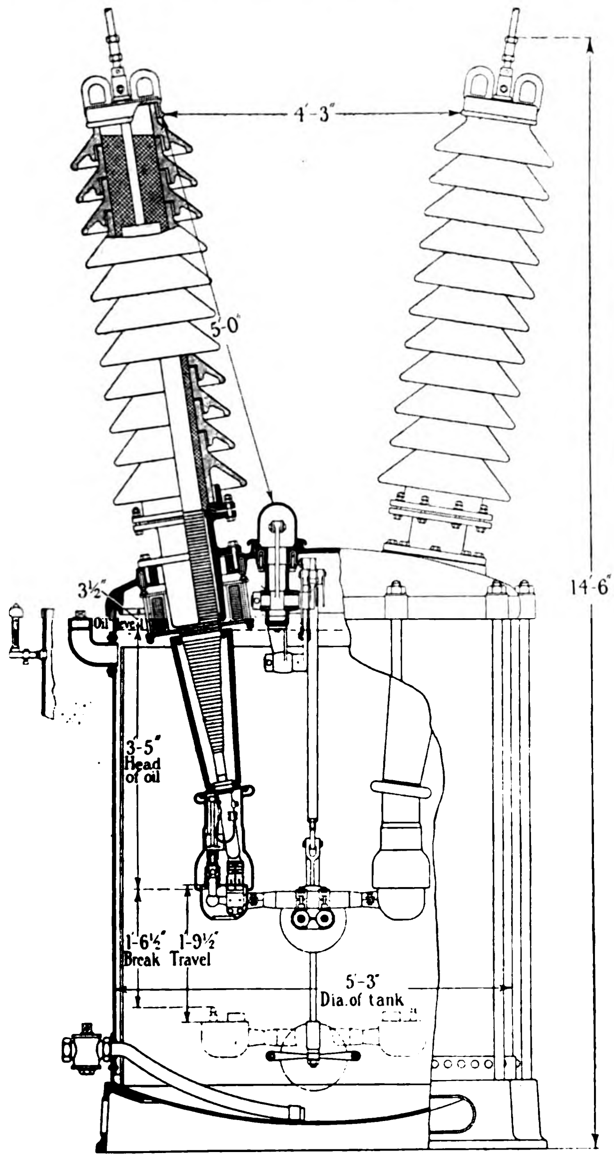

FIG. 44.—135-kV outdoor oil circuit breaker.

to resist the instantaneous short-circuit stresses and the repeated shocks of normal operation. An internal mechanism is preferable because it eliminates the reclosing tendency due to internal pressures which are developed on short-circuit. Furthermore, there is no earthed metal between the terminals and no chance of gases leaking through the top plate, except along the legitimate path offered by the vent pipes.

It should be possible for a breaker to trip free of the handle, under the action of the release coils at any stage of the closing movement. If the trip gear only functions when the breaker is fully home there is always the possibility of it being held in partial contact and thereby causing considerable damage. The operating and tripping mechanism should be preferably at the front of the breaker in an accessible position, as is the case with British and American designs.

BREAKER STRUCTURE.

The complete structure, consisting of top plate, oil tank, vents and fastenings, should be a good mechanical job. On heavy-duty breakers the structure is built on the lines of steam boiler practice, i.e. cylindrical boiler-plate tanks with belled ends, held to the top plate by means of a steel cradle and tie rods. Up to 88 kV, breakers are frame-mounted, allowing the internal portion to be inspected by lowering the tanks. On higher voltages, breakers are supported directly on the floor by means of the cradle. Access to the interior, after emptying the tank, is gained by means of a manhole.

Oil tanks should be fitted with an insulating lining capable of withstanding the full test voltage. In the ordinary breaker the arc is magnetically attracted to the side of the tank. The lining safeguards the breaker in this respect and allows smaller clearances to be used than would otherwise be the case. Most manufacturers leave a layer of oil between the lining and the tank side.

For outdoor service the breaker terminals are shrouded in porcelain petticoats, and the structure is made weatherproof. A typical 135-kV outdoor breaker is illustrated in Fig. 44.

RESISTANCE CIRCUIT BREAKERS.

On the Continent, resistances are commonly used in conjunction with oil breakers, either to minimize shocks to the system due to switching operations or to relieve the duty on the breaker. Resistances may be fitted for the following duties :—

(1) To limit the transient currents when switching-in transformers and high-tension motors.
(2) To limit the voltage surge when switching-out a transformer.
(3) To limit the voltage surge when switching long transmission lines.
(4) To limit the duty on oil breakers when opening short-circuits.

Breakers fitted with resistances open or close in two stages, and in the case of resistance breakers for transformers, motors, or transmission lines, a set of auxiliary contacts is provided so that the resistance is first inserted, thus reducing the current rush, and finally it is short-circuited when the main contacts are bridged. Very often the resistances are fitted either to the under side of the moving contact bar or at the bottom of the guide rods, this latter case necessitating a flexible connection. In cases where the resistance is external, a third terminal is required on the breaker. This is generally embodied in a split-conductor terminal, each of the two conductors being lightly insulated from each other. One stem carries the main contacts, whilst the

other is fitted with a leading contact, and the resistance is connected between the stems.

The principle of using a resistance for reduction of the duty imposed on a breaker is an excellent one. The resistance absorbs real energy but becomes heated in the case of delayed operation and may be destroyed. The necessary contacts and insulation for such a resistance and also the question of mechanical forces, form a serious problem, and it is doubtful whether the complications are warranted.

Explosion-Pot Circuit Breakers.

The construction of this type only differs from the plain breaker in that the arcing and main contacts are enclosed in strong steel explosion pots. The latter are of drawn steel and are capable of resisting the impulse pressures or any internal pressures developed due to ignition. Some forms of the explosion-pot breaker have the main contacts in air. Each of the two breaks per phase is effected by the withdrawal of a long plug from a socket in each pot. The two plugs are carried upright on the moving crossbar, which is operated by the breaker mechanism. The small space prevents free expansion of the gases, which are developed when the arc is drawn inside the explosion pot, consequently high internal pressures are obtained and, until the pressure is relieved through the throat of the explosion pot, the arc resistance has a high value. As soon as the plug has left the throat, the hot gases are projected downwards into cold oil and the arc is extinguished. The pressure of the gas generated automatically increases the opening speed as the amount of short-circuit energy increases. The most dangerous explosions are due to secondary gas explosions in the air cushion and not excessive arc energy, and it would be unwise to use a weak tank in conjunction with explosion pots on breakers operating at generating voltages. If the oil tank has sufficient strength to withstand the explosions, then it appears that explosion pots are unnecessary.

The author wishes to acknowledge the help rendered by his assistants, Mr. F. Clegg, Mr. V. A. Brown and Mr. B. Burt, in the preparation of this paper; and also his indebtedness to Messrs. Ferguson, Pailin, Ltd., for all the illustrations, except Figs. 7 and 26, the first of which is reproduced by kind permission of Messrs. British Thomson-Houston Co., Ltd., and the second by Messrs. A. Reyrolle and Co., Ltd.

WIRELESS SECTION: CHAIRMAN'S ADDRESS

By Major B. Binyon, O.B.E., M.A., Member.

(*Address delivered 4th November*, 1925.)

I should like to take this opportunity of expressing my thanks and appreciation for the honour you have done me in electing me Chairman of the Wireless Section.

Since the formation of the Section in 1920, the untiring efforts of your past Chairmen, Prof. Eccles, Prof. Howe and Mr. Shaughnessy, backed by strong and representative Committees, have maintained for the Wireless Section a high standard, and I am duly sensible of the responsibility that now falls upon me at a time which I think is somewhat critical in the further development of this important Section of the Institution.

Prof. Eccles, in his Inaugural Address * as Chairman in November 1920, made reference to a movement which had been started for the formation of a society of professional radio engineers analogous to the Institute of Radio Engineers of America, and many of you will have seen from recent correspondence in the technical Press that this subject has again come to the fore.

The intensive development of wireless during the war necessitated interchange of information and experience gained by radio engineers through the medium of an organized society, and the foresight of the late Mr. C. H. Wordingham, C.B.E., then President of the Institution, and Prof. Eccles, led to the formation of the Wireless Section.

With the advent of broadcasting, the field of radio engineering has again been widely extended and a large manufacturing business developed. With the popular interest which this subject has aroused it is not unnatural that the demand for an independent Institution of Radio Engineers should again arise. I wish to assure you that this matter is receiving the most earnest attention of your Committee, who are making a number of recommendations for submission to the Council of the Institution.

We recognize that the Wireless Section is primarily for professional men engaged in radio engineering—the amateur is already well catered for by other organizations—and it is not to our interests to seek any enlargement of membership at the expense of status. Moreover, it is our duty to uphold the status of the Institution, if only in recognition of the debt of gratitude we owe them for our formation. We must, however, not forget that a large number of new workers have been drafted into the radio field, and that some of the best wireless work has been contributed by physicists and other scientists whose training and vocation is not that of an electrical engineer.

Any narrowness in our outlook will invariably foster the formation of organizations to deal with specialized branches of radio work, and I must confess that I have noticed among the radio engineers of pre-broadcasting days a tendency to regard with some contempt those now engaged upon the design of broadcast receiving apparatus, and it is perhaps significant that with one or two exceptions this subject has hitherto been very largely ignored in papers read before this Section.

Anyone who made a careful survey of the recent wireless exhibitions cannot fail to have been impressed by two things: (1) The magnitude of the industry which the advent of broadcasting has created; (2) the great variety in design of the exhibits. Variety in design is inevitable, and perhaps desirable, in any new industry, and in many cases displays considerable ingenuity, ingenuity which I fear is sometimes directed to secure a sales point rather than a scientific advance, but I think we are now approaching a stage when really scientific methods involving accurate measurement and quantitative investigations will be applied to the design of broadcast receiving apparatus. For example, whilst the human ear may be the public's guide in the choice of a loud-speaker, it is far too unreliable a testing instrument for those engaged on loud-speaker investigations. It is to be hoped, therefore, that the older generation of radio engineers will recognize that this new and growing industry well merits their close attention.

I believe it has become a recognized custom for a Chairman in his Address to present a summary or digest of progress in a general manner rather than to deal with one specific technical aspect, but in reviewing the papers which have been read before the Section I find two phases of the wireless art which have been but scantily dealt with—the first I have already mentioned, namely, the design of broadcasting receiving apparatus, the second is the progress which has been made in marine wireless equipments, papers on which, with one exception, have confined themselves largely to direction-finding at sea.

Marine wireless has come to be regarded in the popular imagination as the most backward section of the art. To the broadcast listener it is often a source of interference and annoyance, and he fails to understand how, in these days of progress, a spark system can be permitted to exist. Whilst it is perhaps true that progress in marine wireless has been slow by comparison with other fields, it must be remembered that the capital invested in marine installations throughout the world is very large and, in the present depressed state of shipping, the wholesale scrapping of obsolescent plant is impracticable. Furthermore, there has been no new international legislation since the Radiotelegraphic Convention of 1912, and although the principal powers have introduced national rules to meet new technical

* *Journal I.E.E.*, 1921, vol. 59, p. 77.

conditions, there is urgent need for the co-ordination of such regulations by international agreement.

If the need for new legislation is long overdue, we have at least had the advantage of being able to gain experience in applying new technical developments to marine conditions, and in consequence it would now seem possible to legislate in a thoroughly practical manner and so ensure consistent progress at the minimum of capital loss. In this connection I should like to pay a tribute to the work of the Departments of State, in particular the General Post Office, the Board of Trade and the Services, who, through Committees on which the wireless companies are represented, are revising and redrafting our national wireless regulations.

I must ask for your indulgence if, in defiance of precedent, I now refer to some aspects of marine wireless which are of general interest. I propose to deal only with some of the more recent developments, touching on those features of design where experience gained in maintenance has shown that special precautions are necessary. I also hope to be able to show you some laboratory experiments indicating the lines on which I think future developments may take place.

Spark Sets.

Ships' spark sets are usually made in three standard sizes, $1\frac{1}{2}$, $\frac{1}{2}$ and $\frac{1}{4}$ kW, the rating being defined as the power supplied from the motor-alternator to the primary of the high-tension transformer.

In the earlier types of sets it was the usual practice to supply all the components separately and to erect the apparatus in the wireless cabin in the most convenient position, the motor-alternator and spark-gap being placed in a specially built silence cabinet.

Modern practice is to supply the transmitter components completely assembled, usually in an iron structure of the switchboard type. The advantages of this construction are :—

(1) Compactness;
(2) Less time taken to install in a ship which in some cases may be in port for only a few hours;
(3) Standardization of circuit arrangements in all ships;
(4) Ability to run full-load duration tests on each complete transmitter in addition to tests on separate component parts. This ensures that no small change in the design of a component can have an adverse effect on the working of the whole transmitter without attention being called to the fact.

From the lantern slides shown it will be seen that expanded-metal gates are employed to enclose the components. These gates are generally fitted with protective switches, the opening of a gate breaking the alternator excitation and thus avoiding risk of accidental shock when making adjustments.

The use of expanded mild steel is quite satisfactory in most cases, but care in design is necessary in regard to the distribution of the magnetic field from the high-frequency inductances, otherwise appreciable losses can be set up. In the case of the $\frac{1}{2}$kW set the losses were as much as from 30 to 50 watts; this loss was, however, reduced to a negligible quantity by using a gate of identical dimensions and mesh, but constructed in brass in lieu of mild steel. Serious losses may also occur due to the iron structure itself forming a closed loop in the vicinity of a high-frequency coil, and this must be carefully avoided in any compact design. When making tuning adjustments on any transmitter fitted with steel gates, readings on the aerial ammeter or wave-meter should always be taken with the gates closed.

Spark-Gaps and Systems of Transmission.

The principal types of spark-gap in use to-day are the synchronous gap and the quenched gap. Mr. Lea, in a paper* read before the Wireless Section in June 1922, dealt with the merits of the synchronous gap and showed that as a high-frequency generator it had an efficiency of the order of 70 per cent. He pointed out, however, that the only criterion which is of importance is the ratio of the power used to the signal strength received. In order to make a comparison on this basis some tests have recently been carried out by my company to compare the two types of spark transmission and at the same time to ascertain their merits compared with those of what is commonly called I.C.W. (interrupted continuous waves). The use of I.C.W. in the Mercantile Marine is a matter of importance, for it is the only reasonable method by which a gradual transition from the spark system to C.W. (continuous waves) can be effected without undue capital loss. In the tests referred to, transmission was carried out at Barnes on 700 m, reception being at Slough and Brentford (Middlesex). Measurements of field strength and audibility were made at the receiving stations.

Measurements of field strengths.—Dashes of 15 secs. duration were transmitted on quenched gap, synchronous gap and I.C.W. At the receiving stations the readings were recorded on a Moullin voltmeter placed across the tuned circuit of an aerial, having only a loading inductance and parallel tuning condenser. Owing to the small readings obtained on the Moullin voltmeter at Slough, due to weak field strength, it was thought that the results were not sufficiently reliable and the whole of the tests were repeated with reception at Brentford.

A type "A" Moullin voltmeter was used and, since the maximum readings did not exceed 1·5 volts, the damping due to the voltmeter may be considered to be negligible in comparison with the aerial resistance and radiation resistance. The decrement of the receiver was not accurately measured, but was observed by means of the resonance curve to be of the order 0·1.

Audibility measurements.—Morse transmission was employed and audibility measured by the simple shunted-telephone method as being the most likely to give practical comparative results. The same simple tuned circuit was employed with a crystal detector of the zincite-tellurium type, and the telephone shunt was adjusted to a point at which signals were just sufficiently audible to give accuracy of reading.

To enable a real comparison to be obtained, all

* *Journal I.E.E.*, 1922, vol. 60, p. 942.

conditions were maintained as constant as possible. Transmissions were conducted on the same day, quickly following one another. For example, quenched gap was operated for 5 minutes, immediately followed by 5 minutes of synchronous gap and 5 minutes of I.C.W.

The same motor-alternator was employed for all tests, and by careful adjustment to give good speed regulation over variations of load the note was maintained constant to within a few cycles throughout the tests.

I.C.W. was produced by means of double-wave rectification with a small feed condenser so as to give sensibly 100 per cent modulation.

TABLE 1.

Equal Power Inputs.

Type	Input power	Aerial current	Audibility factor	Field strength
	kW	amps.		volts
Quenched gap ..	1·0	4·4	1·0	0·68
Synchronous gap ..	1·0	3·4	2·3	0·39
I.C.W.	1·0	5·6	3·0	1·23

TABLE 2.

Equal Aerial Powers.

Type	Input power	Aerial current	Audibility factor	Field strength
	kW	amps.		volt
Quenched gap ..	0·83	4·0	1·0	0·57
Synchronous gap ..	1·4	4·0	3·0	0·45
I.C.W.	0·51	4·0	2·3	0·88

TABLE 3.

Equal Audibility Factors.

Type	Input power	Aerial current	Audibility factor	Field strength
	kW	amps.		volts
Quenched gap ..	7·5	12·0	1	1·7
Synchronous gap	1·4	4·0	1	0·45
I.C.W.	0·86	5·2	1	1·16

The same transmitting aerial and receiving aerial were employed in all cases.

Results.—The results are given in three tables showing comparisons of the systems with equal power imputs (Table 1), equal aerial powers (Table 2), and equal audibility factors (Table 3).

The results show the efficiency of I.C.W. over the spark systems, both for field strength and audibility (Table 1).

The audibility of quenched gap is singularly poor for the field strength (Table 2).

Table 2 shows that the synchronous gap gives good audibility with a weaker field strength than either quenched gap or I.C.W.

I.C.W. gives good field strength, good audibility and good tuning, and the same audibility (on crystal) may be obtained in comparison with synchronous spark with much less power (Table 3). If lower receiver decrements were employed, I.C.W. should give even better results on account of its sharper resonance curve.

From Table 1 it will be seen that, power for power, a larger aerial current is obtained with quenched gap than with synchronous gap. This is of especial interest in view of a regulation recently introduced by the Post Office basing the range of ships' stations upon the metre-ampere standard. This regulation is very convenient for ship-inspection purposes, but, by ignoring the factors of audibility and tuning, it definitely favours the adoption of quenched gap, particularly on the smaller class of ship having low masts and low-power sets.

I am fully aware that some of these results are directly contrary to the generally accepted view that I.C.W. gives poor audibility with crystal reception, but with the exception of some data given by Mr. Shaughnessy in his Chairman's Address * to this Section in 1923 very few actual results seem to have been published.

Whilst the greatest care was taken over the tests, they may be a little unfair to the quenched-gap system, as it is probable that this type of transmitter was not working quite up to its maximum efficiency, and although the figures may be relied upon to within 10 per cent the tests have not been repeated as frequently as in my opinion is generally desirable. The matter is of great importance, not only from the point of view of marine communications, but also for reasons of safety of life at sea.

All ships now fitted with C.W. installations also carry spark sets, and more information is urgently needed as to whether I.C.W. can be relied upon to carry out all the functions of a spark transmitter, bearing in mind the receiving conditions aboard other ships. If the results given do nothing more than cause others to investigate this matter more closely, they will have proved of some value.

EMERGENCY SETS.

Regulations require that an independent source of power be supplied for operation of the wireless set in the event of the failure of the ship's main electric supply in times of emergency. It is still almost universal practice to supply a battery for this purpose, owing to the difficulty of producing a prime mover of the internal-combustion type which can be guaranteed to start quickly under all conditions met with at sea. The accumulator battery, however, is expensive to install and maintain and, due to the irregular manner in which it is used, often standing idle for long periods, deterioration is fairly rapid. With the lead–acid type an average life of about three years is all that can be expected. Nickel–iron batteries are now being tried in lieu of the lead type, and it is hoped that they will stand up better to sea conditions.

* *Journal I.E.E.*, 1924, vol. 62, p. 51.

It is possible that in the future a satisfactory type of internal-combustion engine will be developed for this purpose, though at the present time insurance companies and shipowners object to the use of petrol aboard ships, and this increases the difficulties of producing an engine which can be relied upon to start quickly. Electric starting would again introduce the objectionable features of the battery, although this could be of a smaller capacity than the usual emergency batteries now supplied. As the engine employed need not exceed 2 h.p., there would seem to be possibilities in the development of a reliable mechanical starter of either the spring or foot-pedal type; preferably the design should be such that the engine could be started without the operator leaving his seat.

It is usual to employ the same high-frequency circuits for both power and emergency purposes, though with synchronous spark sets an emergency fixed spark-gap is usually employed. In very large liners having high masts and a long aerial span there is greater risk of the aerial being carried away in a storm, and it is customary to provide an emergency aerial fixed on outriggers to the funnels.

For a number of years the radio-frequency circuits were excited by means of a spark coil driven from the battery. Such an arrangement is, however, not efficient, and the signal note produced is of such low frequency that reception is difficult under conditions of interference. This matter is of considerable importance in connection with the operation of automatic watch-keeping devices, which, experience has shown, cannot be depended upon when a low spark frequency is employed. It is probable that future legislation will fix a minimum note frequency for emergency installations.

Higher spark frequencies of, say, 850 per sec. may be obtained with a rotary interrupter, transformer and tuned musical circuit. A rotary interrupter, however, is somewhat troublesome to maintain in good order, even when the musical circuit is carefully designed to reduce sparking to a minimum; the most modern practice is to employ a 500-cycle motor-alternator driven from the battery. This arrangement, although more expensive, is certainly to-day the most satisfactory form of emergency equipment.

Lifeboat Installations.

Legislation has recently been introduced for the compulsory fitting of wireless sets of the spark type to ships' lifeboats. The more important considerations in the design of such apparatus are:—

(1) Weatherproofness;
(2) Simplicity and ease of manipulation;
(3) Light weight and small dimensions;
(4) Technical considerations such as endurance, prime mover, insulation, etc.

(1) *Weatherproofness.*—This may be secured by installing all the component parts in a small cabin which, to be effective, should be of sufficient size to accommodate the operator. It is, however, obviously difficult to fit a cabin of this nature in an open boat without seriously encroaching on passenger space. The alternative method is to encase the entire transmitter and receiver with all controls and switchgear in a watertight case of small dimensions, operation being effected through a small hole which may be fitted with a watertight sleeve.

(2) *Simplicity and ease of manipulation.*—In an emergency it is not possible to ensure that a qualified wireless operator will be available in the lifeboat. The set must therefore be so designed that it can be operated by any seaman or ship's officer having only a knowledge of the Morse Code.

(3) *Weight and dimensions.*—In the set illustrated in the lantern slides the dimensions of the watertight case containing all the wireless apparatus are 25 in. × 12 in. × 17½ in., and the weight is 65 lb. The total weight with nickel–iron battery and motor-alternator is 370 lb. If a lead battery of equivalent capacity is used, the weight of the battery only is 400 lb.

(4) *Technical considerations.*

Prime mover.—There is still a wide difference of opinion as to whether the petrol engine or the storage battery is the more suitable for the power supply of lifeboat sets, and the point is not likely to be settled until some experience is gained of the behaviour of lifeboat sets under actual emergency conditions.

Weight for weight, more power can be stored in the form of petrol than as electrical energy in a battery, but against the petrol engine is the probable difficulty of starting up in cold weather and under shipwreck conditions, and also the necessity for stopping the engine during the periods of reception. In any case, some batteries must be supplied for operating the filaments and high-tension supply of the valve receiver.

Driving the motor-alternator from a battery of the nickel–iron type is probably the simplest proposition. The battery can be more easily protected from spray and may be stowed under the thwarts out of the way of passengers.

Arrangements must be made for charging the battery in situ from the ship's mains by means of a flexible lead to a plug socket near the lifeboat davits.

The Board of Trade regulations specify that the battery shall be of sufficient capacity to provide for transmission of morse signals for 6 hours continuously with a power of 15 metre-amperes in the aerial. The accepted definition of "morse" load is 60 per cent of the increase in load produced when the key is pressed.

In the set illustrated in the lantern slides the average current at 18 volts taken by the motor running light is 11 amperes and the "key down" full-load current 22 amperes. The required battery capacity for 6 hours' morse transmission is therefore $\{11 + 0 \cdot 6\,(22 - 11)\} \times 6 = 105 \cdot 6$ ampere-hours. The battery supplied is 18 volts, 120 ampere-hours, at the 6-hour rate. If a searchlight is also fitted, the capacity must be increased to 140 ampere-hours.

The main battery is also used for supplying filament and high-tension current for the valve receiver.

Transmitter circuits.—The quenched-gap system is unquestionably the most suitable for lifeboat sets. The circuits can be simple and auto-coupled, and the

gap needs no adjustment and is unaffected by moderate variations in alternator speed.

The Board of Trade regulations require only one wave, viz. 600 m, with 15 metre-amperes in the aerial. The primary circuit can therefore be permanently tuned to the wave, and the aerial is most conveniently tuned in by means of a variometer, an aerial ammeter being employed to indicate the correct tune.

The height of a lifeboat aerial averages 6 to 7 metres; hence to obtain 15 metre-amperes an aerial current of not less than 2·5 amperes is required. To attain this current in a very small aerial (the average capacity is 0·00019 μF) very high potentials are necessary, and these considerably increase the insulation difficulties under wet conditions. The aerial potentials (crest value) measured under working conditions are of the order of 40 000 volts.

To test the efficiency of the lead-in insulator, salt water was poured over the set while in operation; the aerial current soon fell from 3 to 2 amperes and steam began to rise from the canvas-covered wood immediately surrounding the lead-in insulator. Ultimately the wood dried and charred. These difficulties were overcome by fitting a large metal cowl over the insulator and a flat earthed plate of similar diameter over the woodwork surrounding the insulator. The guard-ring effect of this arrangement reduces the electrical stress, and the set proved quite satisfactory in operation when drenched with sea water.

Receiver circuits.—Reception conditions in an open boat in stormy weather and with a poor aerial are likely to be very difficult, consequently valve amplification is essential.

A detector valve followed by two stages of low-frequency amplification gives a simple arrangement entailing no filament rheostats or other adjustments.

If dull-emitter valves of the peanut type are employed, the filament current can be supplied from a single cell of the main nickel-iron battery (1·2 volts), the entire battery of 18 volts being used for the high-tension supply. High-tension batteries of the dry-cell type deteriorate too rapidly, when not in use, to be depended upon.

Since under "S.O.S." conditions extreme selectivity is of no importance, the detector may be connected directly across the transmitting variometer. A single adjustment then provides for the tuning of both transmitter and receiver. The closely coupled transmitter primary circuit does not damp the aerial circuit when receiving, as it is interrupted by the spark-gap. With the correct design of variometer the receiver can be tuned from 550 to 650 m on all aerials whose capacities lie between 0·000125 μF and 0·000250 μF.

General Characteristics of Ships' Aerials.

On account of the varying types of aerials fitted to ships, the disturbing effects produced by the ship's rigging, and the uncertain character of the path to earth from the wireless cabin, this subject can only be treated in a general manner based on data obtained from the tuning curves of several hundred ships.

The T aerial is most generally employed and is usually convenient as regards the disposition of the down-lead clear of other rigging. This form of aerial also enables a lower natural wave-length to be obtained without appreciably reducing the wave-length obtainable when the maximum loading inductance is of the order 300 μH.

Except in special cases, multi-wire aerials are undesirable, the latter being subject to the following disadvantages:—

(1) More complicated to rig and keep in order.
(2) The reduction in conductor losses is usually so small as to be unimportant in relation to other losses.
(3) The insulation losses are usually greater, due to a number of insulators being placed in parallel, since it is undesirable to employ insulators for holding up the spreaders.

Most ships' aerials in use to-day are of either the twin or single-wire type. The latter is coming largely into favour for the reason that, having no heavy spreaders, the inertia and wind forces are less. For single-wire aerials it is usual to employ a special type of heavily galvanized steel wire with a hemp core. A large number of tests at sea have been carried out to obtain a comparison between the twin copper-wire aerial and the single steel wire, and although with the latter the aerial current obtained is less, there seems to be no drop in signal range.

Regulations still provide that all ships shall be capable of transmitting on 300 m; the natural wave-length of aerials in large ships often exceeds this figure, consequently it is necessary either to provide a series condenser or to split the aerial and lead in the two down-leads separately. This latter method involves the use of an additional lead-in insulator, the cost of which is approximately the same as that of a series condenser. The expenditure in either case is wasteful, since the efficiency of such arrangements is poor, and in practice 300 m is rarely, if ever, used by large and medium-sized vessels. The continuance of this regulation is therefore very undesirable.

The application of the rough formula for the calculation of the natural wave-length of a T aerial, viz.

$$\lambda_0 = 4(H + \tfrac{1}{2}l) \text{ metres}$$

is by no means accurate for ships, owing to the disturbing effects of the rigging.

Tuning data obtained from a large number of ships all having a uniform type of aerial-tuning inductance indicates that the following approximate constants in the formula are more nearly correct:—

Twin T aerials $\lambda_0 = 5\cdot 2(H + \tfrac{1}{2}l)$ metres
Single T aerials $\lambda_0 = 4\cdot 6(H + \tfrac{1}{2}l)$ metres

where H is the height from the water line and l the aerial span.

It is impossible to estimate accurately the capacity of ships' aerials even by the aid of an empirical formula, owing to the many disturbing factors, but it is found in practice that the long-wave (static) capacities of T aerials in merchant ships vary from 600 to 1 300 cm

in the case of twin wires and 500 to 650 cm in the case of a single wire.

In most cases the effective capacity at the natural wave-length is about half the long-wave capacity.

Aerial insulators.—Three types are in general use:

(*a*) Rubber strop;
(*b*) Porcelain rod;
(*c*) Porcelain chain (various forms).

The rubber strop has far too great a dielectric loss to be used on ships fitted with C.W. It deteriorates rather rapidly in the tropics, or if in the vicinity of hot gases from the funnels, but being flexible it is not easily broken and is very convenient for use on those cargo ships where the aerial must be lowered to work the derricks. Strop insulators have been known to fail under torsion, due to the pull on a twisted aerial wire or halyard.

Straight porcelain rods are less expensive, but are only satisfactory for C.W. work if fitted with drip-rings. In the event of fracture due to overload in heavy weather the falling porcelain is a real source of danger, and although in practice no actual injury to passengers or crew has occurred, some narrow escapes have caused my company to abandon the use of this type of insulator.

The porcelain-chain type of insulator, if carefully designed, is probably the most satisfactory for marine purposes, though it is heavier and more expensive than either the porcelain rod or strop. It is mechanically very strong and safe in use, and with a properly designed chain the losses when employing a 1½-kW C.W. set should not exceed 15 watts on the most difficult wave-length and with the insulator sprayed with water, making the equivalent of a heavy tropical rain.

Automatic Call Devices.

The maintenance of a continuous watch aboard ship is important from the point of view of safety of life at sea. Since, however, a continuous watch necessitates the employment of three operators, the expense is prohibitive on the smaller class of vessel conducting only a very limited amount of wireless telegraph traffic.

The regulations under the Merchant Shipping (Wireless Telegraph) Act, 1919, made provision for the possibility of the development of a reliable automatic watch-keeping device capable of ringing an alarm bell on the receipt of a distress signal.

The introduction of a call device would effect a considerable economy to the shipowner, and apparatus of this character has been under almost continuous development since 1920.

Attempts were made to construct apparatus capable of responding to the distress signal (S.O.S.) and the ship's own call sign, but after a number of tests at sea and ashore it soon became apparent that any apparatus operating on the Morse Code was too susceptible to interference to be approved as reliable from the point of view of safety of life at sea.

During 1923 and 1924 the Admiralty, at the request of the Board of Trade, conducted a series of tests with calling appliances submitted by the Post Office, the Marconi Company and the Radio Communication Company, with a view to ascertaining what, in principle, is the most satisfactory form of signal and apparatus.

Full details of these trials were recently published in a White Paper entitled "Report by the Admiralty on Tests of Automatic Wireless Calling Devices." Generally, the results of these trials demonstrated that the long-dash call gave too many false calls and that the most suitable form of signal consisted of a series of dashes of 4 seconds each, separated by an interval of 1 second, and that it should be possible to develop apparatus to register 90 per cent effective calls.

A description of one of the appliances used in these tests, and subsequent improvements thereon, may be of general interest. The telephone terminals of the receiver are connected to a note amplifier, and the amplified current is then rectified a second time and passed to a sensitive relay of the moving-coil type. The tongue of this relay therefore follows all incoming signals, whether morse or the special signal it is desired to receive and select.

The timing element of the selector consists of a very simple form of electric motor, the armature comprising a simple iron bar without any windings. The speed is controlled by a governor of the gramophone type. The motor drives a magnetic clutch through a reduction gearing, the speed of the clutch shaft being 2 revs. per min. When the magnetic clutch closes, it drives an extension shaft on which the selecting cam mechanism is mounted, and if the signal be of the correct type the clutch is held closed until a final cam operates a contact which rings the alarm bell. If, however, the signal is incorrectly timed, the selector mechanism breaks the clutch circuit and the cam is instantly reset to the zero position by means of a spring.

The selector mechanism is necessarily of a somewhat complex nature and is shown diagrammatically in Fig. 1. All the selector cam contacts are cut on a single circular disc, but for purposes of clarity they have been shown as straight strips which, on the commencement of operations, we must imagine all advance upwards and together, and open or close contact with the contact points E, F, G, M and J. It will be seen that the alarm-bell contact is the last of the series and can only operate if the entire cam mechanism advances to the end of the series of operations, i.e. the bell only rings if the signal conforms to the correct timing as shown on the time scale. This is accomplished in the following manner: On the commencement of the first dash the tongue of the sensitive relay moves over to "mark" (contact M), and current from the battery excites the clutch relay coil CR through the contacts G and F, whose functions will be explained later. The relay CR then closes contacts A and B, the latter completing the magnetic clutch circuit, and all the cams commence to advance (upwards in the figure). Now, after 3 seconds, contact E closes; this is in parallel with the "mark" contact of the sensitive relay, so that if during the period E is closed, a space in the signal occurs, as it should do, between the fourth and fifth seconds, the relay CR will not be opened, and contacts A and B remain closed, the latter exciting the clutch, and the cams continue to advance.

But how are we to know that a space has occurred during the period when contact E is closed, for the apparatus must not be capable of responding to a continuous dash? This is accomplished by means of the space test cam, the contact G and the space relay SR. If the "tongue" of the sensitive relay has touched the space contact S, even only momentarily, in the period 3–6 seconds during which time contact E is closed (as it should do with the correct signal), then the space relay SR closes contacts C and D. Now contact C is in parallel with the "space" contact on the sensitive relay, consequently a momentary closing of the former causes the space relay SR to

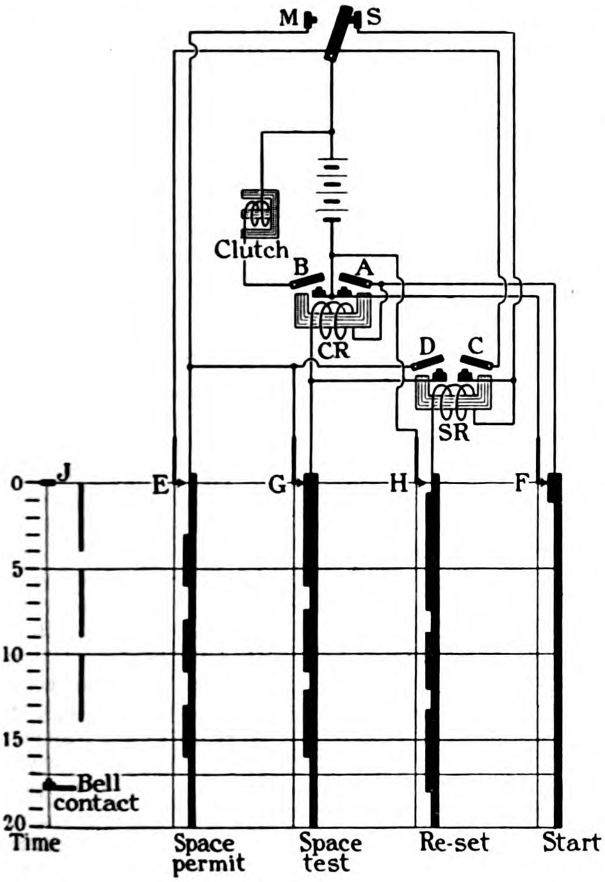

FIG. 1.

remain closed. Before the end of the 6th second, therefore, the space relay should have become "set" closed if a space has occurred, and this must now be checked. This is done by the space test cam which, after the sixth second, opens the contact G. This contact G is in parallel with the contact D of the space relay; if D is closed, as it should be, then the opening of G makes no difference, but if D is not closed, i.e. if a space has not occurred in the signal, then the opening of contact G breaks the excitation of the relay CR. A and B open, the clutch is demagnetized and all cams reset to zero position by the action of a spring.

After testing, if a space has occurred in the manner described, it is necessary to reset the space relay SR so as to be ready to carry out its space-testing functions during the 8th to 11th seconds, and this is accomplished by means of the re-set cam which opens the contact H, so de-exciting the relay SR, contacts C and D then opening to normal position. This cycle of operations is then repeated for the second and third dashes until the alarm-bell contact is ultimately closed.

Now it is important that if an incorrect or badly timed signal is received the whole mechanism should re-set instantly to zero, and it must not be capable of being restarted at an intermediate position, as might occur if the "mark" contact of the sensitive relay were closed while the apparatus was resetting to zero. This is prevented by means of the start cam which opens the contact F as soon as the cams have started to advance. Contact F is in parallel with the sustaining contact A, which, as we have seen, opens if there is anything wrong with the signal. The relay CR can only be re-excited for the purposes of restarting operations if the contact F is closed, and this cannot occur until the entire cam mechanism has returned to zero.

It will be noted that in the cutting of the cams there is a certain amount of latitude to allow for slight inaccuracies in sending. For example, the dashes may be clipped by a second at either end and a space may occur anywhere between the 3rd and 6th, the 8th and 11th, and the 13th and 16th seconds. Latitude of this character tends to increase the chances of false calls, though, with the degree of latitude shown, an average of only 1 false call in 500 was registered in the Admiralty trials, and this may be considered quite satisfactory.

The fact that the shortest space suffices and that spaces up to 3 seconds may be made, tends to minimize the liability of failure from interference by jamming signals and atmospherics.

Direction-Finding.

The modern tendency in the Mercantile Marine is to adopt small multi-turn loops, either fixed or revolving, in place of the larger single-wire triangular loops formerly employed. It is obviously possible to secure small loops in a more rigid manner, and, as they need not be disturbed when handling cargo, errors due to any deformation of the aerial system are avoided.

Direction-finding as applied to the Mercantile Marine has already been very well dealt with in papers read before this Section, and I propose only to describe some improvements which have recently been made to the Robinson system. In this system two coils are fixed rigidly at right angles to one another and revolve about a vertical axis. One coil called the "main coil" has a smaller number of area turns than the second coil, usually called the "auxiliary coil." The coils are connected in series, and by means of a switch the sense of the auxiliary coil in relation to the main coil can be reversed. By revolving the whole system, points may be obtained where, on operating the reversing switch, signals are found to be of equal strength in either position of the switch. Two such points 180° apart are sharp and well-defined and indicate the correct bearing, but there are also two points 90° to the correct bearing where a balance can

be obtained, though less well-defined. In unskilled hands, therefore, this 90° ambiguity may be a source of danger unless a preliminary observation be made on the main coil only, and a special switch is usually provided to cut out the auxiliary coil for this purpose. The reason for this 90° ambiguity will be seen by studying the E.M.F.'s induced in the coils by the incoming signal and the angle between the plane of of the main coil and the direction of the signal. This is shown in Fig. 2 for the main coil and in Fig 3 for the auxiliary coil. The scale of E.M.F.'s is purely arbitrary,

the signals are loudest. The auxiliary coil is then brought into use and the accurate balance obtained.

I now propose to describe a new device designed to obviate the necessity for any preliminary observation. In this arrangement the reversing switch and operating handwheel are mechanically interconnected. The handwheel is no longer rigidly connected to the spindle carrying the coils, but drives the coils through a coupling permitting a certain amount of backlash * (say 1° of arc).

The relative motion of the handwheel and shaft

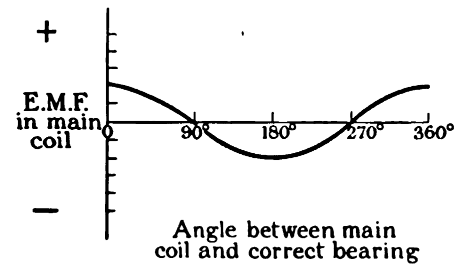

Fig. 2.

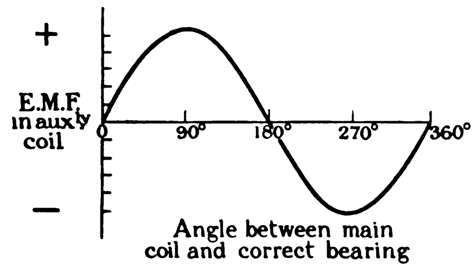

Fig. 3.

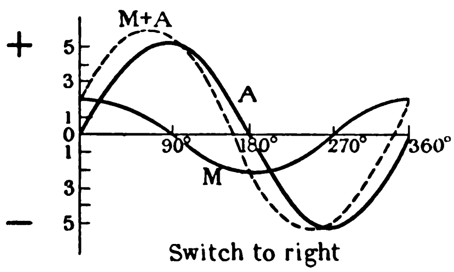

Fig. 4.

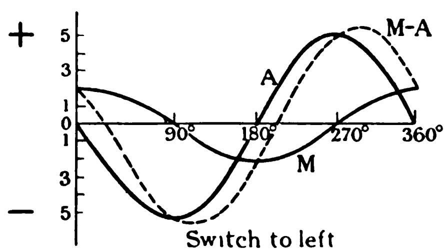

Fig. 5.

but as the auxiliary coil has a greater number of area turns the E.M.F. amplitude has been shown greater. The two coils are connected in series through a reversing switch, and if we suppose that in the right-hand position of the switch the E.M.F. in the auxiliary coil assists those in the main coil, we shall obtain the dotted curve ($M + A$) in Fig. 4, which represents the resultant E.M.F. from the algebraic sum of the E.M.F.'s of the two coils.

Now if the switch is moved to the left the auxiliary coil will now oppose the main coil, and we can represent the resultant E.M.F. by turning the curve for the auxiliary coil upside down (Fig. 5).

Now if we assume that the strength of signal is roughly proportional to the numerical value of the E.M.F., we can draw two new curves (Fig. 6) showing the strength of signal with the reserving switch to left or right. The points of balance are where the curves intersect (Fig. 6) at 0°, 90°, 180° and 270°. The correct balance, i.e. that obtained when the plane of the main coil is in the direction of the distant station, is at 0° or 180°, the incorrect balance (90° out) being at 90° and 270°. It can be seen from the slope of the curves that a sharp balance will be obtained at 0° and 180°, and an ill-defined balance when 90° out. To obviate this ambiguity a preliminary observation is usually made on the main coil only, the system being rotated until

is utilized to operate the reversing switch. If the leads to the switch are connected in the correct sense the device will operate in the following way: The signal from the distant station is heard on the telephones, and the handwheel moved to and fro to the extent of the backlash. This operates the reversing switch. Generally, the two positions give unequal signals.

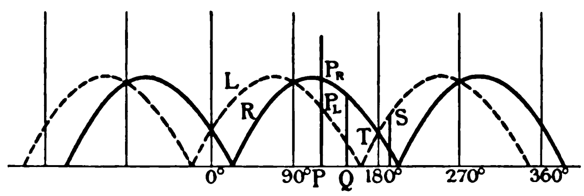

Fig. 6.

The operator is told to turn the handwheel in the direction giving the weaker signal, and to continue turning it in that direction, thus turning the whole system. We see that he then is driven away from the "90° out" bearing towards the "correct" bearing. After he has turned a few degrees he again moves the handwheel to and fro and judges the relative signal

* This backlash in no way affects the accuracy of bearings, since the indicator dial and coils are rigidly fixed on the same shaft.

strength. He again rotates the system in the direction corresponding to the weaker signal, and after a few attempts gets a balance. The "correct" bearing is now indicated by the pointer on the dial.

The reason for this is as follows: Referring again to Fig. 6, suppose that at the beginning of the operation the angle between the coils and the transmitter is given by the point P. The ordinate at P cuts the curves L and R at P_L and P_R, and P_RP is greater than P_LP, or, in other words, the signal is weaker with the wheel turned to the left. In accordance with the rule the system is turned more to the left, say to Q. The balance is tested again and the wheel is moved more to the left, say to S. Here S_L is greater than S_R. The signal is weaker with the wheel to the right. The system is turned to the right, and so on, until the correct balance is obtained at T.

It will be seen that each operation takes the system further away from the "90° out" position, and so completely eliminates the latter.

Visual indication.—Any aural system depends to some extent on the personal element, and in consequence varying results may be obtained. The system at present, only in experimental form, has been devised to give a direct *visual* indication of the balance. The method is based on the principle that when an alternating current with a small direct current superimposed on it is passed through a d.c. moving-coil galvanometer of sufficiently slow period, the galvanometer will show the value of the direct current and, more particularly, will show when it reaches a zero value.

The standard Robinson system is used, but the reversing switch is replaced by a special motor-driven commutator. This commutator has two functions: (1) To reverse the relative connections of the main and auxiliary coils; and (2) to reverse the rectified output from the amplifier to the galvanometer in synchronism with (1).

If we suppose first that the commutator is at rest and the coil system is in the position of balance, and that a signal is being received, the galvanometer will show a deflection of, say, 10° due to the rectified signal current from the amplifier. On turning the commutator through 180° the "Robinson" reversal is carried out, and the current through the galvanometer is also reversed. Since we supposed that the coil system was in the position of balance, the galvanometer will again read 10° in the opposite direction.

If the commutator is now run sufficiently fast, the galvanometer will not be able to follow the alternation of direction, and will stay at zero.

If we now suppose that the coil system is turned so that the balance is not obtained, the galvanometer will receive more current in one direction than the other, and will be deflected from zero. It will therefore be seen that if the coil system is rotated until the galvanometer pointer is at zero, the coil system is indicating either the correct or the "90° out" bearing.

How are we to eliminate the "90° out" bearing? This is done in a way similar in principle to the device just described, namely, by correlating the movement of the galvanometer pointer with the movement of the operating handwheel. The galvanometer is preferably placed so that its pointer when on zero lies on a line passing through the centre of the coil spindle and points outwards. If the galvanometer is connected up in the right sense the following rule will avoid the "90° out" bearing. Turn the handwheel in such a direction that if the galvanometer pointer were imagined as being connected mechanically to the direction-finding coils, this direction of rotation would bring the pointer towards zero, i.e. if the pointer is to the *left* of zero, turn the handwheel to the *right.*

The great advantage of the visual indicator method is the speed with which really accurate bearings may be taken, and that little or no previous practice is necessary. In the case of a man who has never worked a direction-finding set before, the galvanometer method will give an accuracy of $\pm \frac{1}{4}°$ compared with $\pm$ 2° or 3° by the aural method. This system therefore is well suited for installation on the bridge or in the chart room of a ship, where it may be operated by the navigating officer.

Automatic direction-finding.—By replacing the galvanometer by a sensitive relay of the moving-coil type a series of interesting developments are possible. The relay may be made to light one of two lamps, say, red or green, showing whether the coil system is to be turned to port or starboard. In aircraft employing fixed coils an indicator of this character should prove of value in enabling the pilot to "home" on a ground station by watching two lamps on his dashboard. If the relay is made to operate a reversible motor or a magnetic clutch mechanism with a reversing gear, the direction-finding coils can be made to turn automatically in the direction of the correct bearing and, assuming that the connections of the driving mechanism have been correctly arranged, the coils will always move automatically away from the "90° out" bearing. I hope to be able to demonstrate this now by experiment.

It may be argued that any system dependent on a visual indicator, whether operated by hand or automatically, can have little practical application, on account of the erroneous bearing which would result from interfering signals.

The accuracy of any direction-finding observations is affected by interference, but in the case of aural methods any interference is at once apparent to the operator.

In the case, therefore, of any visual indicator or automatic system, it would be necessary to provide also an aural indicator which, in the case of a ship's installation, might take the form of a loud-speaker, in order that the observer may know if any interference is present and also for the purpose of identifying the transmitting station whose bearing is being observed.

I believe, however, that when an efficient system of I.C.W. beacon stations is introduced, operating upon a wave-length of 1 000 m, troubles from interference will largely disappear, particularly as ranges in excess of 50 miles are not generally required.

I feel somewhat diffident in making any forecasts of developments of this character, but let us try to visualize the situation on the bridge of a ship navigating

near the coast in thick weather, and let us also imagine an automatic direction-finder installed with a loud-speaker indicating the periodic signals of a beacon station. Almost simultaneously with the call of the beacon the pointer on the direction-finder moves to the correct bearing and the commander may see at a glance how the bearing is altering as he proceeds on his course.

I should like, in conclusion, to express my indebtedness to Mr. Lea and Mr. Bainbridge-Bell for their assistance in connection with the experiments I have been able to show this evening.

INSTITUTION NOTES.

Honorary Member.

At the Ordinary Meeting held on the 5th November, 1925, the President announced that the Council had elected Dr. S. Z. de Ferranti an Honorary Member of the Institution.

List of Members.

Copies of the new List of Members (corrected to the 1st September, 1925) are now ready, and any member wishing to receive a copy should apply to the Secretary.

Associate Membership Examination Results: October, 1925.

Passed.

Bainbridge, S. R. (Sunderland).
Braendle, E. W. (London).
Cain, S. J. (Lutón).
Dennison, J. D. (Wotton-under-Edge).
Dick, R. (Penicuik).
Drummond, C. W. B. (Eastbourne).
Forster, W. J. (Stoke-on-(Trent).
Greenwood, E. R. (Douglas, I.O.M.).
Greenwood, H. J. (Manchester).
Hall, M. H. (Sheffield).
Hands, H. F. (Sutton Coldfield).
Harmer, L. B. (London).
Hodgson, C. H. (Crewe).
Hollin, A. S. (Bradford).
Hortop, C. L. (Southampton).
Ingamells, G. H.(Grimsby).
Jewell, E. H. T. (London).
Linsell, A. A. (Brentwood).
McMillan, D. (Newcastle-on-Tyne).
Orchard, F. C. (Birmingham).
Pank, J. C. (Norwich).
Phoenix, W. (Warrington).
Platt, E. (St. Helens).
Price, J. M. (Birmingham).
Rigg, R. (Glasgow).
Shepherd, J. H. (Manchester).
Stretton, L. W. (London).
Sykes, P. (Manchester).
Taylor, L. N. (Chislehurst).
Tumilty, H. G. (Dovercourt).
Waring, A. J. (Torquay).
Weller, B. F. (London).
Winwood, W. (Coalville).
Yorke, G. (London).

Passed Part I only.

Rogans, T. H. (Liverpool).
Stewart, C. E. (London).
Taylor, J. (Darwen).
Tyacke, N. A. (Chichester).

Passed Part II only.

Aust, J. H. (Stoke-on-Trent).
Grepe, F. Y. (London).
Hawkins. E. J. (Braintree).
McGrath, T. (London).
McNicholl, J. G. (Maghera, Co. Derry).

Further results relating to candidates who sat for the Examination abroad will be published later.

National Certificates and Diplomas in Electrical Engineering.

The following Institute and College have been approved under the scheme drawn up by the Board of Education and the Institution : —

Approved for Ordinary Grade Certificates (Senior Part-time Course).

Northampton Polytechnic Institute, Clerkenwell, E.C. 1.

Wednesbury, Staffs, County Technical College.

Approved for Higher Grade Certificates (Advanced Part-time Course).

Northampton Polytechnic Institute, Clerkenwell, E.C. 1.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 October–25 November, 1925 :—

	£	s.	d.
Anonymous		5	0
Blackiston, H. E. (London)		5	0
Evans, R. L. (Shanghai)		6	6
Farrer, M. (Twickenham)		5	0
Hills, R. (Cromford, Derbyshire)		10	0*
Lamb, H. C. (Manchester)	2	2	0
Line, W. J. (Birmingham)		5	0*
North-Midland Centre	8	2	6
Taylor, V. A. (Wolverhampton)		5	0*
The " 25 Club "	21	0	0
W. T. Henley's Telegraph Works, Ltd.	25	0	0

* Annual Subscriptions.

Committees 1925–26.

Among the Committees appointed by the Council for 1925–26 are the following :—

Informal Meetings Committee.

The President.

Mr. A. H. Allen.	Mr. A. G. Hilling.
Mr. J. W. Beauchamp.	Mr. C. L. Lipman.
Mr. J. Coxon.	Mr. W. Riggs.
Mr. P. Dunsheath, O.B.E., M.A., B.Sc.	Mr. M. Whitgift.
	Mr. H. T. Young.

Lt.-Col. K. Edgcumbe, R.E. (T.A.) (representing the General Purposes Committee).
The Chairman of the Papers Committee.
The Chairman of the London Students' Section.

Library and Museum Committee.

The President.

Col. R. E. Crompton, C.B.	Mr. S. W. Melsom.
Major E. O. Henrici, R.E. (Ret.).	Mr. W. M. Mordey.
	Mr. R. W. Paul.

Col. T. F. Purves, O.B.E.

Local Centres Committee.

The President.

Mr. B. A. M. Boyce.	Prof. Magnus Maclean, D.Sc., LL.D., F.R.S.
Mr. J. W. Burr.	Mr. A. E. Malpas, Wh.Sc.
Sir J. Devonshire, K.B.E.	Mr. F. J. Moffett, B.A.
Mr. E. Edwards.	Mr. W. F. Mylan.
Mr. A. G. Ellis.	Mr. A. Page.
Lt.-Col. K. Edgcumbe, R.E. (T.A.)	Col. T. F. Purves, O.B.E.
Mr. R. W. Gregory.	Mr. J. H. Shaw.
Mr. J. S. Highfield.	Mr. J. S. Thomson.
Mr. S. D. Jones.	Mr. S. J. Watson.

Mr. W. B. Woodhouse.

"Science Abstracts" Committee.

The President.

Mr. Ll. B. Atkinson.	Mr. W. M. Mordey.
Mr. F. Gill, O.B.E.	Mr. C. C. Paterson, O.B.E.

Dr. D. Owen .. Mr. T. Smith ..	Representing the Physical Society of London.

Ship Electrical Equipment Committee.

The President.

Mr. A. G. S. Barnard.	Mr. N. W. Prangnell.
Mr. J. H. Collie.	Lt.-Col. A. P. Pyne.
Mr. B. M. Drake.	Mr. P. Rosling.
Mr. A. Henderson.	Mr. S. G. C. Russell.
Mr. J. W. Kempster.	Mr. T. A. Sedgwick.
Mr. J. F. Nielson.	Mr. H. D. Wight.

And	*Representing*
Sir W. S. Abell, K.B.E. .. .. Mr. H. Ruck Keene	Lloyd's Register of Shipping.
Mr. T. Carlton ..	Board of Trade.
Mr. W. Cross ..	Electrical Contractors' Association.
Mr. J. Foster King	British Corporation for the Survey and Registry of Shipping.
Mr. J. Lowson ..	Institution of Engineers and Shipbuilders in Scotland. Electrical Contractors' Association of Scotland.
Mr. A. W. Stewart	Institution of Naval Architects.
Mr. H. Walker, O.B.E.	N.E. Coast Institution of Engineers and Shipbuilders.

Wiring Rules Committee.

The President.

Mr. Ll. B. Atkinson.	Mr. P. V. Hunter, C.B.E.
Mr. H. J. Cash.	Mr. S. W. Melsom.
Mr. A. C. Cockburn.	Mr. J. F. Nielson.
Mr. J. R. Cowie.	Lt.-Col. A. P. Pyne.
Mr. W. Cross.	Mr. E. Ridley.
Mr. J. Frith.	Mr. S. G. C. Russell.
Dr. C. C. Garrard.	Mr. C. P. Sparks, C.B.E.
Mr. R. Grierson.	Mr. A. L. Taylor.

And	*Representing*
Mr. B. M. Drake ..	Contractors (unofficially).
Sir T. O. Callender Mr. J. F. W. Hooper	Cable Makers (unofficially).
Mr. J. Howard Blood Mr. E. B. Hunter .. Mr. W. B. Trafford	Fire Offices Committee.
Mr. E. G. Batt .. Mr. H. H. Berry .. Mr. J. R. Dick .. Mr. A. R. Everest .. Mr. C. Rodgers, O.B.E., B.Sc., B.Eng.	British Electrical and Allied Manufacturers' Association.
Mr. W. F. Bishop..	Cable Makers' Association.
Mr. F. R. Baldock	Independent Cable Makers' Association.
Mr. W. R. Rawlings Mr. S. H. Webb ..	Electrical Contractors' Association.
Mr. R. A. Ure ..	Electrical Contractors' Association of Scotland.
Mr. O. M. Andrews	Conference of Chief Officials of the London Electric Supply Companies.
Mr. E. T. Ruthven Murray	Incorporated Association of Electric Power Companies.
Mr. J. Christie .. Mr. F. W. Purse ..	Incorporated Municipal Electrical Association.
Mr. F. T. Alldread	Association of Supervising Electricians.

Wireless Section.

The Committee of the Wireless Section for 1925–26 is constituted as follows :—

Major B. Binyon, O.B.E., M.A. (*Chairman*).

The President.

Mr. R. C. Clinker.
Mr. P. R. Coursey, B.Sc.
Mr. C. F. Elwell.
Professor C. L. Fortescue, O.B.E.
Professor G. W. O. Howe, D.Sc.
Captain N. Lea, B.Sc.
Mr. C. F. Phillips.
Captain H. J. Round, M.C.
Commander J. A. Slee, C.B.E., R.N.
Mr. E. H. Shaughnessy, O.B.E.
Mr. C. F. Trippe.
Mr. L. B. Turner, M.A.

Mr. F. Gill, O.B.E. (representing the Council).

Colonel T. F. Purves, O.B.E. (representing the General Purposes Committee).

The Chairman of the Papers Committee (*ex-officio*).

And	*Representing*
Commander G. C. Candy, O.B.E., R.N.	Admiralty.
Major A. G. Lee, M.C., B.Sc. ..	Post Office.
Lt.-Col. H. P. T. Lefroy, D.S.O., M.C.	Air Ministry.
Major H. C. B. Wemyss, D.S.O., M.C.	War Office.

Representatives of the Institution on Other Bodies.

The following is a list of representatives of the Institution on other bodies, and the dates on which they were appointed :—

Birmingham Chamber of Commerce :
Mr. S. T. Allen (27 Mar., 1919).

Bradford Public Libraries Committee :
Mr. T. Roles (27 Feb., 1919).

Bristol University :
Mr. H. F. Proctor (8 Jan., 1925).

British Cast Iron Research Association :
Mr. E. B. Wedmore (25 Sept., 1924).

British Electrical and Allied Industries Research Association :
Mr. Ll. B. Atkinson (2 April, 1919).
Mr. F. Gill, O.B.E. (2 Nov., 1922).
Mr. R. T. Smith (30 Oct., 1919).
Mr. C. P. Sparks, C.B.E. (20 Nov., 1924).
Mr. W. B. Woodhouse (5 Mar., 1925).

Sectional Committee on Electric Control Apparatus Research :
Major H. C. Gunton (2 Feb., 1921).
Mr. W. E. Highfield (19 Mar., 1925).

British Electrical Development Association :
Mr. R. A. Chattock (5 Feb., 1925).
Mr. R. Hardie (18 Jan., 1923).
Mr. W. R. Rawlings (17 Jan., 1924).

Electric Vehicle Committee :
Col. R. E. Crompton, C.B. (22 Oct., 1925).
Mr. W. R. Rawlings (22 Oct., 1925).

Sub-Committee on Constitution :
Capt. J. M. Donaldson (4 Dec., 1924).

British Engineering Standards Association :

Main Committee :
Mr. Ll. B. Atkinson (17 Jan., 1924).
Col. R. E. Crompton, C.B. (17 Jan., 1924).
Mr. C. P. Sparks, C.B.E. (5 Mar., 1925).

Sectional Electrical Committee :
Lt.-Col. K. Edgcumbe (5 Mar., 1925).
Mr. F. Gill, O.B.E. (21 May, 1914).
Mr. J. S. Highfield (21 May, 1914).
Mr. R. T. Smith (21 May, 1914).
Mr. W. B. Woodhouse (19 Dec., 1918).

Sectional Committee on Ball and Roller Bearings :
Mr. W. M. Selvey (26 July, 1921).

Sectional Committee on British Standards in Colonial and Foreign Trade :
The President (*ex-officio*).

Sectional Committee on Colliery Requisites :
Mr. C. T. Allan (3 July, 1924).

Birmingham Regional Committee :
Mr. C. Jones.

Glasgow Regional Committee :
Mr. F. Anslow.

Manchester Regional Committee :
Mr. W. T. Anderson.

Newcastle Regional Committee :
Mr. S. A. Simon.

Sheffield Regional Committee :
Mr. M. Wadeson.

Sub-Committee on Mining Electrical Plant :
Mr. C. P. Sparks, C.B.E. (23 April, 1925).

Sectional Committee on Illumination :
Lt.-Col. K. Edgcumbe (28 Feb., 1924).
Mr. P. Good (28 Feb., 1924).
Mr. H. T. Harrison (28 Feb., 1924).
Prof. J. T. MacGregor-Morris (28 Feb., 1924).
Mr. J. M. G. Trezise (19 Mar., 1925).

Sectional Committee on Petroleum Products :
Mr. H. W. Clothier (1 Feb., 1923).

Sectional Committee on Pipe Flanges :
Mr. W. M. Selvey (14 April, 1921).

Sub-Committee on Electrical Accessories :
Mr. H. J. Cash (31 Mar., 1925).
Mr. F. W. Purse (31 Mar., 1925).

Sub-Committee on Electrical Instruments :

Lt.-Col. K. Edgcumbe (15 Feb., 1923).

Sub-Committee on Electrical Nomenclature and Symbols :

Mr. C. C. Paterson, O.B.E. (8 Jan., 1920).

Sub-Committee on Overhead Transmission Lines Material :

Mr. P. Rosling (5 Mar., 1925).

Sub-Committee on Standardization of Wireless Apparatus and Components :

Mr. E. H. Shaughnessy, O.B.E. (30 Sept., 1925).

Panel on Prime Movers for Electrical Plant :

Mr. F. Bolton (22 Jan., 1925).

Panel on Switches, Ceiling Roses and Wall-plug Sockets :

Mr. H. J. Cash (23 Jan., 1924).
Mr. F. W. Purse (23 Jan., 1924).

Sub-Panel on Graphical Symbols for Interior Installations :

Mr. J. R. Cowie (13 Nov., 1924).

Engineering Joint Council :

Mr. J. S. Highfield (5 Mar., 1925).
Mr. R. T. Smith (5 Mar., 1925).

Imperial College of Science and Technology, Governing Body :

Mr. W. M. Mordey (12 April, 1923).

Imperial Mineral Resources Bureau Conference :

Mr. J. H. Rider (23 Jan., 1919).
Mr. W. B. Woodhouse (23 Jan., 1919).

Copper Committee :

Mr. B. Welbourn (18 Sept., 1919).

Miscellaneous Minerals Committee :

Prof. E. Wilson (18 March, 1920).

Institute of Metals, Corrosion Research Committee :

Mr. W. M. Selvey (19 July, 1923)

Institution of Civil Engineers, Engine and Boiler Testing Committee :

Mr. R. A. Chattock (19 Oct., 1922).
Mr. C. P. Sparks, C.B.E. (19 Oct., 1922).

Institution of Heating and Ventilating Engineers, Committee on Utilization of Exhaust Steam and Waste Heat :

Mr. P. V. Hunter, C.B.E. (29 Sept., 1922).
Mr. W. M. Selvey (29 Sept., 1922).
Mr. J. C. Wigham (29 Sept., 1922).

International Illumination Commission, British National Illumination Committee :

Lt.-Col. K. Edgcumbe (27 Nov., 1913).
Mr. P. Good (18 Sept., 1919).
Mr. H. T. Harrison (27 Nov., 1913).
Prof. J. T. MacGregor-Morris (27 Nov., 1913).
Mr. J. M. G. Trezise (19 Mar., 1925).

International Scientific Unions :

Committee on International Union in Physics :

Dr. A. Russell, F.R.S. (18 Mar., 1920).

Committee on International Union in Radio Telegraphy :

Dr. W. H. Eccles, F.R.S. (18 Mar., 1920).
Prof. G. W. O. Howe, D.Sc.(18 Mar., 1920).
Prof. E. W. Marchant, D.Sc. (18 Mar., 1920).

Leeds Civic Society :

Mr. E. C. Wallis (27 Mar., 1919).

Leeds Municipal Technical Library Committee :

Mr. W. B. Woodhouse (19 Dec., 1918).

Loughborough Technical College, Advisory Committee :

Mr. R. B. Leach (27 Mar., 1919).

Metalliferous Mining (Cornwall) School Governing Body :

Mr. J. S. Highfield (18 Sept., 1919).

Middlesbrough Technical College, Governing Body :

Mr. E. Edwards (1 Oct., 1925).
Mr. J. M. Gibson (1 Oct., 1925.)

National Physical Laboratory, General Board :

Mr. Ll. B. Atkinson (21 Oct., 1920).
Dr. A. Russell, F.R.S. (22 Nov., 1923).

National Register of Electrical Contractors :

Col. R. E. Crompton, C.B. (5 Mar., 1925).
Mr. P. V. Hunter, C.B.E. (12 April, 1923).
Mr. W. R. Rawlings (15 Mar., 1923).
Mr. W. M. Selvey (15 Mar., 1923).

Professional Classes Aid Council :

Sir James Devonshire, K.B.E. (28 April, 1925).

Royal Engineer Board :

Mr. W. B. Woodhouse (19 Mar., 1925).

Royal Society :

Alloys of Iron Research Committee :

Mr. J. Swinburne, F.R.S. (15 Feb., 1923).

National Committee for Physics :

Dr. A. Russell, F.R.S. (16 Dec., 1920).

National Committee on Radio-Telegraphy :

Dr. W. H. Eccles, F.R.S. (4 Aug., 1920).
Dr. J. Erskine-Murray (3 July, 1924).

Union of Lancashire and Cheshire Institutes (Panel for Engineering) :

Mr. A. P. Fleming, C.B.E. (28 Feb., 1924).
Prof. Miles Walker, D.Sc. (28 Feb., 1924).

Women's Electrical Association :

Mr. A. P. M. Fleming, C.B.E. (18 Dec., 1924).

Women's Engineering Society :

Mr. A. P. M. Fleming, C.B.E. (25 Sept., 1924).

DIELECTRIC PROBLEMS IN HIGH-VOLTAGE CABLES.

By P. DUNSHEATH, O.B.E., M.A., B.Sc., Member.

(*Paper first received* 15*th August, and in final form* 27*th November*, 1925; *read before* THE INSTITUTION 5*th November*, *before the* NORTH-EASTERN CENTRE 9*th November, and before the* NORTH-WESTERN CENTRE 17*th November*, 1925.)

SUMMARY.

The paper deals with several important problems of particular theoretical and practical interest at the present time in connection with the design, manufacture, and operation of high-voltage impregnated-paper cables.

In the first place, the phenomenon of dielectric absorption is discussed as a question of fundamental importance and as a basis for a proper understanding of dielectric losses. It is shown how dielectric resistance must be carefully defined in order to be of any value as a characteristic of cable quality, or in analytical discussion, and the results of experiments are given to show that whilst the usually accepted absorption expression departs from the truth, it can be used within limits. Experimental work on absorption in different dielectrics and on the effect of moisture and temperature on the constants is also described.

The dependence of alternating dielectric losses on direct-current characteristics is discussed, and the author suggests a conception of the former in which they can be explained as I^2R losses, without retaining the difficulties of a dielectric hysteresis.

Several new points are brought to light and supported by experimental evidence in a discussion of the relationship between d.c. and a.c. losses. The nature of the " V " curve connecting dielectric power-factor and temperature is investigated, and an explanation of the " V " curve is suggested based on the I^2R theory of losses.

The paper also discusses the rise of power factor with voltage, the important effect of time on the breakdown strength, and the bearing which this has on the effect of surges in a system. In conclusion, some suggestions are made on the nature of breakdown and the assessment of cable quality.

CONTENTS.

(I) INTRODUCTION.

There are many questions affecting the design, manufacture and operation of high-voltage cables which are of considerable interest at the present time, and the scarcity of communications to the Institution on the subject is a sufficient justification for the present paper, if only because of the opportunity which it will afford for the discussion of some of these questions.

The author found in attempting to arrange the paper that the selection of material presented a very real difficulty. There is so much of what may be called " half knowledge " that one is liable on the one hand to take for granted much that is doubtful, or, on the other hand, to restate partially-accepted fundamentals and so risk the charge of being unoriginal.

The paper is intended neither as an exact exposition of any part of the subject nor as a complete summary of all published knowledge. The author feels that in a subject like dielectrics any conception which makes the ideas more tangible to the general body of electrical engineers is of as much value as, if not more value than, a rigid mathematical treatment. He has been content, therefore, to bring together certain items from widely divergent sources, some of which were conceived without any thought of their connection with high-voltage cables, and to add some of the results of six years of his own personal investigations in the hope that the *mélange* so produced may add to our common stock of knowledge of this most important factor in modern electrical engineering.

With all that has been done and written the field of dielectric theory is so widely unexplored to-day that any communication, such as the present one, must necessarily expose many gaps in our knowledge. If at these points, however, the better appreciation of our present ignorance, either through the paper or through the discussion thereon, should also show the way to some probable explanation, a good purpose will have been served.

The three dielectric characteristics most generally considered in high-voltage cable work are :—

Alternating-current losses ;
Alternating-current breakdown strength ;
Dielectric resistance (measured by direct current).

The order of importance is a matter of opinion, and the connection between the three is not at all understood. The third item was considered to be of prime importance for many years, whilst to-day the one receiving most attention in connection with high-voltage cables is that of a.c. losses. In the following pages attention is called to the claims of breakdown strength when measured in a particular manner, which might almost be considered to be a test of a fourth characteristic, the ability to withstand operating conditions satisfactorily over long periods of time ; and the shortcomings of loss and power-factor tests are emphasized.

For some time there has been a growing conviction

that the phenomena displayed under the conditions employed for measuring the d.c. resistance are at the bottom of a.c. losses. For this reason, and as the view seems reasonable, prominence has been given in the paper to the consideration of dielectric absorption, on the lines of the valuable conceptions of Maxwell,* Hopkinson,† Pellat ‡ and Schweidler,§ whose contributions on the operation of dielectrics are generally unknown to electrical engineers.

The correlation between a.c. and d.c. phenomena has been hindered in the past by the fact that d.c. resistance has usually been measured at voltages of 500 or less, whilst a.c. loss measurements have been carried out at very much higher voltages—10 000 and upwards—and the uncertainty of the effect of voltage has made it impossible to bridge the gap between the two sets of published results. The former difficulties of carrying out d.c. tests at the higher voltages have now largely disappeared, through the recent advances in the design of mechanical and thermionic rectifiers, but in the author's experiments the subject has been approached from the other point of view, viz. that of retaining the low voltage for the d.c. tests and developing methods of dielectric-loss measurements for the same low voltage. Alternating-current tests carried out under these conditions admittedly do not bring to light the phenomena connected with the ionization of air entrapped in the dielectric, as met with in super-tension cable work; but the investigation and discussion of this factor separately are an advantage rather than otherwise in throwing light on the operation of the dielectric. In any case, the bringing together of a.c. and d.c. data for the same dielectric seems to be imperative for the fuller understanding of the complicated phenomena encountered. It does not take us the whole way, but it enables us, for example, to obtain a new conception of dielectric losses independent of that much-worn word "hysteresis." By the theory here put forward alternating dielectric losses are explained as I^2R loss, caused simply by a current flowing through a resistance as in other types of electrical loss, and the idea of dielectric hysteresis becomes unnecessary.

Apart, too, from theoretical considerations, the d.c. phenomena in cable dielectrics are assuming importance in connection with the proposals to transmit large quantities of power by high-tension direct current, as well as by the use of unidirectional pressure-tests on high-voltage a.c. cable systems. The connection between alternating and steady potential characteristics may be considered from many different points of view, some of which are discussed in this paper.

Recent experience on high-voltage cables has demonstrated the need for improved tests which, while not damaging the cable, will enable a purchaser to discriminate between a cable that will fail within a few months under ordinary conditions of service and one that will stand up satisfactorily in operation over a long period. The question of assessment of cable quality has, consequently, been given attention, following on the more fundamental considerations. The question of the mechanism of breakdown in cables has received a good deal of attention by many investigators, but is by no means fully understood. The author has ventured to add still one more to the alternative suggestions already advanced.

* See Appendix II, (6). † *Ibid.*, (7). ‡ *Ibid.*, (8). § *Ibid.*, (9).

Owing to the intricacies of the subject, confirmation of any theory of dielectric operation is difficult. The allocation of insufficient weight to the evidence of any one particular phenomenon may result in conclusions entirely opposed to the truth, so that long and detailed research with much hard thinking will be necessary before all the problems now presenting themselves are solved with certainty. In these circumstances, any original views advanced in this paper are put forward tentatively and with a full appreciation of the possibility of the conclusions being negatived by further experimental evidence.

In view of the many excellent bibliographies recently compiled on the subject of cable dielectrics, it has not been considered necessary to attempt a complete list in this instance, but a list of contributions actually referred to in the paper has been given in Appendix II.

(II) Dielectric Absorption (Theoretical).

For more than half a century the various phenomena exhibited by a dielectric when subjected to a steady difference of potential have been studied by many investigators. As long ago as 1861 some very interesting observations were made on the subject by expert witnesses before a Royal Commission on Submarine Telegraph Cables,* and in 1873 Professor Boltzmann † by means of experiments on the attraction between suspended balls of various dielectrics showed how the apparent specific inductive capacity varied with the duration of charge. The phenomenon of "electrification" has long been known in connection with the testing of gutta-percha cables, and it has recently appeared in a new form in connection with the testing of a.c. power cables with high-pressure direct current generated either by the Delon apparatus or by rectifying valves.‡ If a cable for a working pressure of, say, 33 000 volts be charged up to 100 000 volts for a few minutes and afterwards short-circuited, it is not safe to remove the short-circuit for some time, as the residual charge absorbed by the cable will leak back and charge the conductor to a dangerous value.

For two distinct reasons the study of dielectric absorption is important in connection with high-voltage cables. In the first place it is becoming increasingly evident that a.c. dielectric losses are largely the result of this d.c. absorption; and secondly, the demands for the consideration of the claims of direct current for high-voltage long-distance transmission are becoming more and more insistent. For both reasons a summary of the underlying principles of absorption are called for in a paper of this kind.

When a dielectric is subjected to a steady difference of potential there is at first a rush of current, which gradually dies away in the manner indicated in Fig. 1, ultimately approaching asymptotically a steady finite value which, with high-class dielectrics, appears to be extremely small. The time during which the current continues to fall may be weeks, and possibly longer.

* See Appendix II, (1). † *Ibid.*, (2).
‡ *Ibid.*, (3, 4 and 5).

If we consider the quantity of electricity stored in an absorptive condenser, we find that a certain charge is taken immediately on the application of the difference of potential, and a further charge continues to accumulate at a decreasing rate as shown diagrammatically in Fig. 2. The ordinate RS represents the charge acquired suddenly, and the total charge at the time t is the sum of RS and QS, where QS is the charge "absorbed" up to time t. After infinite time the total charge is given by PR.

On discharging an absorptive condenser which has been charged for some time, the discharge current falls away from an initially high value in the same way as the charging current (Fig. 1). The quantity of electricity

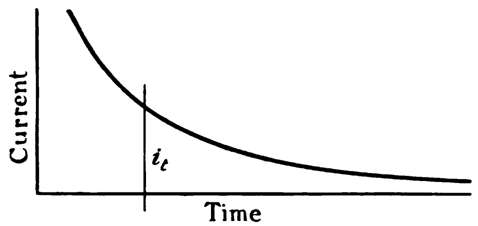

FIG. 1.—Charging current in an absorptive condenser

stored decreases as shown in Fig. 3, first suddenly by a given quantity RS and then more and more gradually. The ordinate PQ of the curve ST at any time after the instant of short-circuit represents the charge still held, or absorbed, by the dielectric and known as the residual charge. If the short-circuit is removed soon after the initial discharge the residual charge, in leaking out of the dielectric, may build up the potential difference of the plates of the condenser to a value approaching that of the original charge.

Consideration of the three elementary diagrams of Figs. 1, 2 and 3 illustrates one or two points which are

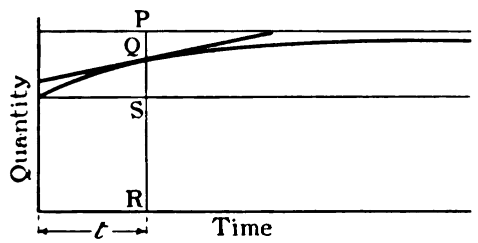

FIG. 2.—Variation of charge with time during charging.

not always appreciated in connection with the meaning of dielectric resistance and capacity. It is common practice in the commercial testing of electric cables to define the dielectric resistance as the ratio between the applied voltage and the current which is flowing 1 minute after the application of the testing battery. As will be seen, this must be an entirely arbitrary value and by no means a true resistance. As a means of arriving at any scientific understanding of the dielectric the 1-minute resistance is useless. The result 2 minutes after the application of the battery will be very much higher than the 1-minute value, and a cable which has quite a low 1-minute value may, after being charged for 24 hours, give a value of dielectric resistance approaching infinity as considered on the usual standards.

As regards the capacity measured by a ballistic galvanometer on charge or discharge, it will be seen that the measured value has two components :—

(*a*) That based on the instantaneous charge or discharge RS (Figs. 2 and 3) ;
(*b*) That based on the charge absorbed or released subsequently on discharge (SQ, Figs. 2 and 3).

(*a*) is known as the geometric capacity and (*b*) as the absorptive capacity.

The relative proportion of the two components included in the value given by the ballistic galvanometer depends on the period during which the galvanometer is connected ; the shorter this time the nearer will the value be to the true or geometric capacity.

Two main theories claim to explain in different ways the mechanism of dielectric absorption and residual charge. The first one, advanced originally by Maxwell,*

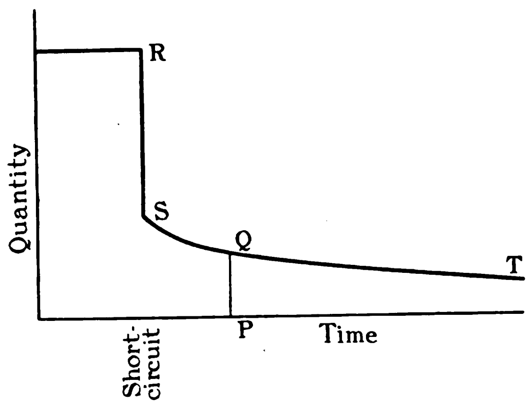

FIG. 3.—Variation of charge held during discharge.

depends on the distribution of charge throughout a non-homogeneous dielectric. He considered the component capacities and resistances in the dielectric and showed that the distribution of potential under transient conditions is settled largely by the arrangement of component capacities, whereas that under steady conditions is fixed by the arrangement of component resistances. The time-lags of electrification and de-electrification are considered in this theory to be due to the time occupied in the rearrangement of potential between one of these conditions and the other.

In the second theory advanced originally by Hopkinson † and since elaborated by other writers, the phenomena are connected with the movement of the electron in the atom. Dielectric polarization is assumed to have two components, a perfectly elastic one accounting for the geometric capacity and a viscous one resulting in absorption. The rearrangement of the electrons during polarization is supposed to take place in two stages : first a sudden jump on the application of the difference of potential, and secondly a steady creeping up to a higher value.

In addition to the development of physical conceptions of the operation of dielectrics, a good deal of

* See Appendix II, (6). † *Ibid.*, (7).

work has been carried out along the lines of mathematical analysis originating with the classical contribution of Pellat,* followed by that of Schweidler † and others.

The adoption of Maxwell's original idea of a heterogeneous dielectric seems to be most useful for cable work, and by the use of this conception it is possible to build up a very simple theory which at the same time conforms exactly to the deductions of Pellat and Schweidler. The theory has, moreover, the advantage that it can be used not only for explaining dielectric absorption under d.c. conditions, but also as a basis for a simple conception of dielectric losses under a.c. conditions.

Various arrangements of pure condensers and resistances have been proposed to imitate a practical dielectric (see, for instance, Fleming and Dyke ‡ and MacLeod §). If we take two condensers and resistances connected as in Fig. 4 we can obtain an approximation to a practical absorptive condenser. The one condition to be met is that the ratio of the capacities must be different from the inverse ratio of the resistances, that is :—

$$\frac{R_A}{R_B} \neq \frac{C_B}{C_A} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

It is evident that under steady conditions the potential of the centre point of the combination is settled by the ratio of the resistances, the capacities having no effect. Under transient conditions, however, such as occur at the instant of applying a difference of potential across the group, the potential of the centre point is controlled by the ratio of the capacities, and the resistances have relatively no effect. The potential distribution will be as shown in Table 1, where E is the applied E.M.F.

TABLE 1.

Condition	Potential difference across A	Potential difference across B
Steady	$\dfrac{R_A}{R_A + R_B}E$	$\dfrac{R_B}{R_A + R_B}E$
Transient	$\dfrac{C_B}{C_A + C_B}E$	$\dfrac{C_A}{C_A + C_B}E$

At the instant of switching on, therefore, such an arrangement acts as a pure capacity taking a heavy momentary charging current. Immediately, also, the redistribution of potential described above commences and requires further current, which dies away until, when steady conditions are attained, only that flowing through the resistances remains. Thus all the requirements of an absorptive condenser during charge are met.

In the same way the phenomena of residual charge are imitated on discharging. When short-circuited, a sudden rush results in the total discharge of the smaller condenser and the taking from the other of an equal quantity. At this instant a quantity of electricity equal to the difference between the full charges of the two component condensers is set free and commences to discharge partly through its bridging resistance and partly through the other resistance component and the external circuit, the latter part representing the residual charge. If, after the initial short-circuit, the external circuit is opened, the discharge of the larger condenser which is still in progress charges the outside plates, giving rise to another phenomenon noted with absorptive condensers—the repeated reappearance of a charge on the plates after temporary short-circuits. It is evident, then, that such an arrangement of condensers and resistances, in addition to giving all the charging characteristics of an absorptive condenser, also imitates the conditions during discharge. Exact expressions for the rate of charging of such a combination can be obtained from very simple considerations in order to form a basis for discussing the various phenomena encountered.

If i is the instantaneous current flowing into a condenser of capacity C after time t through a resistance R due to a steady E.M.F. E, then the various quantities are connected by the expression :—

$$E = Ri + \frac{Q}{C} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where Q is the charge in the condenser after time t and

$$E = Ri + \frac{1}{C}\int_0^t idt \quad . \quad . \quad . \quad . \quad . \quad (3)$$

the solution of which gives

$$i = \frac{E}{R}e^{-t/(CR)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

and $$Q = EC(1 - e^{-t/CR}) \quad . \quad . \quad . \quad . \quad (5)$$

Now let us apply this to the charging of the combination shown in Fig. 4. Assume that $C_B > C_A$ and

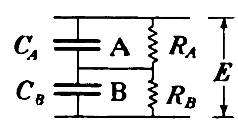

FIG. 4.—Simple arrangement of condensers and resistances to illustrate absorption effects.

$R_A = R_B$.* and that the applied E.M.F. is maintained at the value E.

There are three component currents to be considered:—

α, the initial rush of current which charges the two condensers in series by equal amounts ;

β, the current which flows directly through R_A and R_B ;

γ, the current which flows through R_A to supply the additional charge required by C_B the larger condenser in order to adjust the potential across A and B equally for ultimate steady conditions.

The charges carried by items α and γ are as follows :—

(α) $$Q_1 = \frac{C_A C_B}{C_A + C_B}E$$

This has an instantaneous and definite value.

* See Appendix II, (8). † Ibid., (9). ‡ Ibid., (10). § Ibid., (11).

* This assumption complies with the condition $\frac{R_A}{R_B} \neq \frac{C_B}{C_A}$.

(γ) Applying Equation (5) we get :—

$$Q_2 = E(C_B - C_A)\,[1 - e^{-t/R_A(C_B - C_A)}]$$

Substituting C for $\dfrac{C_A C_B}{C_A + C_B}$

ϵC for $(C_B - C_A)$

and α for $\dfrac{1}{(C_B - C_A)R_A}$

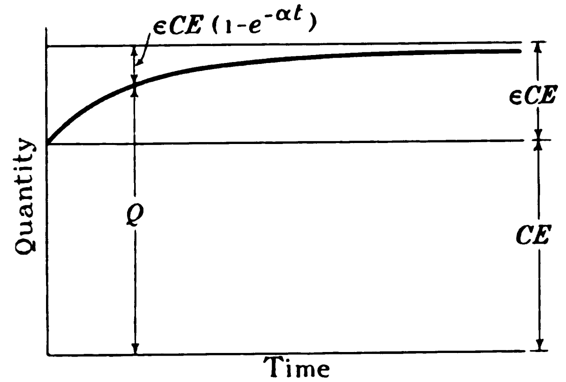

FIG. 5.—Variation of charge, illustrating Equation (6).

we find that the charge stored in the combination t secs. after the E.M.F. was applied is the sum of α and γ and is given by

$$Q = CE + \epsilon CE\,(1 - e^{-at}) \quad . \quad . \quad . \quad (6)$$

This equation is equivalent to that obtained in Pellat's classical and fundamental analysis, and is shown graphically in Fig. 5.

Suppose now that instead of taking only two condensers and two resistances, we consider an infinitely large number of them as shown in Fig. 6. As before

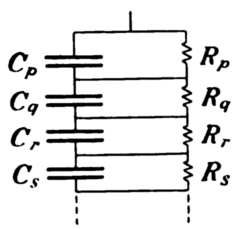

FIG. 6.—Model dielectric to illustrate absorption.

we will assume the resistances to be equal and the capacities to increase downwards. Then we shall have an infinite number of circuits between the upper plate of the condenser and the lower one. These circuits will be made up as follows :—

Circuit No. 1.—C_p, C_q, C_r, C_s . . .
Circuit No. 2.—R_p, C_q, C_r, C_s . . .
Circuit No. 3.—R_p, R_q, C_r, C_s . . .
etc.

Circuit No. 1 is a pure capacity and the remaining circuits form a series with different time-constants. Extending the argument used above in connection with the two condensers, we now obtain for the total quantity of electricity stored up to time t the following expression :—

$$Q = CE + CE\int \epsilon\,(1 - e^{-at})dt \quad . \quad . \quad (7)$$

and this is equivalent to the expression obtained by Schweidler as representing more nearly the operation of an absorptive condenser than did the original expression of Pellat.* At the instant of closing the circuit the charge CE enters the condenser. Immediately also an infinite number of additional charges commence to increase from zero at different rates, as indicated by the collection of curves in Fig. 7. The dotted line represents the sum of these component curves and approaches asymptotically the ordinate $CE\,(1 + \epsilon)$.

The charging current flowing into the combined circuit of Fig. 6 can be obtained either by differentiating the expressions already deduced for the charge or, better still, by the application of Equation (4). One of the elementary currents is given by

$$i_t = \frac{E}{R}e^{-t/(CR)}$$
$$= \frac{E}{R}e^{-at}$$

From the same considerations as those which led to Equation (7) for the charge we obtain the following

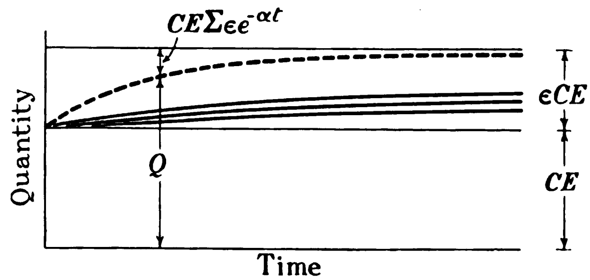

FIG. 7.—Effect of different time constants of component circuits in model dielectric.

expression for the total current flowing after time t through the series of circuits with various time-constants :—

$$I_t = \frac{E}{R}\int_{a=0}^{a=\infty} e^{-at}dt \quad . \quad . \quad . \quad . \quad . \quad (8)$$

It is obvious that this analysis does not lead to a formula which can be employed for the practical estimation of the current flowing in an absorptive condenser after a given period, so that for this purpose we are compelled to fall back on an empirical expression. The form of the charging-current/time characteristic has been studied by various investigators and several different expressions to approximate to the results of tests have been published. Trouton and Russ † gave the formula

$$I_t = \frac{A}{t + B}$$

* See Appendix II, (8 and 9). † *Ibid.*, (12).

where t is the time,
I_t is the current flowing, and
A and B are empirical constants.

Malcolm * found that for one gutta-percha cable

$$I = A + B/\sqrt{t}$$

but that this expression was not satisfied by results obtained on another cable.

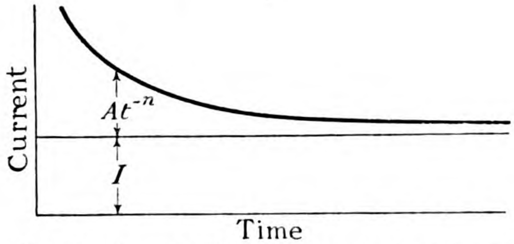

FIG. 8.—Usual empirical charging curve for absorptive condenser.

The most commonly used expression, which has been adopted within recent years by, for instance, Ashton,† MacLeod,‡ and Granier,§ is as follows :—

$$I_t = I + At^{-n} \quad . \quad . \quad . \quad . \quad . \quad (9)$$

where I is a true conduction current still flowing after infinite time. A and n are constants, the latter having a value less than unity, and the quantity At^{-n} represents the current supplying the absorbed charge (see Fig. 8).

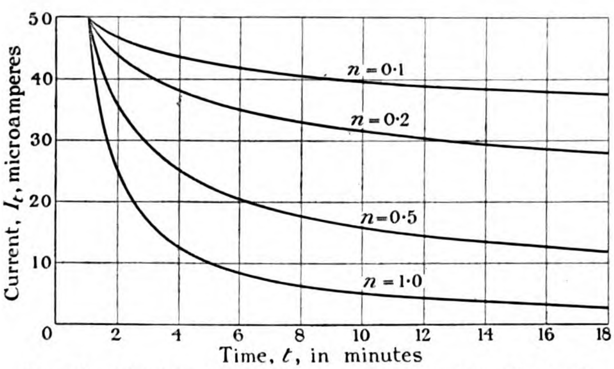

FIG. 9.—Empirical absorption curve, showing effect of varying n.

It will be shown later by examination of results already published, as well as by the author's own experiments, that this expression never does represent accurately the actual variation of current in a cable dielectric over any considerable period of time. It appears to be sufficiently accurate over short intervals (seconds) to make it useful in connecting the d.c. and a.c. characteristics of a dielectric, and if we adopt the convenient reservation that n itself varies with time, we can use the expression in the form given with considerable advantage both for analytical discussion and for the interpretation of practical results. Fig. 9 shows the relative shapes of current/time curves calculated for different values of n from $0 \cdot 1$ to $1 \cdot 0$ and, to anticipate for a moment, curves plotted from experimental results obtained on cables appear to start on one value of n and to change gradually with time to a different value. It is at once evident from Fig. 9 that the 1-minute value is an imperfect indication of the nature of the dielectric. A number of cables may all have the same 1-minute value and yet have widely different characteristics depending on the value of n.

Two methods of determining the values of the constant from an experimental curve are worked out in Appendix I allowing for the presence of I in the formula $I_t = I + At^{-n}$. In passing, it may be noted that in view of the change of n with time which is found to take place in all cable dielectrics so far examined, the determination of the constants from different finite parts of the curve may lead to different values of I, in some cases the early portion giving a negative value, as shown in Fig. 10.

To sum up the theoretical considerations at this stage it is evident that whether we are discussing the correct

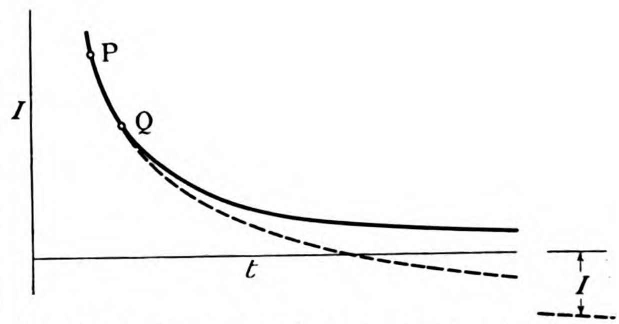

FIG. 10.—Empirical absorption curve, showing change of I.

ratio to adopt between d.c. and a.c. pressures for high-voltage testing, comparing d.c. and a.c. losses for theoretical interest, attempting to show that a.c. losses are partly due to d.c. resistance, or any other of the similar problems that are receiving special attention to-day in connection with high-voltage cables, we cannot be too precise in our definition of the d.c. resistance. Although the whole phenomenon of absorption can be shown as above to be based on resistance within the dielectric, the value of this resistance is elusive. If there is such a quantity as a true dielectric resistance, it is reasonable to take the final value based on the current after infinite time, and this is difficult to determine experimentally. The 1-minute value usually accepted in cable tests, although quite an arbitrary quantity, is as useful for practical purposes as any other that can be suggested at the present time from theoretical considerations, but a more complete knowledge of the dielectric may be obtained by taking into account not only the value at 1 minute, but also the ultimate value and the rate at which the value varies with time, in other words the values of I and n in the tentative expression $I_t = I + At^{-n}$.

* See Appendix II, (33). † *Ibid.*, (13). ‡ *Ibid.*, (11). § *Ibid.*, (14).

(III) Dielectric Absorption (Experimental).

Several investigators have experimented with a view to determining absorption data on different dielectrics, but when examined in detail the results so far obtained on cables do not form a very useful supplement to the theory as outlined in the previous section. Fundamental problems which at once suggest themselves are the following :—

(1) The determination of I and n in the expression $I_t = I + At^{-n}$.
(2) The effect of temperature change on these quantities.
(3) The effect of moisture content.

In attacking this apparently simple programme very considerable difficulties are encountered. The determination of the charging-current/time curve is fairly straightforward, but the deduction of the values of I and n from it is not so easy. In Appendix I two methods adopted for the determination of these quantities from a series of charging currents are indicated. In the first the results are plotted to a large scale and the value of n is deduced from the ratios of tangents drawn to the curve. Method (*b*) arrives at the result arithmetically by the use of three points on the curve. Method (*a*) is less cumbrous than (*b*), but suffers from the disadvantage that errors in drawing the tangents have a large effect on the accuracy of the results. A method of curve analysis given in a recent German book * promises more accurate results by the use of a development in spherical harmonics, but the methods shown have been sufficient for the purposes of this paper.

The results of a large number of experiments carried out by the author show that n may change considerably between, say, 15 seconds and 5 minutes, and, in addition, the final value of I to which the curve is approaching may be different at different times. In a curve, for instance, which ultimately approaches zero the application of the empirical absorption formula to the early part of the curve may lead to a negative value for I, as already shown in Fig. 10. The methods of Appendix I enable the values of these quantities to be obtained nothwithstanding these vagaries. For comparison of different dielectrics, or for checking the effect of moisture or temperature, it is not necessary to consider this change of n with time, but the value can be calculated over the whole period as though it were constant. The approximation is sufficient to show the phenomena under consideration.

The most important dielectric to consider for high-voltage cables is, of course, impregnated paper, but as gutta-percha has been studied from the point of view of absorption for so many years in connection with telegraph cables, and as the empirical formula referred to at the end of the previous Section has been derived from these results, it is of interest first of all to look briefly at the charging-current curve obtained on a cable insulated with this material. Fig. 11 shows the curve obtained by plotting the currents recently given for a gutta-percha cable by Beauvais and shown in Table 2.

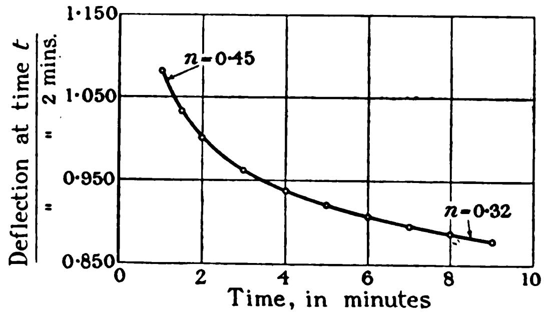

Fig. 11.—Charging current of a gutta-percha cable

Plotting these results on a large scale, measuring tangents and deducing n by the first method of Appendix I, gives $n = 0·45$ at 1 minute, falling to $0·32$ at 9 minutes. Different values of I and A are obtained for the two points, and the limits of the curve may be represented by the expressions

Table 2.

Time	1	1½	2	3	4	5	6	7	8	9
Deflection at time t / Deflection at 2 mins.	1·081	1·031	1	0·961	0·937	0·920	0·906	0·896	0·887	0·879

$$I_t = 0·8 + 0·281t^{-0·45} \text{ (at 1 minute)}$$
$$I_t = 0·49 + 0·397t^{-0·32} \text{ (at 9 minutes)}$$

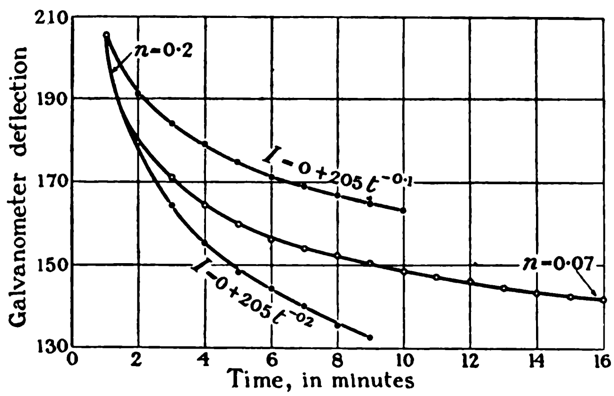

Fig. 12.—Charging current of a gutta-percha cable.

Fig. 12 shows a set of figures obtained on another gutta-percha cable from 1 to 16 minutes, in which the calculated index falls from 0·2 to 0·07. The curves

* See Appendix II, (34).

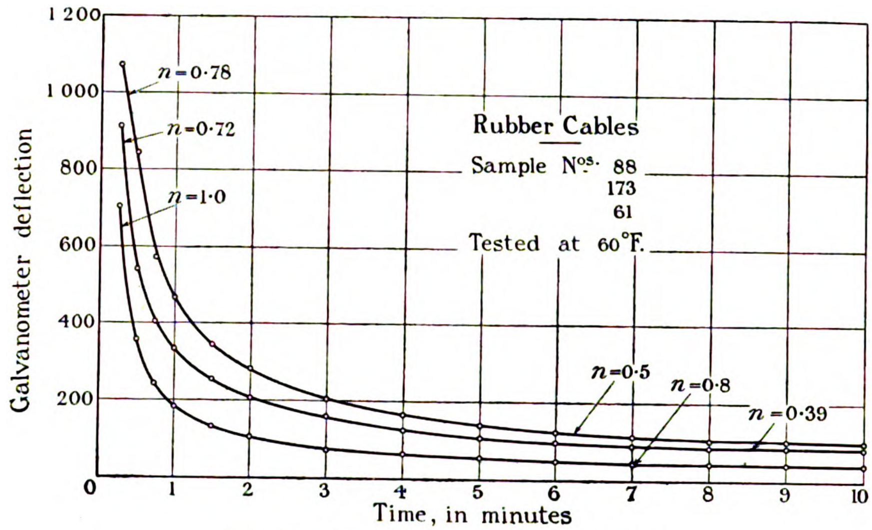

FIG. 13.—Charging current of rubber cables.

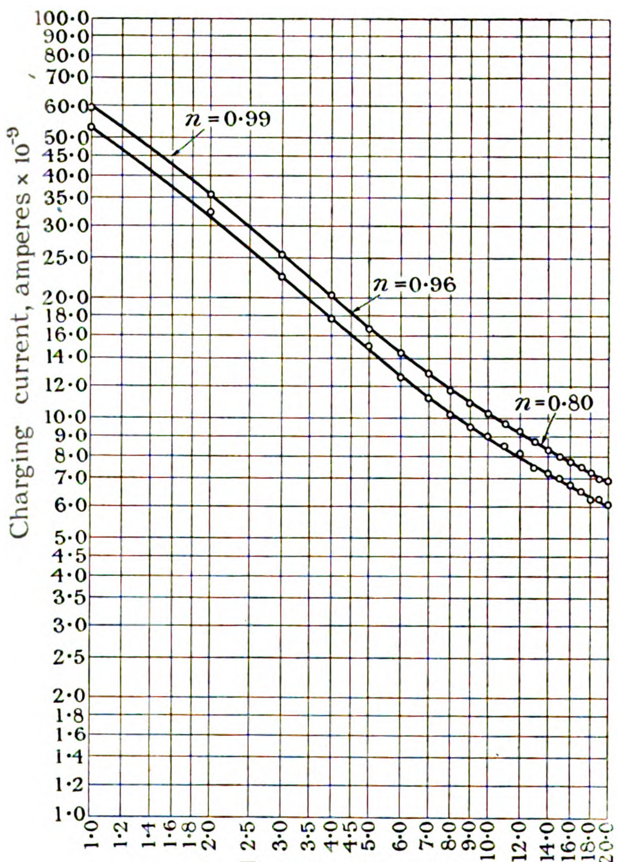

FIG. 14.—Charging current of single-core paper cable.

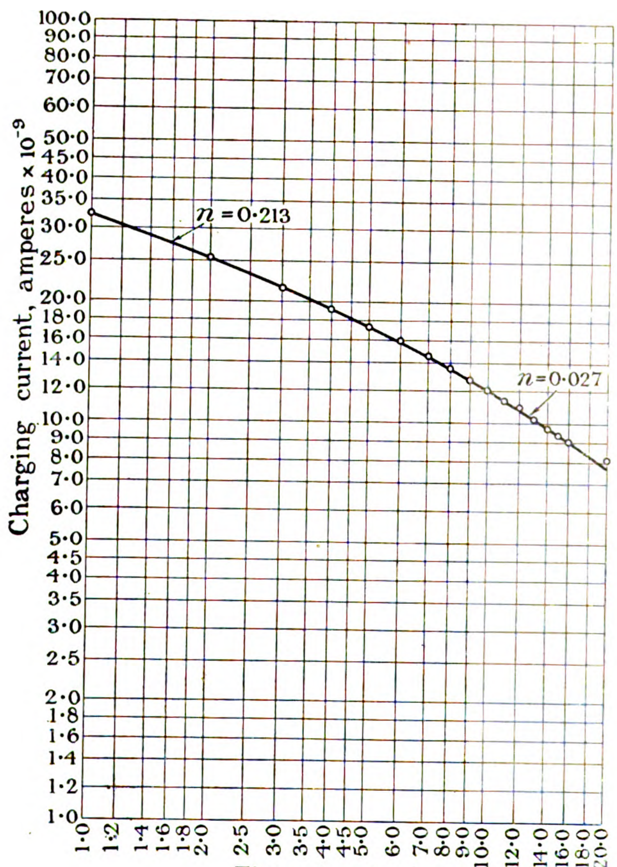

FIG. 15.—Charging current of single-core paper cable, showing effect of change in the empirical constant *I*.

$I = 0 + 205t^{-0\cdot 1}$ and $I = 0 + 205t^{-0\cdot 2}$ are plotted for comparison.

The three curves in Fig. 13 show the results obtained on three samples of 7/·064 vulcanized-rubber cables having different percentages of rubber. The voltage used was 500 and the samples were at laboratory temperature. Here again it will be seen that the value of the index n falls away during the charging. It is interesting to note in passing that the cable with the highest percentage of rubber had the highest value of n throughout.

Quite a large number of tests have been carried out on various types of impregnated-paper cables, and a selection is made below to illustrate the general results obtained. In Fig. 14 the d.c. charging currents obtained with a pressure of 100 volts on two similar 50-yard lengths of single-core super-tension cable are plotted logarithmically. The values of the index n determined for one of the lengths by the second method of Appendix I are indicated. The value approaches unity for short times, and falls to lower values as the time period is lengthened.

Fig. 15 brings out an interesting point noticed in many of the tests. Plotting the results logarithmically may give a drooping curve while the actual value of the index as calculated is falling. The explanation, of course, lies in the variation of the value of I, the assumed constant in the expression $I_t = I + At^{-n}$. The droop due to change in I more than compensates for the rise due to change in n. If n is constant with zero value of I the graph is a straight line, and with a positive value of I the graph is everywhere concave upwards.

Fig. 16 shows the charging currents obtained on three samples of oil at 40° C. The samples were mixtures of two ingredients used in the manufacture of cables in the following percentages :—

Compound	Ingredients	
	P	Q
	per cent	per cent
A	100	0
B	90	10
C	80	20

They were tested between a brass-disc electrode suspended 1 mm above the flat bottom of a brass container. Statements have been made to the effect that liquid dielectrics show no absorption, although Hopkinson and Wilson in 1897 * gave some figures to show that castor oil did exhibit the phenomenon. The curves of Fig. 16 show that without doubt these compounds are absorptive in their liquid state. The calculated values of the absorption index are also given, and it is interesting to note that although the dielectric resistances of the three oils at any instant during the test are not a direct function of their composition, the values of n are. The index increases rapidly with the addition of ingredient Q.

In order to investigate the effect of moisture content on dielectric absorption it is, of course, necessary to choose a dielectric in which the moisture content can be conveniently controlled during the tests. Paper was at first tried, but was abandoned because of its very great susceptibility to rapid atmospheric change. Other materials were tried, but the selection ultimately fell on celluloid as being homogeneous, subject to humidity conditions and yet changing so slowly as to make handling during the tests practicable. A number of sheets 9 in. square and 0·062 in. thick were placed in closed biscuit boxes containing beakers of sulphuric acid, the strengths of which were adjusted to give a definite

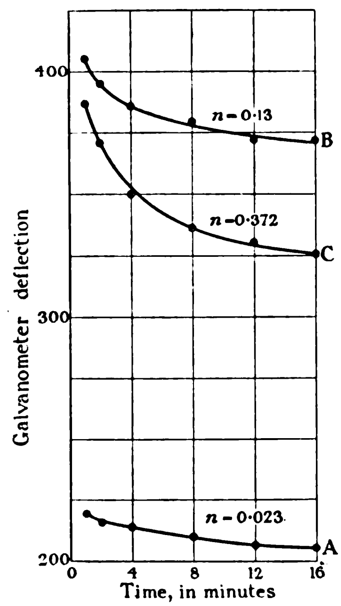

FIG. 16.—Charging current of 3 samples of cable compound.

range of relative humidity of the enclosed air. No. 1 sample had a beaker of phosphorus pentoxide in order that perfect dryness might be simulated as near as possible. The range of humidities covered and strengths of acids used are shown in Table 3

TABLE 3.

Sample No.	Sp. gr. of H_2SO_4	Relative humidity
		per cent
1	(P_2O_5 used)	0
2	1·608	5
3	1·550	10
4	1·510	15
5	1·475	20
6	1·448	25

In order to check the progress of the conditioning of the samples a small piece of the same material weighing about 3 grammes, kept with each main sample in the controlled atmosphere, was taken out and weighed at intervals of 1 week. The weights of the samples steadily changed until after 10 weeks they had settled down sufficiently for the tests to be commenced. Throughout

* See Appendix II, (35).

the tests, which occupied a further 4 months, the samples were kept in the conditioning chambers except during the actual tests, and the strengths of the controlling acids were carefully maintained.

At the time the tests were started, check samples were weighed and put away in a desiccator where they remained until the end of the investigation. They were then re-weighed and it was found as a result that sample No. 1 had continued to lose weight during the investigation. This is an important observation in view of the results, as it shows that the "dry" sample was not perfectly dry.

Care was taken throughout this part of the research to allow a considerable period of time to elapse between any two tests on the same sample, as it was soon dis-

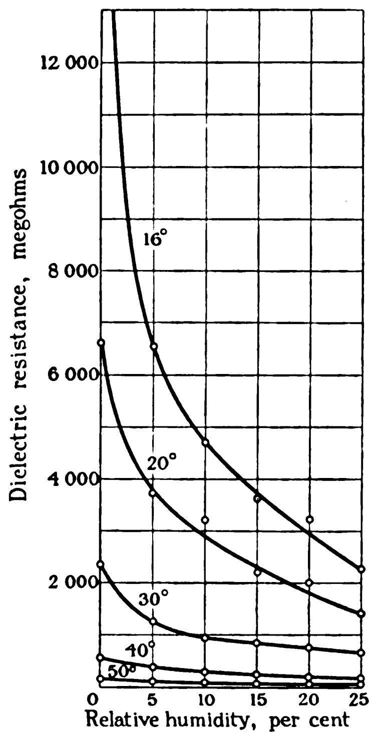

FIG. 17.—Variation of dielectric resistance of conditioned celluloid (82 days' state) with relative humidity and temperature.

covered that the effects of absorption persisted for a surprisingly long time after a test. As a general practice a period of 2 weeks was allowed, and in no case was this reduced to less than 1 week.

In a typical series of tests the samples were inserted in turn between mercury electrodes and the current was measured at the end of 2 hours with a 100-volt battery applied. This test was repeated at 5 different temperatures and the ultimate value of dielectric resistance determined. The curves in Fig. 17 show the definite connection between the dielectric resistance and the relative humidity of the atmosphere under which the samples were stored. In Fig. 18 the logarithm of the dielectric resistance of the extreme cases is plotted against temperature (the other cases lie between) and the results indicate that the law connecting dielectric resistance and temperature is the same for all humidities. It is :—

$$R_\theta = R_0 e^{-0\cdot 06\theta}$$

where R_θ = resistance at θ° C., R_0 = resistance at 0° C., and θ = temperature, °C.

In another set of tests samples 1, 2 and 3 were tested at intervals of 1 minute for an hour and the constants

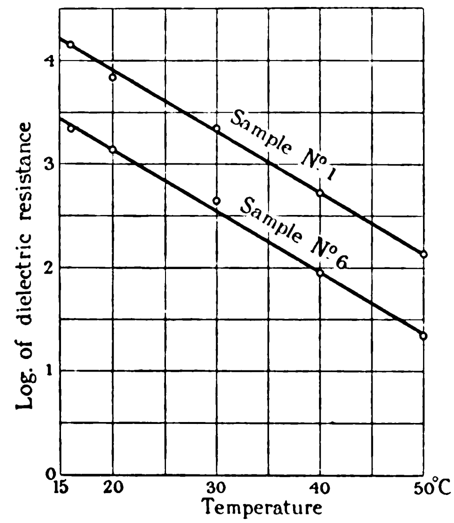

FIG. 18.—Variation of dielectric resistance of conditioned celluloid (82 days' state) with temperature.

in the absorption expression determined. The laws so deduced were as follows :—

Sample No. 1 (dry)

$$I_t = 45\cdot 45 + 14\cdot 55t^{-0\cdot 97}$$

Sample No. 2 (5 per cent relative humidity)

$$I_t = 80\cdot 58 + 24\cdot 82t^{-0\cdot 85}$$

Sample No. 3 (10 per cent relative humidity)

$$I_t = 123\cdot 46 + 27\cdot 54t^{-0\cdot 74}$$

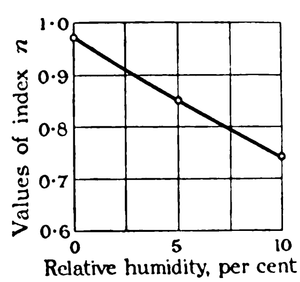

FIG. 19.—Conditioned celluloid (110 days' state). Variation with relative humidity of n in formula $I_t = I + At^{-n}$.

The variation of the index n with the relative humidity of the controlling atmosphere is shown in Fig. 19. It is evident from these results that the presence of moisture lowers the value of n, and it seems probable from the values obtained that if No. 1 sample had been perfectly dried its index would have been unity.

As an example of the effect of temperature on the absorption constants, results obtained on a 30-yard length of 0·1 sq. in. single-core impregnated-paper cable

with 0·1 in. thickness of dielectric will be given. At each of four temperatures from 17° C. to 55° C. a steady pressure of 156 volts was applied for 2 hours and the current/time curves were obtained. From an analysis of these curves the following expressions were obtained for the currents :—

$$I_t = 0\cdot00891 + 0\cdot046t^{-0\cdot885} \text{ (at 17° C.)}$$
$$I_t = 0\cdot0475 + 0\cdot0805t^{-0\cdot645} \text{ (at 29·5° C.)}$$
$$I_t = 0\cdot230 + 0\cdot170t^{-0\cdot508} \text{ (at 41·1° C.)}$$
$$I_t = 1\cdot037 + 0\cdot663t^{-0\cdot341} \text{ (at 55° C.)}$$

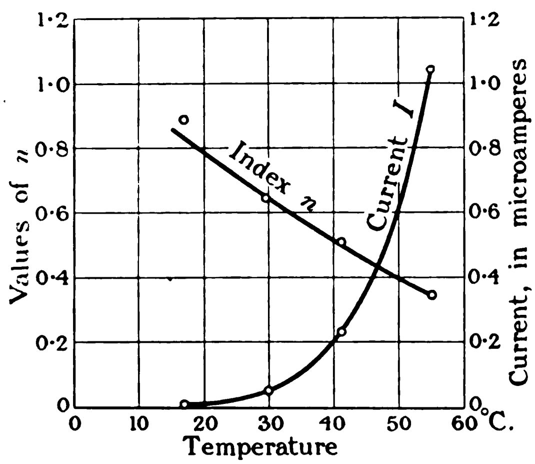

FIG. 20.—Impregnated-paper cable. Variation with temperature of factors n and I in equation $I_t = I + At^{-n}$.

where I_t is the current in microamperes t minutes after the application of the testing voltage.

The values of n and I are plotted in Fig. 20, from which it will be seen that raising the temperature of a paper cable reduces the value of the absorption index.

(IV) FUNDAMENTALS OF A.C. LOSSES.

In Section II the flow of current into an absorptive condenser under a steady unidirectional E.M.F. was considered. Let us now consider what happens when such a condenser is connected to an alternating-current supply. Referring back to the diagram of Fig. 7 and to the d.c. argument, it is evident again that the magnitude of the alternating current flowing will depend on three separate quantities :—

α, the current charging the geometric capacity. This will be a pure wattless current and comparable with that component of the d.c. ballistic capacity current associated with the charge $C E$ (Fig. 7).

β, the current flowing through the dielectric entirely by conduction or leakage.

γ, the current into the capacity associated with absorption or the slow charging of component condensers through resistances.

The component α will be directly proportional to the frequency, and β will be independent of the frequency. The higher the frequency the less will be the charge taken in per cycle under γ, and it is at once evident that the geometric capacity is that calculated from the charging current at infinite frequency. Of the three components of the alternating charging current only β and γ give rise to loss, the first to conduction loss and the second to what is usually styled hysteresis loss (see, for instance, such recent contributions as those of Granier,* Höchstädter,† Frigon,‡ Bruckmann § and Wagner ‖). This idea of hysteresis based on a viscous molecular movement seems to the author to be quite unnecessary for explaining a.c. dielectric losses, and the following outline of an alternative conception, styled for convenience the I^2R theory of dielectric loss, seems to have claims for consideration on the score of simplicity and probability. By this theory, as mentioned in the introduction, dielectric losses are considered to be due to currents flowing through circuits having definite resistances. When an absorptive and leaky condenser

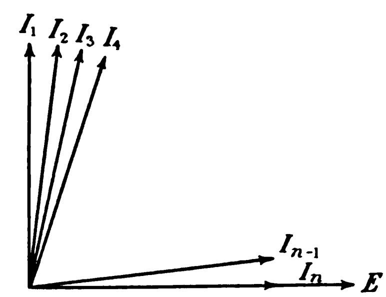

FIG. 21.—Component a.c. vectors in model absorptive dielectric.

is subjected to an alternating E.M.F. the current flowing may be considered to be made up of three distinct components :—

(1) A pure displacement current due to repeated and reversed polarization or elastic displacement of electrons;
(2) An electrolytic conduction from one terminal plate to the other, depending entirely on the movement of free ions;
(3) A combination of (1) and (2) in which elements of distributed or absorbed charge are carried into position by electrolytic conduction.

These three are again associated with α, β and γ above, and as there is complete continuity between them the third assumes supreme importance. It is composed in turn of an infinite number of component currents varying in phase relationship with the E.M.F. from zero to quadrature, as will be clear by referring back to the model of the dielectric in Fig. 6. If the current I_1 flows straight through all the condensers, I_2 first through R_p then through condensers C_q, C_r, C_s, etc., I_3 through R_p, R_q, C_r, C_s, etc., then the vector relationship of the different currents will be as shown in Fig. 21. Each of these imaginary circuits has a distinct power factor ranging from zero with I_1 to unity with I_n (all resistances in series) and in each circuit (apart from the 90° one) energy is dissipated by the flow of current through a resistance. Looked at from this point of

* See Appendix II, (14). † Ibid., (15). ‡ Ibid., (16). § Ibid., (17). ‖ Ibid., (18).

view, it thus becomes evident that a.c. dielectric losses can be considered to be I^2R losses and can be divided into non-cyclical losses, losses due to leakage, and cyclical losses due to absorption. Both presumably have the same origin, but the latter, being due to a current which flows through a condenser in series with the resistance, is thus dependent on the frequency. The value of the resistance in the second case is, of course, experimentally indeterminate.

The above remarks show that a very close connection may exist between the a.c. and d.c. characteristics of a dielectric, and it will be of interest now to investigate the possible interpretation of a.c. dielectric losses in terms of the absorption equation $I_t = I + At^{-n}$ of Section II. In Equation (4) of that Section we have the fundamental expression for the current flowing into a capacity C in series with a resistance R at a time t seconds after the application of an E.M.F. E,

$$i_t = \frac{E}{R}e^{-t/(CR)} = \frac{E}{R}e^{-at}$$

The current flowing into the compound condenser of Fig. 6, representing the absorptive dielectric under d.c. conditions, is then given by a summation of such currents, and Granier has shown * mathematically that the solution leads to a function containing t^{-n}, so connecting up the theoretical considerations with the empirical formula.

If we now consider an alternating E.M.F. applied to our model dielectric and adopt Granier's treatment again, we are led to the following expressions for the in-phase and reactive components of the charging current :—

Energy component $I_w = \frac{1}{2}E_{max.}M\omega^n\Gamma(\frac{1}{2}n)\Gamma(1 - \frac{1}{2}n)$
Reactive component $I_c = \frac{1}{2}E_{max.}M\omega^n\Gamma\frac{1}{2}(1+n)\Gamma\frac{1}{2}(1-n)$

This leads us to a definite expression for the a.c. power factor in terms of the d.c. absorption index n.

For small power factors

$$\cos\phi = \frac{I_w}{I_c} = \frac{\Gamma(\frac{1}{2}n)\Gamma(1 - \frac{1}{2}n)}{\Gamma\frac{1}{2}(1 + n)\Gamma\frac{1}{2}(1 - n)}$$

Values of $\cos\phi$ have been calculated from this expression, and the results are plotted in Fig. 22 to cover a usual range of power factors obtained on impregnated-paper cables. It follows at once from the relationship brought to light in this diagram that, *so far as the losses due to absorption* are concerned, the perfect cable dielectric is that in which the index n in the absorption equation equals unity, giving zero power factor, and the nearer this index approaches its maximum value of unity the lower will be the a.c. power factor. The conclusion also receives considerable support from the experimental results of Section III where the drier and cooler a dielectric the nearer n approaches unity. This is an important conclusion and illustrates the very close connection that does exist between the a.c. and d.c. characteristics of a dielectric. It suggests also a method for the determination of a.c. power factor in which only d.c. tests are applied. The total losses in a given dielectric, however, comprise not only these due to absorption but a further source of loss due to ionization of enclosed air, as will be explained later. The actual power factor determined experimentally will therefore be some value in excess of that given by Fig. 22, by a quantity due to this other cause.

* See Appendix II, (14).

From the above analysis of a.c. conditions it is of interest at this point to make one or two other deductions. The final equation shows that the power factor associated with absorption is independent of frequency, whilst as regards the effect on the losses it follows from the expression for I_w that the energy component and, therefore, the losses due to absorption, are proportional to the nth power of the frequency. In other words, the lower the power factor due to absorption losses the nearer will n be to unity, and the greater will be the dependence of the losses on the frequency. The loss due to direct conduction is, of course, independent of frequency, so that the power factor associated with conduction is inversely proportional to frequency. It follows that in a dielectric having both absorption and

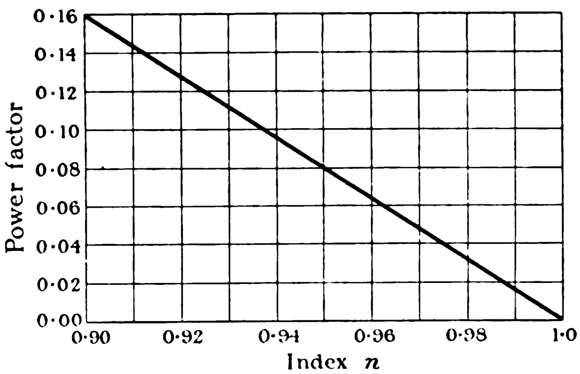

FIG. 22.—Relation between power factor and absorption index (n in equation $I_t = I + At^{-n}$) for losses due to absorption. Calculated from

$$\text{Power factor} = \frac{\Gamma(\frac{1}{2}n)\Gamma(1 - \frac{1}{2}n)}{\Gamma\frac{1}{2}(1 + n)\Gamma\frac{1}{2}(1 - n)}$$

direct leakage the power factor is independent of frequency when the leakage is negligible, and when the leakage predominates over the absorption effect the power factor is inversely proportional to the frequency. Taking 25- and 50-cycle ratios as an illustration, we have

With leakage negligible :

$$\frac{\cos\phi_{25}}{\cos\phi_{50}} = 1$$

With leakage predominating :

$$\frac{\cos\phi_{25}}{\cos\phi_{50}} = 2$$

(V) THE "V" CURVE FOR LOSSES AND POWER FACTOR.

A very important and interesting relationship in the study of cable dielectrics is the variation of dielectric loss with temperature. It has been shown by a number of investigators in America, France, Holland and

Germany during the past few years that over the working temperature-range the dielectric loss in most cables falls to a minimum at about 40°C. and then rises again. The variation when plotted gives rise to what is known as the " V " curve of dielectric loss. The power-factor curve is of the same shape owing to the charging currents being practically unaffected by temperature. So far no satisfactory explanation of the shape of this curve has been given. Clarke and Shanklin,* Proos and others † have attributed the phenomenon to ionization of entrapped gas bubbles. This factor of ionization, which is dealt with more fully later in the paper, does not provide a very satisfactory explanation, and the most promising explanation yet published is that of Höchstädter.‡ He assumes that two types of loss are going on in the dielectric, one a " hysteresis " loss, which definitely falls with rise of temperature, and the other a conduction loss, which has a positive temperature

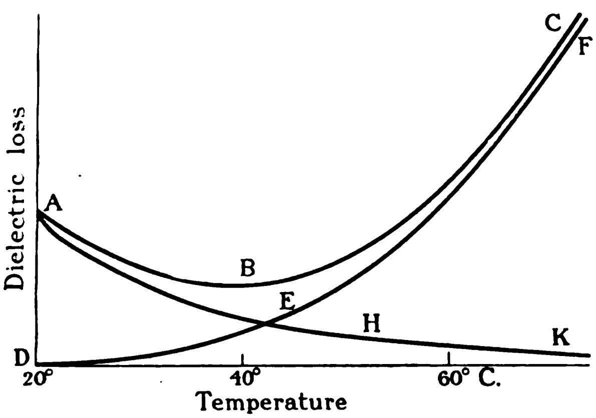

FIG. 23.—The " V " curve resolved into two components.

coefficient. The combination of these two factors produces first a fall and subsequently a rise of the losses as the temperature is increased. Höchstädter takes for granted that the resistance is that obtained by d.c. tests.

The I^2R theory of dielectric losses formulated in an earlier section to replace the hysteresis conception seems to offer a better explanation of the " V " curve. Reverting for a moment to the early part of Section IV, where the component circuits in the model absorptive dielectric of Fig. 6 were considered, we recall that the elementary power factors were in each case proportional to the assumed series resistance. Now this conducting path in a dielectric is of an electrolytic nature with a negative temperature coefficient of resistance. If the temperature be raised the resistance falls and with it the power factor $\cos \phi = \omega CR$. This simple consideration leads at once to an explanation of the " V " curve. Both falling and rising portions are due to change of resistance with temperature. In the former case the resistance is in series with capacity, in the latter it is in parallel. The point is illustrated by Fig. 23, where A B C is the curve obtained experimentally. Curve A H K is the component falling due to the decreasing resistance in series with capacities, and D E F the component attributed to direct leakage.

* See Appendix II, (19). † *Ibid.*, (20). ‡ *Ibid.*, (15).

As the measurement of cable-dielectric power factor is to-day a matter of routine testing, there would be no object in giving here the results of ordinary tests. The

author has, however, carried out a series of tests embodying one or two unique features illustrating the question of the " V " curve, which may be described with

advantage. In most dielectric-loss tests on cables high voltages are employed and, in order to explore a new field, it was decided to carry out a voltage/temperature range of loss tests at quite low voltages. The limits adopted were 50 to 110 volts, and the temperatures varied from 17° C. to 85° C. The cable selected for the test was a 30-yard length of single-core impregnated-paper lead-covered cable with a 0·1 sq. in. conductor and a thickness of dielectric of 0·11 in. A simple modification of the "null" wattmeter method due to Parry and Owen * was adopted for these tests, a Dolezalek electrometer fitted with an extended head and a Wollaston wire suspension being found to give

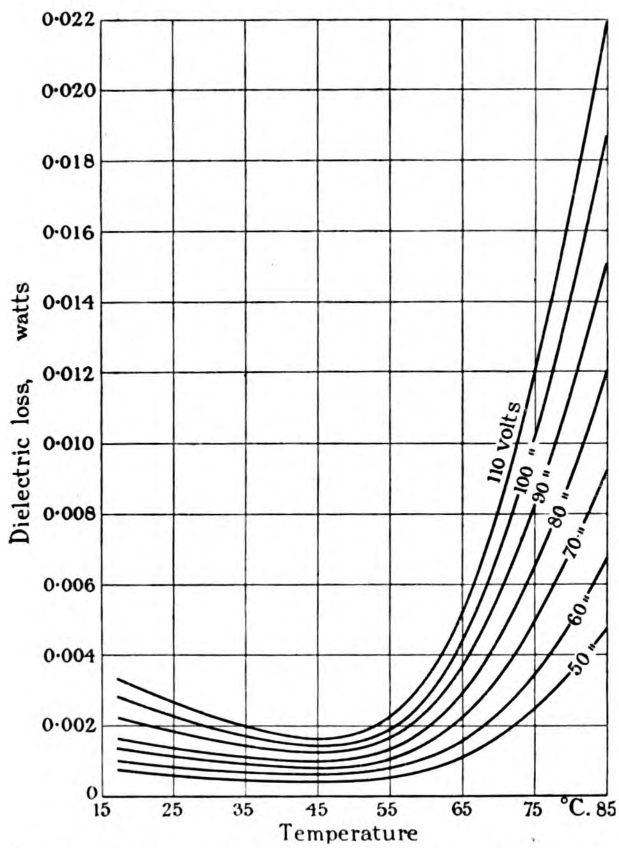

FIG. 24.—Impregnated-paper cable (30 yds., 0·1 sq. in.). Variation of dielectric loss with temperature at low voltages.

the necessary sensitivity for these low-voltage tests. One frequency only, viz. 50 cycles, was adopted and the length of cable was heated by air in an iron tank fitted with circulating fans. The results obtained for loss and charging current are given in Table 4.

In Fig. 24 the dielectric losses are plotted against temperature for the different voltages, and the outstanding feature is the existence of the "V" curve. It is of considerable importance in the explanation of the "V" curve to note that it exists at such low voltages. Fig. 25 gives the power factors plotted from the 110-volt result.

The shape of the "V" curve obtained from power-factor tests on a high-voltage cable may be deliberately

* See Appendix II, (21).

changed by the use of different papers, impregnating compounds, and methods of manufacture. As examples the two curves of Fig. 26 were obtained on two 0·2 sq. in. single-core cables with 0·5 in. thickness of dielectric impregnated with the same compound and manufactured under identical conditions. The only difference between them was that the papers employed for the two lengths were composed of different fibres. Fig. 27 shows the results obtained on another pair of similar cables in which both had the same insulating paper and treatment, but in which different impregnating compounds were employed. The tests recorded in Figs. 26

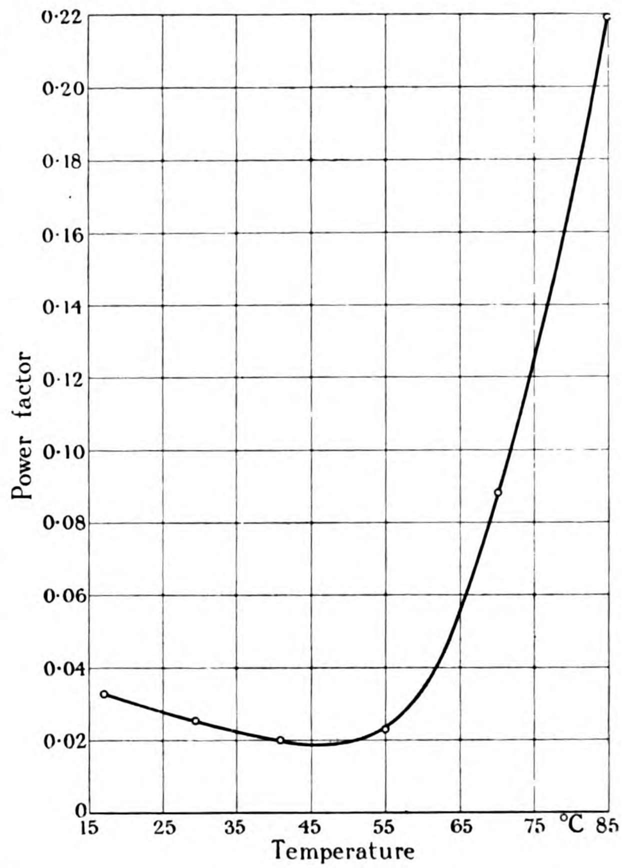

FIG. 25.—Impregnated-paper cable (30-yard length). Variation of power factor with temperature.

and 27 were all carried out at 10 000 volts and 50 cycles. In all cases of impregnated-paper cables, where there is a minimum point in the "V" curve it seems to occur at a temperature about 30° C. to 40° C., but the minimum point can be eliminated entirely by certain treatment. For instance, Fig. 28 shows two curves exhibiting this feature. Cable E was known to be imperfectly dried and the power factor, starting off on an abnormally high value at normal temperature, continues to rise with temperature with no attempt at a minimum point. Cable F was impregnated under special conditions and with a special compound, both of which are known to produce a low power factor. In this case the power factor remains independent of temperature from 20° C. up to 40° C. and then only

rises very slowly. Our present knowledge is insufficient to explain these curious variations in the " V " curve, but they may possibly be based on some peculiarity in the distribution of the elementary currents assumed in our treatment of absorption. If, for instance, the presence of moisture without actually adding direct conduction loads the system of condensers and resistances towards the conductance end of the series, the effect might be to produce a curve like E in Fig. 28. Employing the same mental picture, a curve like F in Fig. 28 could be produced by a " spreading " of the characteristics over the whole of the series. Further reference

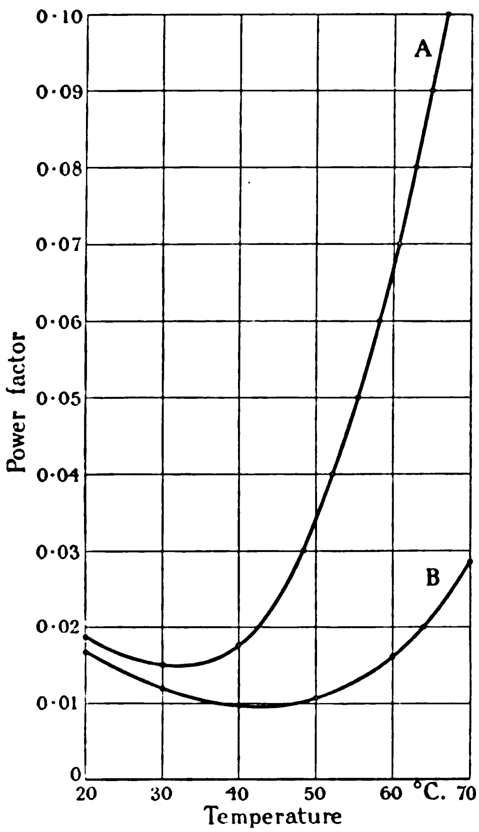

Fig. 26.—Effect of type of paper on power-factor/temperature curve.

is made to this feature in the next Section arising out of the connection between d.c. and a.c. losses.

Considerable light is thrown on the nature of the " V " curve by plotting the results of dielectric-loss tests taken on a length of cable at two different frequencies. Figs. 29 and 30 show the variation of loss and power factor with temperature at 25 and 50 cycles on a length of 33 000-volt cable tested in water over a temperature-range from 50° F. to 150° F. It will be seen that while the 50-cycle loss is approximately double that at 25 cycles at the low temperature, the values run together as the temperature rises and at 150° F. the loss is the same for both frequencies. As the charging current is proportional to the frequency the power-factor curves have the opposite characteristic —they run together at the lower temperature and separate at the higher (see Fig. 30). Considering these curves in the light of the analysis at the end of Section IV, we may be led to deduce that at 50° F. the leakage is negligible and that at 150° F. it predominates,

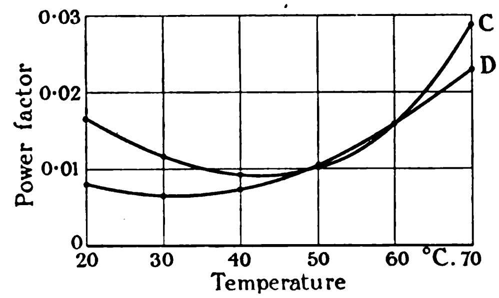

Fig. 27.—Effect of type of compound on power-factor/temperature curve.

but it will be shown in the next Section that this assumption is incorrect. Notwithstanding the fact that the 25- and 50-cycle loss curves run together at the higher temperatures, it does not follow that at this

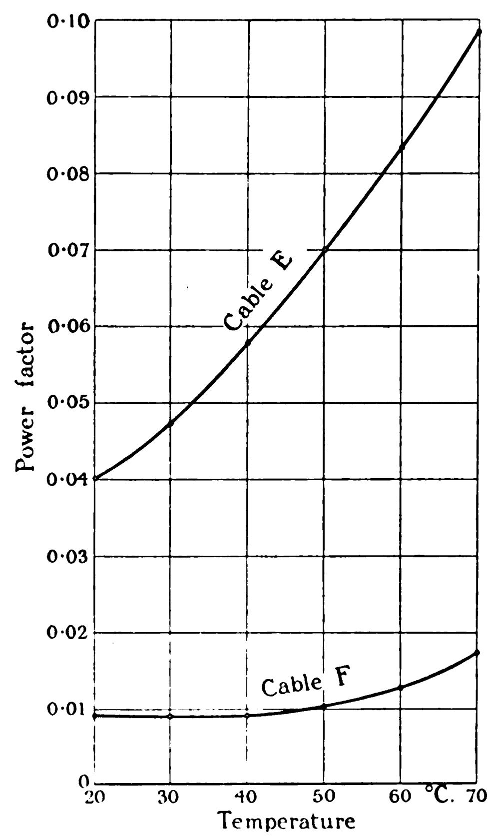

Fig. 28.—Effect of imperfect drying on shape of " V " curve.

temperature the loss is all direct conductance. The evidence is fairly clear that if tests were taken at much lower frequencies than 25, the two curves would separate at 150° F. and for frequencies of the order of

a fraction of 1 per second would separate very widely. The point is further clarified by the experimental results given in the next Section.

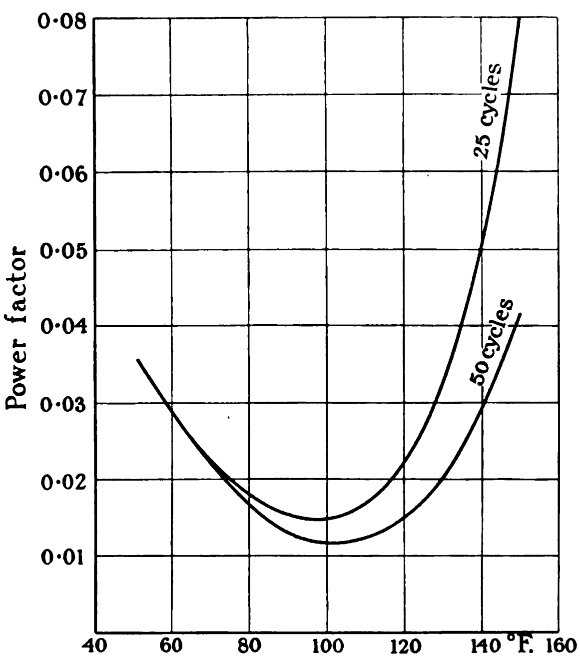

FIG. 30.—Impregnated-paper cable. Variation of power factor with frequency and temperature.

(VI) CONNECTION BETWEEN A.C. AND D.C. LOSSES.

Very little information has been published on the connection between a.c. and d.c. losses in a cable dielectric, but as the question is of considerable interest in connection with the other characteristics under discussion, some steady-current tests have been carried out on the cable referred to in the previous Section (see Table 4) and the connection between the a.c. and d.c. results has been calculated. Check-tests have also been carried out by an entirely different method in order to confirm the important conclusions, but the results from the two sets of tests will be given separately. Addenbrooke has given * a number of ratios of d.c. to a.c. losses on a wide range of dielectrics but only at one temperature, and to broaden the scope of the present tests a temperature range has been

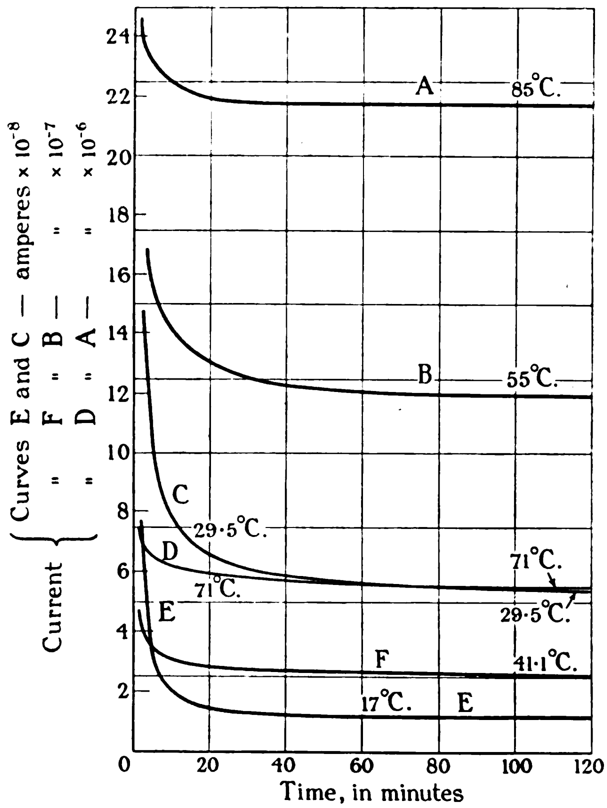

FIG .31.—Impregnated-paper cable (30 yds., 0·1 sq. in., single-core). Variation of d.c. charging current with time.

taken. The steady charging-currents were also recorded at different time-intervals up to 2 hours in the first series and up to 5 minutes in the second, instead of after the attainment of steady conditions as in Addenbrooke's experiments.

Applying d.c. tests to the cable of Table 4 gave the series of current/time curves shown in Fig. 31. Fig. 32 shows the variation of dielectric resistance with temperature for different time-intervals, and Fig. 33 the same plotted logarithmically. Taking the expression

$$R_\theta = R_0 e^{-K\theta}$$

as representing the variation of resistance with temperature, it is interesting to note in passing that the

coefficient K is not the same for all time-intervals, nor is it constant over the temperature range for any one time-interval. At the lower temperature it has a value of 0·045 calculated on the 2-minute readings and 0·055 calculated on the 2-hour readings, whilst in the neighbourhood of 80° C. the values are 0·038 and 0·045 respectively.

Table 5 summarizes the results obtained by comparing the d.c. tests just described and the a.c. tests of the previous Section taken on the same piece of cable.

These results establish several important points. In the first place it is seen that the ratio of a.c. to d.c. losses in a paper cable at low voltages varies between

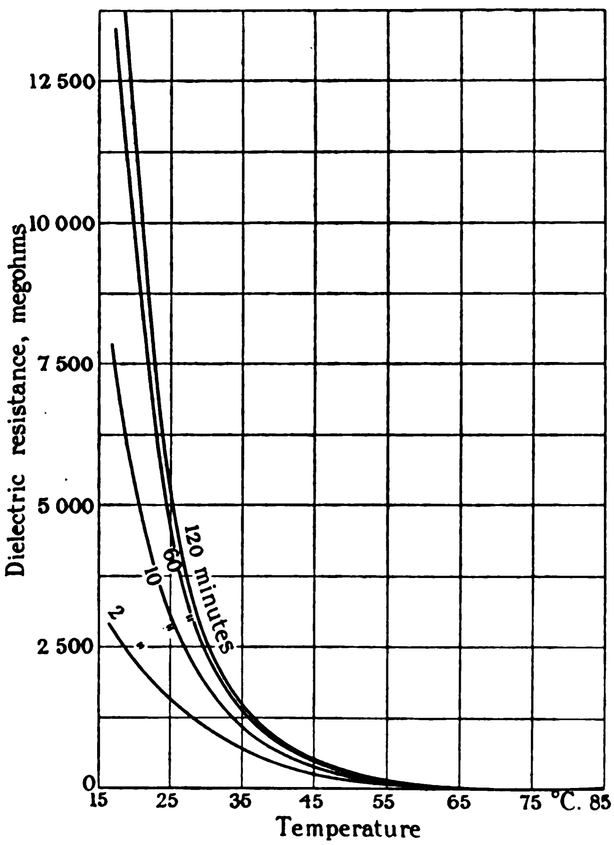

FIG 32.—Impregnated-paper cable. Variation of dielectric resistance with temperature for different time-intervals.

wide limits (in this case from 3 460 to 12·3) depending on the temperature and the time of charging under d.c. conditions. Also the duration of the d.c. charge has a more marked effect on the ratio at low temperatures than at the high ones.

The most important result of all is in connection with the " V " curve explanation advanced in a previous Section. The view sometimes expressed that at the higher working temperatures of paper cables the greater part of the dielectric loss can be attributed to conduction based on d.c. values seems to be wrong. The results obtained in these tests indicate that at 85° C., which is in excess of normal maximum cable temperatures, the a.c. loss is more than 13 times the value calculated on

the d.c. conductance, even on 120-minute d.c. results. As the conductance was still falling at the end of this time the ratio of a.c. to d.c. loss at 85° C., based on final conductance, must have considerably exceeded the value of 13. The results are plotted in Fig. 34 and show at once that around 80° C. by far the greater part of the 50-cycle losses are cyclical. Following up the argument of Section IV, the difference between the ordinates of the upper and lower curves represents the I^2R losses due to the absorption currents flowing through component resistances, and it seems to follow that the absorption losses have definitely in themselves the two components to produce the dipping curve.

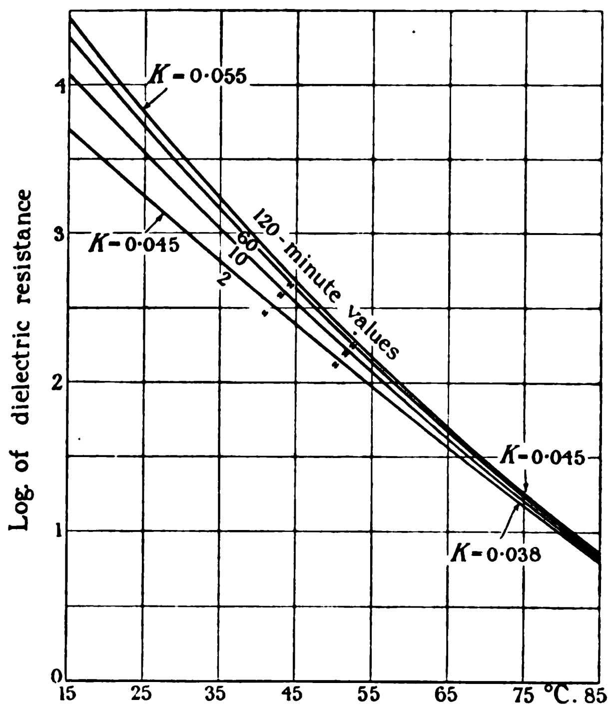

FIG. 33.—Impregnated-paper cable. Effect on the temperature coefficient of resistance of the time-interval adopted

In the second series of tests a length of 550 yards of 0·2 sq. in. low-tension single lead-covered cable was placed in a tank of water heated by steam to different temperatures from 21·5° C. to 70° C. The d.c. charging current from a 500-volt battery was measured at each temperature at 15-second intervals up to 5 minutes and the dielectric loss at 500 volts alternating current (50 cycles) was also measured at the same temperatures by means of a dynamometer wattmeter. The results obtained are given in Tables 6 and 7.

In Fig. 35 the power factor for this cable is plotted against temperature, showing that the results again confirm the fact that the " V " curve exists at these low voltages.

Table 8 gives the ratio of a.c. to d.c. losses for this cable at different temperatures and calculated on different d.c. time-intervals from 15 seconds to 5 minutes. It confirms in a remarkable way the deductions made on the results of similar tests carried out by entirely

different methods and given in the earlier part of the Section—that at any ordinary cable temperature the a.c. losses cannot be approximately attributed to d.c. conduction. At 70° C. the 50-cycle a.c. losses in this cable are more than 24 times the d.c. losses.

Attempts have been made by some investigators to throw light on the relationship between a.c. and d.c. losses by determining the effect of frequency under the a.c. conditions. Addenbrooke, in the paper already quoted, showed that, except for very low frequencies of the order of 1 or 2 cycles per second, the loss on a large number of different dielectrics was a linear function of the frequency n and that if expressed as

$$\text{Watts} = A + Bn$$

the higher class of dielectrics gave the lower values of A. The author has examined this characteristic for impregnated-paper cables at different temperatures and at two frequencies. A typical set of results is plotted in Fig. 36 for a length of 3-core super-tension cable subjected to 25- and 50-cycle loss tests while immersed in water at various temperatures from 52° F. to 150° F.

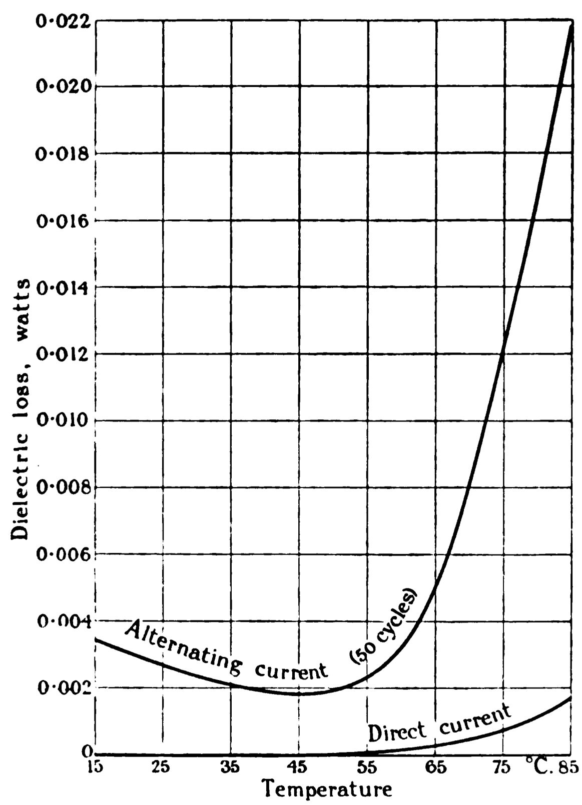

FIG 34.—Impregnated-paper cable. Relation between a.c. and d.c. losses.

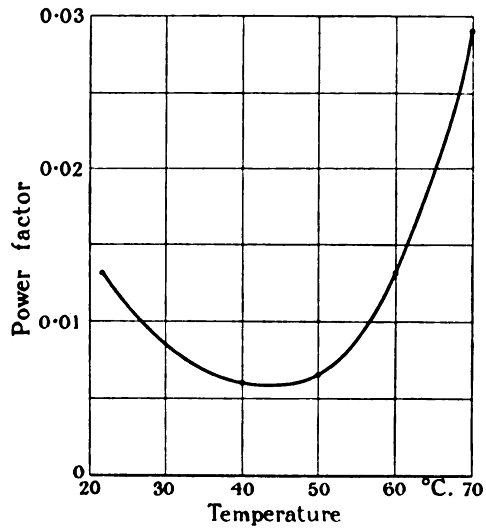

FIG. 35.—Impregnated-paper cable. Relation between low-voltage power factor and temperature.

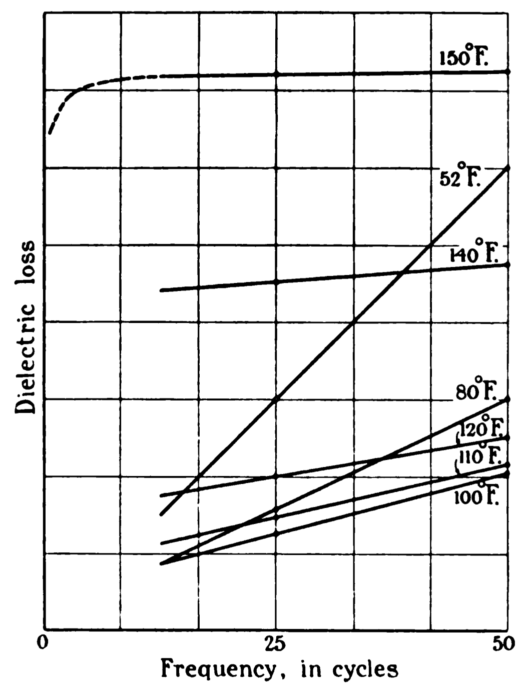

FIG. 36.—Impregnated-paper cable. Variation of dielectric loss with frequency and temperature.

A larger number of frequencies should be taken to make the results more complete, but as they stand the curves show that the characteristic noted by Addenbrooke for different dielectrics is also brought to light by temperature variation in one and the same dielectric. At the low temperature the line connecting 25- and 50-cycle losses passes almost through the origin of co-ordinates, the variation with frequency being high, i.e. A is 0 and B is a maximum. As the temperature rises the slope of the line decreases and the intercept at zero frequency increases, whilst at 150° F. the frequency makes very little difference to the magnitude of the losses. It cannot be assumed, however, from these results that all the loss at 150° F. is "conductance" loss, as is frequently done. The higher-temperature curves in Fig. 36 suggest that at zero frequency, that is, under d.c. conditions, the loss is approximately the same as the a.c. loss, but from the results of actual tests recorded earlier in this Section it is clear that the direct conduction has a very much lower value. The anomaly is is believed to be due to the presence of air entrapped within the cable dielectric. As air has a definite ionizing potential under given pressure conditions it follows that a cable exhibiting ionization at normal voltages should show none at low voltages. Examination of the results of the low-voltage tests given in Section V shows this to be the case. There is no ionization on this cable at 110 volts. The losses for these tests are plotted logarithmically against voltage in Fig. 37, and the results justify very exactly an expression

$$W = PE^m$$

where W = loss in watts,
E = applied voltage, and
P and m are constants. (m is found to be equal to 2 very exactly.)

In other words, the value of W/E^2, sometimes called the a.c. conductance, is constant over the voltage range when measured at a low voltage.

only apparent, however, and would no doubt be cleared up by loss measurements at frequencies of the order of a fraction of a cycle per second. It is evident that the 150° curve at the low frequencies would fall as shown by the dotted line down to the d.c. value.

(VII) Rise of Power Factor with Voltage.

In addition to the variation of power factor with temperature the effect of voltage is of importance. If the power factor of a dielectric is independent of voltage, then, as

$$\begin{aligned}\text{Watts} &= EI\cos\phi\\ &= E^2\omega C\cos\phi\end{aligned}$$

the dielectric losses are proportional to the square of the voltage. Now this condition is not found to exist in ordinary loss tests on high-voltage cables. The power factor usually rises with voltage, and the losses increase at a greater rate than with the square. This phenomenon is generally known as "ionization" and

In order to examine the probability of the dependence of W/E^2 upon voltage being due to ionization of entrapped air, it is of interest to glance at the phenomena met with in physical experiments on gases, and a series of tests carried out by Mackay * is of considerable interest in this respect. This investigator set up a piece of apparatus in which electrons freed from a nickel target by ultra-violet light were accelerated by means of a variable electric field towards an enclosure containing the gas to be tested. A platinum wire collected the positive ions produced by ionization and the rate of collection was measured by an electrometer and stop-watch. Curves produced connecting the ionizing voltage and the rate of charging of the electrometer were of the general form shown in Fig. 38. That is, below a certain voltage V no ionization of the gas occurred, but beyond that voltage, which was a definite point characteristic of the particular gas, the rate of ionization increased with the voltage. For certain

* See Appendix II, (23).

gases, e.g. oxygen, this investigator showed that there was a second bend in the curve at a higher voltage.

In view of these experiments it is interesting to

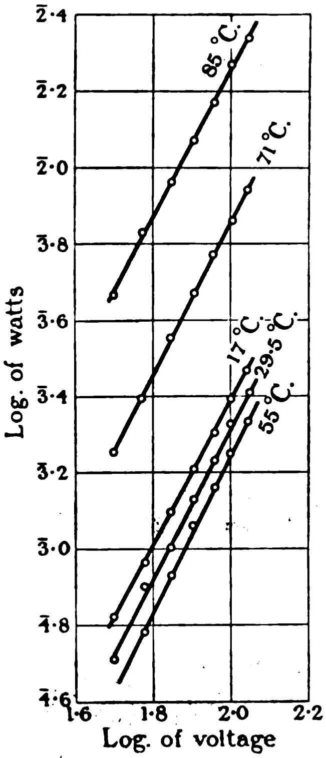

FIG. 37.—Impregnated-paper cable. Variation of losses with voltage at low voltages (50–110 volts, 50 cycles).

examine some of the published results on the ionization of high-voltage cables. Clarke and Shanklin,* and Smit Kleine, Proos and Van Staveren † have investi-

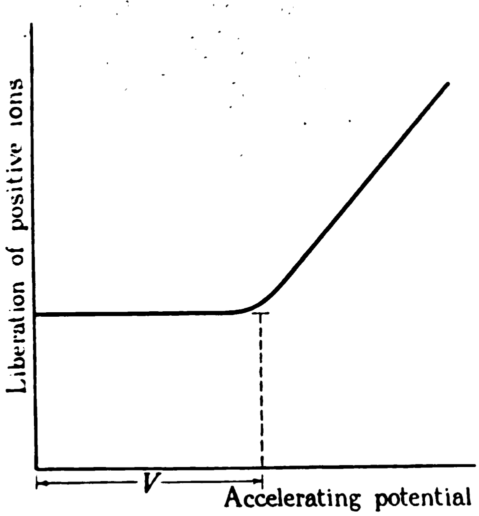

FIG. 38.—Ionizing curve for gas.

gated the question very fully, and have produced curves connecting the power factor of a cable dielectric and the applied voltage which are identical in form with those of Fig. 38. They (particularly the second group of investigators) find that a very sharp cut-off point is exhibited when the power factor or the value of W/E^2, which is the product of the power factor, frequency and capacity, are plotted against voltage. For several reasons the author has always been chary of accepting these results for general application. In the first place, as we have just seen, where a laboratory experiment is set up to determine the ionizing point of a clean uniform gas all at one temperature and pressure, the point of deflection is not sharp owing to all the electrons not having the same energy. In the second place, Dubsky has shown * that the dimensions of an air pocket within a mass of insulating material have a very considerable influence on the ionizing potential. Again, Mackay showed in the experiments just described that different gases had entirely different ionizing potentials. Taking into account these three factors it is difficult to imagine how, in a length of cable, a collection of different pockets of various dimensions, containing different gases and, owing to their different distances from the conductor, subjected

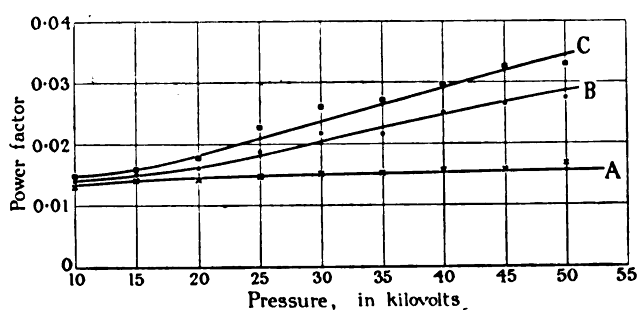

FIG. 39.—Effect of current on power-factor/voltage curve. Single lead-covered 0·2 sq. in. cable.

Curve A.—As manufactured.
Curve B.—After 540 amps. for 4 hours and cooled down.
Curve C.—After 825 amps. for 2 hours and cooled down.

to different ionizing voltages, should all exhibit ionization at one and the same voltage. As a matter of fact, in actual tests on super-tension cables it is unusual to find a sharp bend in the power-factor/voltage curve.

An important factor in any study of the connection between power factor and voltage is the effect of overloading a cable. The tests taken immediately after manufacture may give only a very slight rise of power factor with voltage, but if a heavy current be passed through the cable so as to cause undue heating of the dielectric and expansion of the lead, then the repeat tests carried out on the length after cooling down will give a much sharper rise. This is illustrated by a typical example in Fig. 39, for a 0·2 sq. in. single-conductor lead-covered impregnated-paper cable. After the first series of tests had been taken a current of 540 amperes was passed through the conductor for 4 hours and then the whole cable was allowed to cool to its original temperature and stand for some days, after which the second set of figures was obtained. A current of 825 amperes was then passed through the cable for 2 hours and the loss tests were repeated after

* See Appendix II, (19). † *Ibid.*, (20).

* See Appendix II, (24).

cooling. The third curve shows the results obtained this time.

In view of the dependence of power factor on the

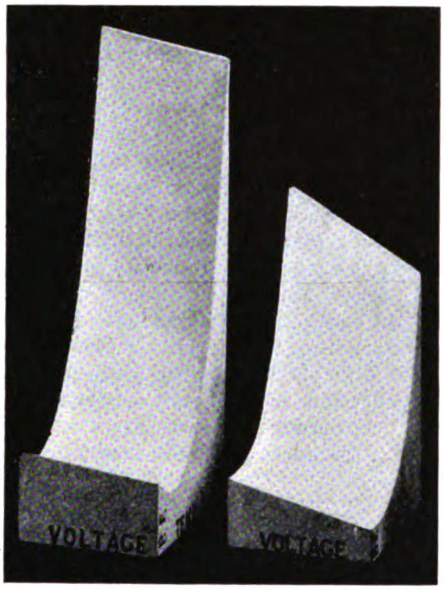

FIG. 40.—Three-dimension diagrams to illustrate the connection between power factor, temperature and voltage. The two curves show the difference brought about by changes in manufacture.

two variables, temperature and voltage, and the need for a quick method of comparing the results on a number of cables, the author has found it convenient to employ solid diagrams for plotting the results. The values of power factor at any one voltage are plotted against temperature, and the curves so formed are cut out of 5-ply wood $\frac{1}{4}$ in. thick. Similar curves are produced for each of the other voltages employed in a series of

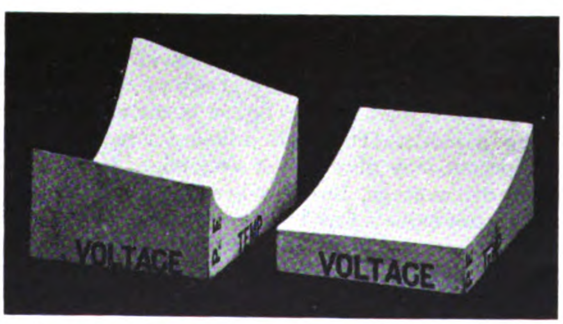

FIG. 41.—Three-dimension diagrams to illustrate the connection between power factor, temperature and voltage. The two curves show the difference brought about by changes in manufacture. These lower values and flatter curves are obtained by the use of special compounds.

tests, and when they are assembled the resulting block gives a very useful bird's-eye view of these particular electrical properties of the cable. In the determination of the effect of modifications in materials or manufacture when carrying out research work on cables, a comparison of two or more such blocks is much easier than the comparison of masses of figures. Figs. 40 and 41 show four sets of results plotted in this way and

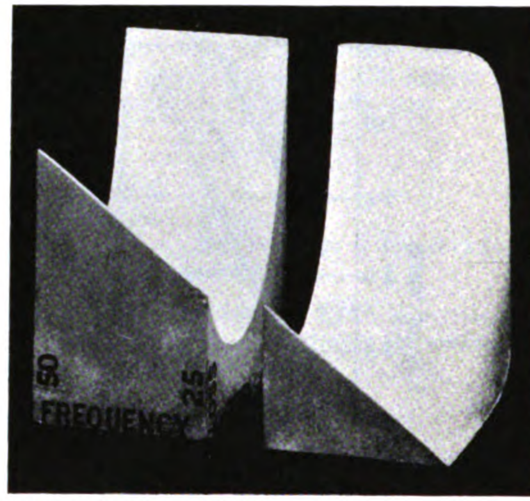

FIG. 42.—Connection between dielectric loss, temperature and frequency from 25 to 50 cycles, with a suggestion for the lower frequencies.

FIG. 43.—Connection between power factor, temperature and frequency from 25 to 50 cycles, with a suggestion for the lower frequencies.

demonstrate the wide variation in shape of the solid power factor-voltage-temperature diagram which may be effected by alterations of materials and processes. The scales of all four diagrams are the same.

The use of similar solid diagrams is also helpful in forming an idea of what happens to the characteristics outside the range actually tested; the left-hand block in Fig. 42, for example, shows a model used to demonstrate the variation of dielectric loss with temperature and frequency, the results being based on 25-cycle and 50-cycle tests. The right-hand block in the same figure shows the probable variation of loss with frequency from 25 cycles downwards to direct-current conditions, and in this connection should be compared with the results illustrated in Fig. 34.

Fig. 43 indicates the manner in which the power factor varies with frequency and temperature, the left-hand block being based on actual test-results, and the right-hand block being a suggestion as to how this quantity varies at the lower frequencies.

(VIII) Breakdown. The Time-Voltage Relationship.

For many years it has been the custom to speak of the breakdown strength of a cable as though it were a definite constant characteristic. We have talked about maximum dielectric stresses of so much—200 kV/cm for instance—and specified that a cable shall withstand such a stress before failure. At the same time anyone who has had experience of cable testing knows that a voltage applied suddenly produces quite different results from one applied slowly, and it has consequently been usual for some time to specify duration pressure tests of 15 or 30 minutes in addition to quick breakdown. It is only quite recently, however, that the exact relationship between breakdown voltage and the time of application to the cable has called for detailed study. One factor leading to the investigation of the matter has been the failure of super-tension cables in operation many months after installation, although they passed the most stringent tests before leaving the factory and on completion of laying. This time effect is quite a new phenomenon and so far very little has been published on the subject. Perhaps the most useful contribution made up to the present time is that by F. M. Clark.* This writer shows that if a fibrous insulating material, such as impregnated paper, be subjected to a succession of voltage applications below the value necessary to cause failure, the dielectric being allowed considerable time for recovery between the applications, its power of resisting a straight breakdown test may be very much impaired. This is a discovery of first-rate importance in the operation of cables. It means that indiscriminate high-pressure tests may seriously affect the life of the cable under working voltage. It also means that a succession of pressure-rises due to surges or lightning on connected open lines, although individually resulting in no failure, may make the cable progressively less able to withstand such voltages.

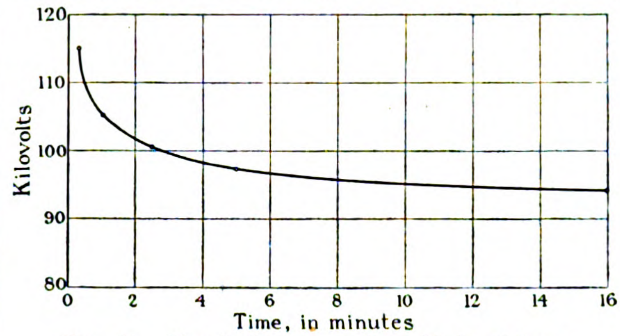

Fig. 44.—Time/voltage curve for cable breakdown.

Developing these ideas the author has made it a practice for some time past to produce time/voltage curves for all cables made under research conditions, with a view to augmenting the information obtained in other tests. The method adopted is to cut up a uniform length of cable into six or eight pieces, each 5 yards long, apply a quick breakdown voltage at a definite rate of increase and then apply 90, 85, 80 per cent, etc., of the value so obtained to the remaining pieces in turn. The time during which the piece holds the

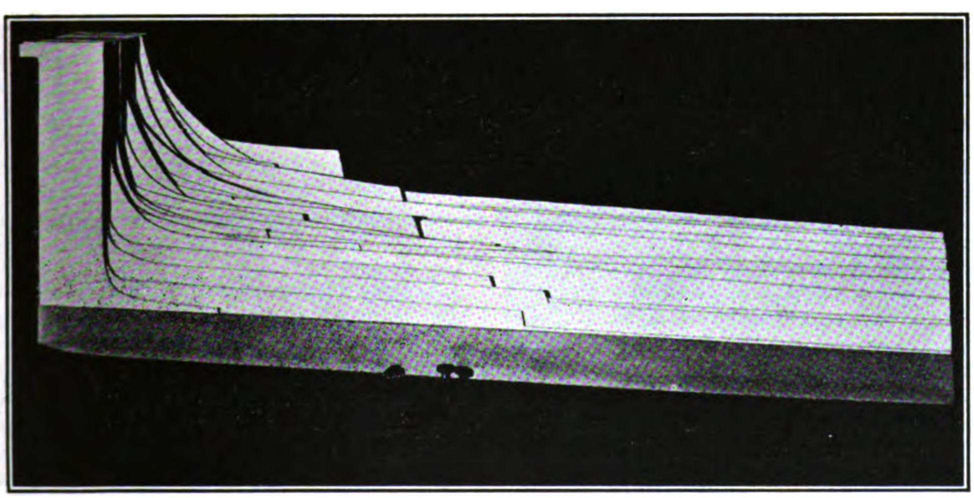

Fig. 45.—Collection of models of time/voltage curves.

* See Appendix II, (25).

voltage is recorded and, as the lower the voltage the longer the time, plotting the results gives a curve as shown in Fig. 44. The slope of the curve is very steep for short times and gradually flattens out until quite a small reduction in the voltage adds enormously to the time that the cable will stand up under it.

Fig. 45 shows a collection of curves produced in this way for experimental cables made up in the investigation of different materials and processes. As an indication of the order of the figures obtained, a good modern 33 000-volt cable will hold 75 000 volts three-phase at normal temperatures for 50 or 60 hours before failure.

It is not clear from these curves whether they ultimately flatten out to a definite voltage or continue to fall at a decreasing rate for ever. By plotting the results in another way, however, we are led to the conclusion that a given cable has a definite voltage below which it would hold up for ever. The method was described by Owen a few months ago.* Instead of plotting the breakdown voltages against time the values are plotted against the inverse fourth root of time. Fig. 46 shows a number of results obtained on single-core and 3-core cables obtained in this way, and it will be seen that the points lie reasonably on straight lines. The greatest merit of the use of this method of plotting seems to be that with it one can deduce with reasonable accuracy the probable voltage that a cable will hold indefinitely. As time progresses from right to left in the diagram the results of tests extending over a few hours only can be used to obtain the straight line which intercepts the axis at the equivalent of infinite time in a definite value of the breakdown voltage for that time. X is the value which would break down the cable if kept on for some centuries, and any value below that would be safe to adopt as a working voltage for the cable in question.

In fairness two weaknesses of the method should be pointed out at once. The safe working voltage so deduced presumes that :—

(1) The sample cut up and broken down is representative of the weakest part of the cable.

(2) The samples are in the same condition as they would be if they had been subjected to the same heating and cooling due to rise and fall of load as would obtain in the practical use of the cable.

Objection No (1) is not very serious—there is little variation between consecutive 5-yard pieces of a well-made cable; but objection No. (2) is not so lightly disposed of. The effect of repeated heating and cooling as shown in connection with the rise of power factor with voltage may also affect the long-time safe voltage. In the present state of our knowledge the best that we can do practically is to determine the point as described and then allow a factor of safety.

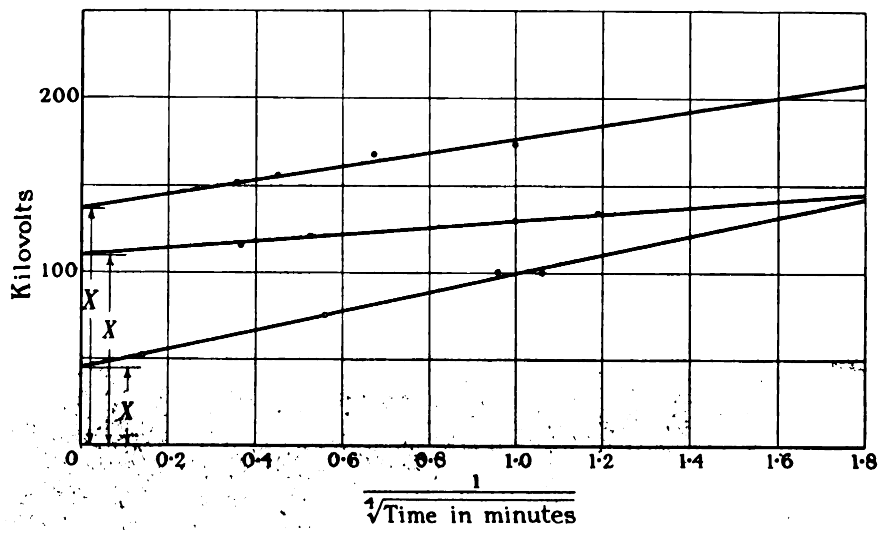

FIG. 46.—Alternative method of plotting time/voltage relationship.

A correct appreciation of this time/voltage relationship leads to an important matter in connection with the operation of large high-voltage cable systems. It is widely appreciated to-day that such systems are liable to obscure pressure-rises in ordinary conditions of service, due to various causes, and that such phenomena are at the root of certain types of cable and transformer failure. As a result there is a tendency to install surge absorbers or protectors, and some very interesting results have already been published in connection with their use. Mr. Partridge, for instance, has shown * that by the installation of a very simple device on a single-phase system working at 10 500 volts to earth he has reduced the number of failures of mains and transformers in a remarkable way. He employs a series of spark-gaps in conjunction with a limiting resistance so arranged as to spark over at 35 per cent over-voltage. He showed by observations over a period of 5 years that the apparatus operated 332 times. If, then, a dielectric may be subjected periodically to these

* See Appendix II, (26).

* See Appendix II, (36).

voltages estimated to rise to several times the working voltage, the results of F. M. Clark quoted at the beginning of this Section, taken in conjunction with considerations of the shape of the time/voltage curve, show that they will have a deteriorating influence greatly in excess of that due to the working voltage. In view of this it is evident that any precautions that can be taken to control the extent of pressure-rises on a cable system are well worth consideration.

(IX) The Nature of Cable Breakdown.

Our views on the nature of cable breakdown are very incomplete. For a long time it has been considered that when the dielectric stress at any point exceeds a certain value that particular part of the material is destroyed as an insulator by molecular disruption. The application of this theory in cable work has led to considerable difficulty. In a concentric condenser such as a single-core cable it leads to the failure being a function of the maximum stress at the conductor, but so far no strong experimental evidence has been advanced in support of this relationship to explain the failure of impregnated-paper cables. In fact quite a reasonable argument has been made by Fernie for attributing failure to the minimum stress at the outer boundary of the dielectric.* An explanation of quite a different kind has been advanced by Wagner † and concurrently by Hayden and Steinmetz.‡ These investigators have attributed the breakdown to a heating of local paths through the insulation, which, having a negative temperature coefficient, may under certain conditions rise to a temperature sufficiently high to cause charring and immediate loss of insulating properties. A weakness of this theory, however, lies in the fact that a certain critical voltage called the "puncture voltage" is assumed to be necessary for puncture, and the existence of the time/voltage relationship covered by the previous Section of this paper is ignored. By the pyro-electric theory, as it is styled, it would only be necessary to allow a cable to cool down after a prolonged high-voltage test and it would be as good as new, but the experiments already described show that this is not so. Without producing breakdown it is definitely established that a high-voltage test may damage the insulation.

As the result of a careful study of the conditions of individual papers taken from different parts of cables both broken down on test and subjected to prolonged pressure test, the author is led to formulate a theory of cable failure differing somewhat from those already advanced. Höchstädter § has discussed failure through tangential stresses, but the true explanation seems to lie somewhere between the tangential-stress theory of Höchstädter and the pyro-electric theory of Wagner.

The detailed examination of cables caught before actual failure in a pressure test reveals the following facts :—

(i) In a single-core cable at any point throughout the dielectric between the conductor and the lead sheath there may be a few consecutive papers showing signs of charring.

* See Appendix II, (27). † *Ibid.*, (28). ‡ *Ibid.*, (29). § *Ibid.*, (30).

(ii) The papers above and below those damaged may be in perfect condition.

(iii) The charred condition is restricted neither to the proximity of the conductor nor to that of the lead. It may occur anywhere in the dielectric.

(iv) In a 3-core cable the same conditions hold, but, generally speaking, the charring occurs mostly on the outer core papers and either along the line of contact between cores or towards the centre of the cable.

(v) In a 3-core cable the belt papers rarely (one hesitates to say never, though this would probably be a correct word) show signs of charring.

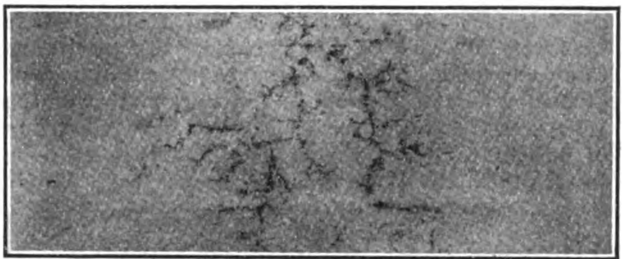

Fig. 47.

The general appearance of this deterioration on papers from a single-core cable is shown in Figs. 47 and 48, the second one showing the action in a more advanced state. Figs. 49 and 50 show two stages in the progress of this deterioration in the papers from a 3-core cable, and similar examples have been given by the author elsewhere.*

In the earlier part of this paper it was contended

Fig. 48.

that all a.c. dielectric losses are I^2R losses, the cyclical ones being due to the dissipation of energy when a current charging a condenser flows through a resistance. Now no cable dielectric is perfectly homogeneous, and to fix our views let us consider what goes on in a single-core cable. If the dielectric were perfect and uniform the lines of current-flow would be radial throughout and the current would be a pure displacement current. In a practical cable, however, we have two important departures from ideal conditions. We have :—

(*a*) A layered dielectric where each layer contains paper fibres which no doubt have tiny quantities of moisture and so form electrolytic conducting paths perpendicular to the theoretical direction of the electric field.

* See Appendix II, (31).

(b) Inequalities in the contact between layers which result in a difference of impedance between one radial path and another.

Fig. 51 shows the result that may be expected from such considerations. Suppose that at point P there is a small patch where the two layers of paper are not making

FIG. 49.

as efficient contact with one another as they do elsewhere. This weakness may be due to slackness of the papers, to an impervious spot in the paper preventing passage of the impregnating compound, or to imperfect drying. Whatever the cause, the result is to deflect the lines of flow of the displacement current and in so doing to turn them out of the radial direction. Immediately,

FIG. 50.

the power factor of this part of the dielectric rises as the current flows along the paper fibres, energy is dissipated and the resulting heat chars the papers and compound in the manner shown in Figs. 47, 48, 49 and 50.

The probable consequence of such action can be

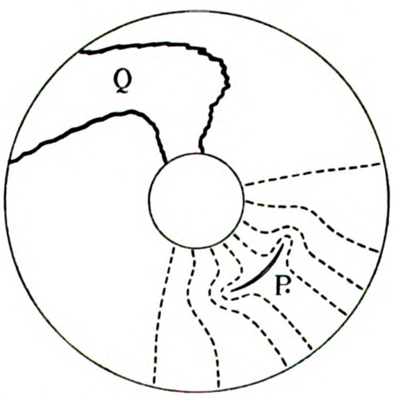

FIG. 51.—Effect of irregularity on dielectric current.

illustrated as follows. If we lay a small cylindrical electrode on a layer of, say, half a dozen impregnated papers which in turn are lying on a flat metal plate, and then apply a pressure of, say, 10 000 volts between the electrode and the plate, we find that after a few hours the free compound has been driven from the upper paper for a space of $\frac{1}{2}$ in. or so all round the electrode. The compound travels across the direction of the field from parts where its strength is high to parts where the field is weaker. It is reasonable to assume, then, that in our hypothetical fault P the compound would be driven away from the edges of the weak patch which would so spread and, given time, ultimately move backwards and forwards, linking up with other similar spots until it opened up an irregular path from the conductor to the sheath. Further supporting evidence for this theory is given by the shapes of charred holes in single-core cable breakdowns. They frequently emerge on the outer surface in a direction oblique to the radius, as at Q.

This same I^2R theory of dielectric losses will explain why during a prolonged test on a 3-core cable the outer core papers become charred where the cores are in contact. It is because the wormings form an inferior contact between the cores; the displacement currents consequently crowd into the line of contact between the cores themselves and in so doing are partially turned from a radial to a circumferential direction, flow along the fibres instead of across them, and so raise the local power factor and heating. Mr. Beaver has shown * that impregnating a 3-core cable made up of previously impregnated papers both on the cores and wormings reduces the power factor. He attributed the difference to the loss in the unimpregnated wormings, but from the consideration advanced in this paper it would appear that in such a case impregnation filled the wormings with compound, created a better contact between them and the cores, and withdrew the displacement current from the line of contact between cores, turning it into directions across the fibres instead of along them. This reduced the conduction losses in the fibres and so lowered the power factor.

The claims of this theory of breakdown in impregnated-paper cables over any theory previously advanced may be briefly summarized by the way in which it explains the following phenomena :—

(i) The presence of the charred patches in isolated places after prolonged test.
(ii) The peculiar designs assumed by the charring.
(iii) The time/voltage relationship.
(iv) The non-recovery, even after cooling.
(v) The shape of burn-outs in thick dielectrics.
(vi) The difficulty in employing the logarithmic formula connecting dielectric stress, dimensions and breakdown voltage.

It is of interest to note, before closing this Section, the bearing which this theory has on the question of intersheaths in cylindrical condensers, such as single-core cables. Suppose that just on the inside or on the outside of the weak spot P there were a metal intersheath. The effect of this would be to alter the shape of the current path in such a way as to reduce the change in stress at the edges of the patch and to turn the currents more into a radial direction. This would reduce the tendency of the weakness to spread, would reduce the

* See Appendix II, (32).

I^2R loss and, without any question of the sheath being held at a definite potential for grading purposes, would strengthen the dielectric simply by its presence.

(X) Assessment of Cable Quality.

A good deal of attention is being given to-day by cable purchasers to the drafting of specifications and tests in order to ensure that the cable shall meet all the conditions of service satisfactorily. These activities may be broadly divided into :—

(i) Instructions to the cable maker as to the making of the cable.
(ii) Details of tests to be applied to the finished cable.

Under (i) naturally fall the general design of the cable, the thickness of dielectric between cores and between cores and earth, the thickness of lead, type and number of armouring wires, details of serving, etc. It was usual, until recently, to specify the paper, but it is now generally appreciated that the established views on this material are not necessarily the correct ones, and that the cable maker is in the best position to settle the matter. The compounds to be used are also sometimes indicated, but, apart from fixing the design or approving a design submitted by the cable maker, there is a good deal to be said for matters under (i) being left to the manufacturer.

In considering (ii) above, it will be appreciated from the previous contents of this paper that the tests which are suitable for cables to work on lower voltage are no longer suitable at **33 000** volts and upwards. The dielectric-resistance test certainly indicates the dryness of a cable and, in spite of its obvious academic weakness as shown in the early Sections, is a valuable test of quality of a finished cable. It has become fashionable during the past few years to decry high resistance values, and certainly a cable with a high dielectric-resistance 1-minute value may be an inferior cable as regards performance. At the same time, a high value of dielectric resistance is not in itself evidence of bad quality. The important question to determine is whether the cable suffers in other respects owing to the means which have been taken to produce the high resistance, but there are other tests to show up this factor.

Dielectric-loss tests are rightly established as a criterion of quality, but it should be remembered that they only indicate the average condition over the length of the cable and may not show up a local weakness. Also, a low dielectric loss may be obtained by the use of a compound so thin that, after some months of service, parts of the cable are drained dry. In taking dielectric-loss tests it is usual to watch the increase of power factor with voltage, but in view of the uncertain effects of heating already demonstrated no very stringent conditions can be imposed in this respect at present. Loss tests over a temperature range are sometimes called for and these may be taken with the cable on a drum immersed in a tank of water or with the cable heated electrically while laid out on the ground. The former is the more satisfactory method. Laying out a drum length and recoiling it on to the drum is not calculated to lengthen the life of a super-tension cable which is afterwards to be laid a second time before being put into operation. Current heating also gives very uncertain results compared with water heating, owing to the temperature of the dielectric not being known with any degree of accuracy.

The author will not presume to frame tests, but there are two guiding principles which might receive more attention by purchasers in selecting tests for use in accepting high-voltage cables.

(A) The tests which may shorten the subsequent life of the cable in service should as far as possible be restricted to special test-pieces not to be used afterwards.
(B) The object of using high-voltage cables is to lower transmission costs, and this object is partially defeated when the tests are made unnecessarily complicated and expensive, as the cost of the tests must be added to that of the cable. Tests on the thermal properties of a drum length, for instance, are very interesting but, in view of all the other factors, are of minor importance to-day for acceptance purposes.

APPENDIX I.

Determination of Constants in the Expression $I_t = I + At^{-n}$.

Two alternative methods employed in this paper to determine the absorption constants from a curve of charging currents are shown below. In the first method

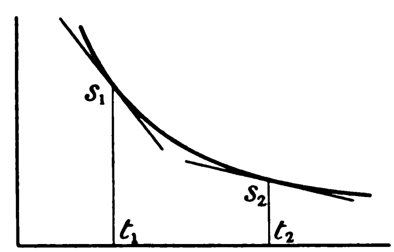

Fig. 52.—Determination of absorption constants.

(*a*) the curve is drawn out on a large scale and tangents are drawn at definite points. The use of the logarithms of the ratio of slopes and inverse ratio of times gives the value of the index n. I follows simply. In the second method (*b*), which is more cumbrous but more certain than method (*a*), the value of I is first determined by trial, or, if equal time ratios are taken, by a simple arithmetical expression, when n follows as before from a ratio of logarithms.

(*a*) *By slopes* (see Fig. 52).

$$I_t = I + At^{-n}$$

Slope $S = \frac{dI_t}{dt} = -nAt^{-n-1}$

$$\therefore \frac{S_1}{S_2} = \left(\frac{t_2}{t_1}\right)^{n+1}$$

$$\log (S_1/S_2) = (n+1) \log (t_2/t_1)$$

$$n = \frac{\log (S_1/S_2)}{\log (t_2/t_1)} - 1$$

$$A = \frac{S_1}{-n} t_1^{(n+1)}$$

$$I = I_t - At_1^{-n}$$

If $t_2 = 2t_1$ then

$$n = \frac{\log (S_1/S_2)}{0 \cdot 301} - 1$$

(*b*) *By calculation.*

Three points on the curve will give

$$I_{t1} = I + At_1^{-n} \quad . \quad . \quad . \quad . \quad \text{(i)}$$

$$I_{t2} = I + At_2^{-n} \quad . \quad . \quad . \quad . \quad \text{(ii)}$$

$$I_{t3} = I + At_3^{-n} \quad . \quad . \quad . \quad . \quad \text{(iii)}$$

Equations (i) and (ii) give

$$\frac{I_{t1} - I}{I_{t2} - I} = \left(\frac{t_2}{t_1}\right)^n \quad . \quad . \quad . \quad . \quad \text{(iv)}$$

Equations (ii) and (iii) give

$$\frac{I_{t2} - I}{I_{t3} - I} = \left(\frac{t_3}{t_2}\right)^n \quad . \quad . \quad . \quad . \quad \text{(v)}$$

Therefore

$$\frac{\log \left(\frac{I_{t1} - I}{I_{t2} - I}\right)}{\log \left(\frac{I_{t2} - I}{I_{t3} - I}\right)} = \frac{\log \left(\frac{t_2}{t_1}\right)}{\log \left(\frac{t_3}{t_2}\right)} \quad . \quad . \quad . \quad \text{(vi)}$$

I can be determined by calculating the value of the right-hand ratio and interpolating on a curve obtained by plotting trial values of I against resulting values of the expression on the left-hand side.

The operation of determining the constants by calculation is simplified by making

$$t_2 = 2t_1$$

and

$$t_3 = 2t_2$$

For instance, 1-, 2-, and 4-minute values are convenient.

Then

$$\frac{t_2}{t_1} = \frac{t_3}{t_2}$$

and

$$\frac{I_{t1} - I}{I_{t2} - I} = \frac{I_{t2} - I}{I_{t3} - I}$$

so that

$$I = \frac{I_{t2}^2 - I_{t1}I_{t3}}{2I_{t2} - (I_{t1} + I_{t3})} \quad . \quad . \quad . \quad . \quad \text{(vii)}$$

Having determined I then n follows from Equation (iv) thus:—

$$n = \frac{\log \left(\frac{I_{t1} - I}{I_{t2} - I}\right)}{\log (t_2/t_1)} \quad . \quad . \quad . \quad . \quad \text{(viii)}$$

and A is obtained by substituting $t_1 = 1$ in Equation (i) whence

$$A = I_{t1} - I \quad . \quad . \quad . \quad . \quad . \quad \text{(ix)}$$

DISCUSSION BEFORE THE INSTITUTION, 5 NOVEMBER, 1925.

Mr. S. W. Melsom: I am inclined to agree with the author's theoretical treatment of the subject. No doubt a great deal more experiment is required before his theory can be adopted, but nevertheless it does seem to me to be established that it is essential, in dealing with such a difficult matter as dielectric losses, that one should study the question from the dielectric point of view and investigate the behaviour of the material of the dielectric under all conditions of stressing. That is what the author has endeavoured to do, and on that basis there should be some explanation of the difference between a.c. and d.c. phenomena. The dissipation of the widely accepted theory as to the relation of d.c. conduction losses to a.c. dielectric loss at the high temperatures is particularly valuable, but here again it is clear that the last word has not been said, and it seems probable that a study of Evershed's paper on "The Characteristics of Insulation Resistance" * might help to a solution of the point. Towards the end of the paper the author goes very briefly into the question of the assessment of cable quality. With a great deal of what he says in that connection I do not wholly agree, and I feel that that section might very well be amplified.

Mr. L. Emanueli: In my opinion it is not necessary to emphasize the result of the theory of dielectric absorption, which shows the strict relation between d.c. and a.c. tests, and probably, from lack of better knowledge of dielectrics from the experimental point of view, we must agree that this theory is simply an attempt to solve the problem. Unfortunately, the physical theory of what is happening in the dielectric, which ought to be the ground on which the mathematical theory can be built up, is rather unknown and uncertain. For this reason we must appreciate the present paper, especially that part which deals with the effect of moisture. The author's experiments give support to the theory according to which the absorption phenomenon is due to the presence in the dielectric of electrolytic ions moving amongst the molecules. I think that this theory is the most probable one. With reference to the "V" curve of dielectric loss, I also plotted several of them using a very low voltage gradient in the dielectric. With only 100 or 200 volts on a cable constructed for any working pressure, one can be absolutely sure that ionization in the air films is absent. The curves which I obtained on cables at different frequencies ranging from 22 to 1 000 cycles per second show a "V" shape similar to that which is well known (see Figs. A and B), but below the ordinary temperature, say 15° C., with decrease of temperature the power factor increases to a maximum and then diminishes again. The maximum corresponds approximately to zero Centigrade. The behaviour of the dielectric at different frequencies is also very interesting. The minimum points of the "V" curves appear to lie on a line parallel to the abscissæ. The power factor diminishes when the frequency increases at high temperature, and increases when the frequency increases at low temperature. In a set of curves taken on the compound alone it diminishes again with increase of frequency at very low temperatures. This is certainly not in accordance with the von Schweidler and Granier theory, in which the power factor appears always to diminish when the frequency increases. The experimental part of the paper does not appear to be complete enough to show it. Heavy

* *Journal I.E.E.*, 1914, vol. 52, p. 51.

mineral oil shows a similar behaviour, but the minimum of the "V" curve appears to be shifted to a lower temperature than for compound. Adding to the oil a different percentage of rosin, the minimum moves always towards the high temperature. Coming now to the behaviour of the dielectric of the cable at high-voltage gradients, I am afraid a complete explanation of what takes place cannot be found in what the author states. I would first mention that the compound itself, and in general all the fluid and semi-fluid dielectrics, show an increase of power factor with the voltage gradient. Mineral oils show a maximum in the power factor which varies inversely with the temperature, i.e. the higher the temperature the lower the voltage at which this maximum appears. The variation of the power factor is also greater in oils which have been heated for a long time in the presence of copper. The most important question in high-tension cable-making is the change of power factor due to air or gas trapped in the insulation. It is certainly true that the so-called ionization curve gives an exact idea of the impregnation of a cable, and it enables one to reject bad cable which would break down in service sooner or later. Although I agree with the author that it only gives an average idea of the impregnation of the cable, in practice perhaps the results of other tests have made me rather sure that the average test is quite safe. It is worth while to note that in considering ionization curves one has to take into account the temperature of the cable, because the influence of the ionization on the value of the power factor varies very considerably with the temperature. At very low temperatures this influence is great; then it diminishes if the temperature increases, owing to the fact that the compound expands and fills up the empty spaces. Above 50° C. the power factor increases when the pressure increases, because the power factor of the compound itself increases. This I proved in my paper read before the last International Conference on Extra-High-Tension Lines in Paris. I believe that a more important point in the paper is that referring to the breakdown of the cable insulation as a consequence of the migration of the compound. I do not think that it is due, at least to a great extent, to the lack of uniformity in the insulation, but chiefly to air or some other gas present in the form of a film between the paper layers. It is very easy to make the following test: Take two electrodes, a metal plate and a needle; on the plate lay a number of sheets of paper impregnated with a cable compound in such a way that between the needle and paper remains a small gap (0·1 in.). If an increasing tension is applied to the electrodes, at a certain value of the voltage the compound is thrown away as though from the needle there issued a powerful current of air towards the plate. The paper sooner or later dries in front of the needle and breaks down. This is a sort of bombardment of the impregnated paper by the ions emitted by the needle. In a cable we do not have needles but in their place we have gas pockets which at a certain tension become ionized. It is easy to see what is happening in those air pockets if we make another test and observe an air film left between an impregnated-paper sheet and the flat bottom of a glass container, the two electrodes being a metallic disc underneath the impregnated paper and some water in the glass container, through which one can see what is happening. The phenomenon is identical to that of the needle, only instead of one needle there are many of them built up in the air film. These at low tension are

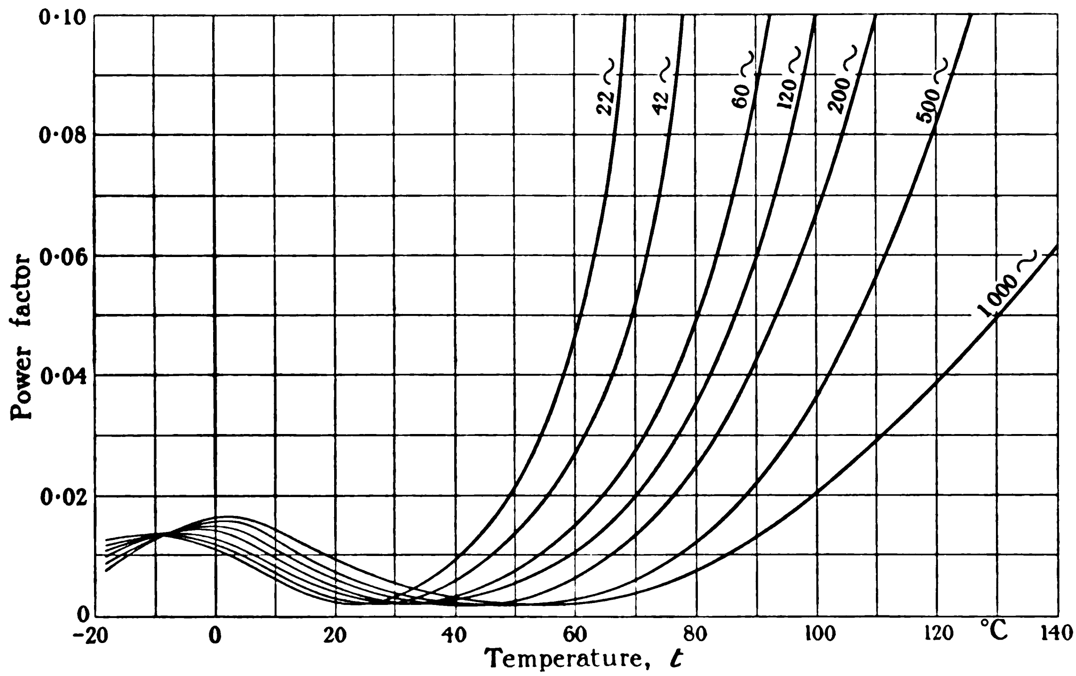

FIG. A.—Variation of power factor with temperature of an impregnating compound at various frequencies.

wandering from point to point, but at higher voltages fix themselves in definite spots and start to throw away the compound from the paper all around. The compound thrown away takes on a white, frothy appearance, and in some cases also alters chemically. The paper first becomes charred and then breaks down. It is possible to obtain also the tree-shaped marks which are often noticeable in a cable core after a long-period voltage test. I will not say that this is the only way in which cable breakdown occurs but I think it is the most probable one. In Italy there is a cable in successful operation at a working pressure of 130 000 volts. This was first put in commission there over 18 months ago. Its construction differs from that of an ordinary cable only in the fact that air or gas bubbles are entirely eliminated from the insulation. With reference to the inspection test on extra-high-tension cables, I think the matter cannot be settled now, the construction of extra-high-tension cables not being advanced enough to enable well-defined rules to be generally agreed upon. I have not much faith in a low-tension d.c. test.; on the contrary I believe in an ionization test properly studied and well determined, taking into account the temperature. I think that the amount itself of the dielectric losses is of no practical importance at all. Reduction in the amount of losses at high temperature is also not very desirable. As a matter of fact in the United States, where cables impregnated with vegetable oil showed enormous values of power factor, they went to the opposite limit, prescribing a very low power factor at high temperatures. This forced manufacturers to use oils which at high temperatures are very thin and which very easily drain into the lower part of the cable, leaving in the upper part big air pockets. I do not think it advisable to measure power factor, using current in the conductor to heat the cable, but would recommend a proper constant-temperature bath. As heating cables to high temperatures spoils the impregnation, I would also recommend that lengths thus heated be not used in actual service. I hope that the whole question will be considered carefully both by the users and by the cable makers, and that some reasonable rules for testing will be agreed upon in time.

Mr. H. A. Ratcliff: A very large portion of the paper is devoted to an explanation of dielectric charging phenomena, and although the information given may not afford much comfort to cable users it certainly does throw light on many of the obscure actions taking place in an extra-high-tension cable. I am particularly interested in the author's views on the connection between the I^2R loss in a dielectric and the so-called hysteresis loss, because when investigating the subject of dielectric loss about 10 years ago I was very much impressed by the possibility of some such connection between the two phenomena, and, moreover, it is only fair to the author to say that opinions expressed recently by investigators in America very largely support his theories. So far as the purely theoretical aspect of dielectric phenomena is concerned, the well-known "V" curve appears to provide one of the most valuable sources of information and therefore in this connection the author's explanation of its characteristic shape merits serious consideration, and is certainly a very valuable step in advance, for it is an extraordinary thing that, although the shape and general characteristics of the "V" curve have been

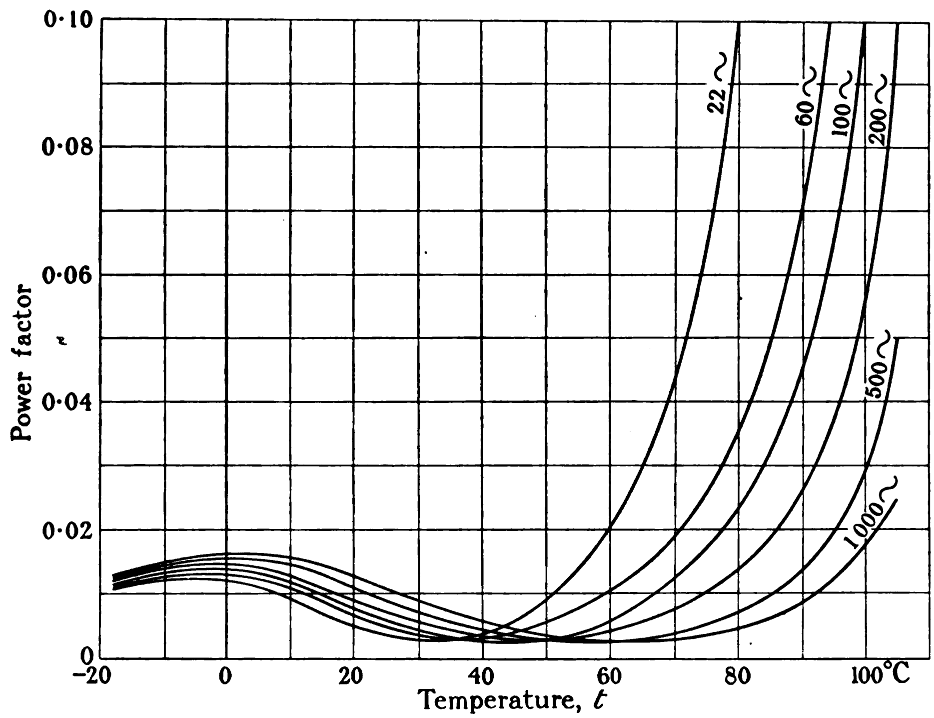

FIG. B.—Variation of power factor with temperature of a cable at various frequencies.

known for years, the real nature of the change which it indicates has never been discovered. Reverting to matters more closely associated with the behaviour of cables under actual working conditions, the author rather emphasizes the importance of the "time/voltage" curve and appears to imply that it explains the breakdown of cables many months after laying. Provided that a cable is constructed so as to have a sufficient factor of safety, I am in the light of actual experience inclined to question this explanation, and in any case it is of little real value unless due consideration is given to the conditions arising from load variations. The factor of safety also has an important bearing on pressure tests. Pressure tests on full drum lengths of cable either before or after laying are merely for the purpose of detecting defects arising during manufacture or laying and the pressure applied should be well within the limits covered by the factor of safety. It is obviously very desirable that cables should be capable of withstanding this requirement, and moreover, the factor of safety of the dielectric should certainly not be less than 2, and preferably more, since a pressure approximating to double the normal working pressure is liable to arise from ordinary switching operations. For example, a cable which would be capable of withstanding a reasonable amount of rough handling and the temperature-changes arising from load variations would, if its breakdown pressure followed a time/voltage curve having an asymptotic value of 66 000 volts, make a thoroughly sound cable for use under normal operating conditions on a 33 000-volt system. Tests which are intended to stress, and ultimately break down, the dielectric should only be conducted on comparatively short experimental lengths of cable. The author's estimate of a reasonable factor of safety under ordinary cable-operating conditions would be both of interest and value. It is not of much interest to the cable user to know that a hypothetical cable will, given ideal conditions, survive for centuries. What he wants is a cable which will last, say, at least 25 years under ordinary operating conditions. The effects of transient high-voltage phenomena are apt to be somewhat overrated, and when they occur there is usually some fairly definite explanation of their origin. In the case of the undertaking with which I am associated all spark-gaps and similar devices on the 6 600-volt system have been scrapped, and so far as I am aware some "over-voltage" or "lightning" dischargers installed on the 33 000-volt system have rarely, if ever, functioned, although set to discharge at rather less than double the working pressure. I am of the opinion that the cables themselves are the most effective absorbers of transient high-frequency disturbances on the system. With reference to the nature of cable breakdowns I agree that the maximum-stress theory has little or no bearing on the actual behaviour of cables in practice, although in this connection many cable manufacturers appear to have rushed to the other extreme and reduced the thickness of the dielectric core wall on 33 000-volt cables before they were thoroughly familiar with the numerous factors involved, and it is therefore significant that they are now increasing the thickness of the core walls. In the case of three-core cables the ultimate breakdown appears to arise as much from mechanical as from electrical causes, although with this form of construction the tangential-stress theory of Höchstädter is by no means lightly to be ignored, since it undoubtedly has some bearing on the behaviour of 3-core cables, and in this connection it is perhaps significant that I have yet to experience a breakdown of a single-core cable. I cannot agree with the author's views on the correct method of conducting a dielectric heating test. It is quite wrong to immerse a drum of cable in a tank of hot water for this purpose. There appears to be little, if any, doubt that the effects of temperature gradient in the cable dielectric, and the electromagnetic effects arising from the currents circulating through the conductors have an important bearing on the behaviour of the dielectric, and, therefore, if for this reason only, it is essential that dielectric heating tests on drum lengths of cable should be made by applying pressure (normal or excess) to the conductors while passing through them, from a separate low-voltage source, heating currents of the necessary extent. In the case of 3-core cables carrying balanced three-phase currents, there is no reason why a test of this nature cannot be carried out with the cable coiled on a suitable drum.

Mr. N. A. Allen: The charging curve of a cable is assumed on page 102 to be of the form $I + At^{-n}$, where the index of time, n, is assumed itself to vary with time. It

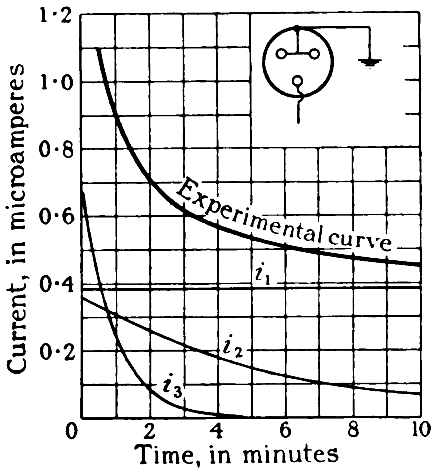

FIG. C.—Charging curve of a 0·3 sq. in. 3-core 6 600-volt cable tested at 1 000 volts.

$$\begin{aligned} I &= i_1 + i_2 + i_3 \\ \left.\begin{aligned} i_1 &= 0{\cdot}3855 \\ i_2 &= 0{\cdot}359\epsilon^{-0{\cdot}171t} \\ i_3 &= 0{\cdot}685\epsilon^{-1{\cdot}093t} \end{aligned}\right\} &\times 10^{-6} \end{aligned}$$

is difficult to get a true physical conception of this change of the time index with time, and moreover it involves certain difficulties with the mathematical solution of the problem. I should like to ask the author whether he has attacked the question of charging currents in the new light shed by the late Dr. Steinmetz's recent paper.* In brief it may be proved that any charging curve for a composite dielectric may be analysed into the sum of a series of exponential curves having various time indices and it is always possible to fit the experimental curve

* C. P. STEINMETZ: "Cable Charge and Discharge," *Transactions of the American Institute of Electrical Engineers*, 1923, vol. 42, p. 577.

mathematically correctly, provided the number of transients is chosen properly. Fig. C shows a charging curve on a 6 600-volt cable where the sum of three transients satisfies the curve. The correct equation for any period of time whatever is given in full. Fig. D shows a charging curve on a low-tension cable where the conditions are such that four transients satisfy the curve. In Fig. E one of the curves given by the author in Table 16 is worked out. Four transients appear to satisfy the observed experimental curve in this case. It will be observed that in each

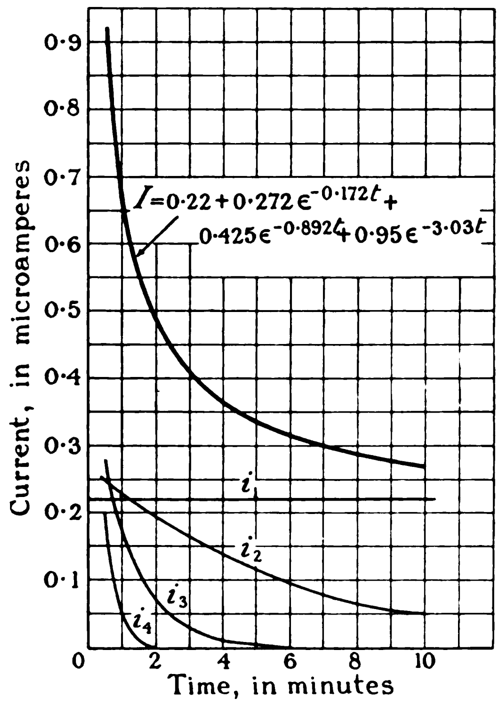

FIG. D.—Charging curve of a 0·75 sq. in. single low-tension cable tested at 1 000 volts.

$$I = i_1 + i_2 + i_3 + i_4$$

$$\left.\begin{aligned} i_1 &= 0{\cdot}22 \\ i_2 &= 0{\cdot}272\epsilon^{-0{\cdot}172t} \\ i_3 &= 0{\cdot}425\epsilon^{-0{\cdot}892t} \\ i_4 &= 0{\cdot}950\epsilon^{-3{\cdot}03t} \end{aligned}\right\} \times 10^{-6}$$

case the first transient, i, is independent of time and must therefore be the steady leakage current which would continue to flow after a long period of time. We therefore have a ready method of finding the true insulation resistance of a cable, by taking readings of charging current over short periods and finding the true leakage current by analysing into the Steinmetz transients. I would suggest that this provides a very easy and accurate way of comparing the quality of different cables. In Fig. 27 the author gives two curves for cables made up with different impregnating oils. It is not stated whether the curve having a high minimum point but a more gradual slope was taken with a heavy oil and the curve with a lower minimum but a steeper slope with a lighter oil, but this is a phenomenon which sometimes occurs. It may be that the explanation of this is connected with the infinitesimally small air bubbles occluded in the insulation. These air bubbles are quite different from the air films and pockets which occur in a badly made cable, they may exist among and even inside the actual fibres of the paper, and it is by no means certain that if they exist they are necessarily deleterious, owing to their extremely high electric strength. On the hypothesis that such finely divided air exists in cable even of the best manufacture as known at present, with a heavy oil the oil expands and compresses the air as the temperature rises, so raising its dielectric properties and reducing the loss to a minimum. As the oil becomes less viscous with rising temperature, the air can expand more and more freely; thus the losses increase as the air pressure falls, and moreover this effect is augmented by the increasing a.c. conductance. In the case of a thin oil the same argument explains the "V" curve, and also why the curve is steeper, since the air can expand much more freely. The author states that there is

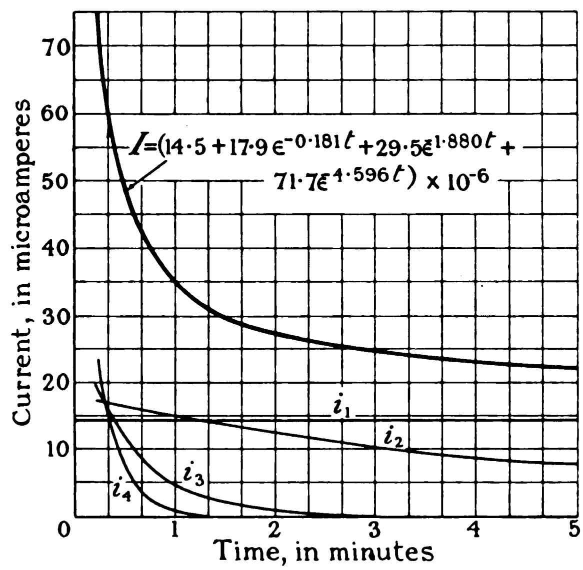

FIG. E.—Analysis of charging curve of a 0·2 sq. in. low-tension cable tested at 500 volts and 50° C.

$$\left.\begin{aligned} i_1 &= 14{\cdot}5 \\ i_2 &= 17{\cdot}9\epsilon^{-0{\cdot}181t} \\ i_3 &= 29{\cdot}5\epsilon^{-1{\cdot}880t} \\ i_4 &= 71{\cdot}7\epsilon^{-4{\cdot}596t} \end{aligned}\right\} \times 10^{-6}$$

little difference between the breakdown voltage of a long length of cable and a 5-yard sample. In view of the large numbers of references in recent literature to the so-called hot-spots in a cable, at which presumably the cable ultimately breaks down, it would seem that the electric strength of a 5-yard sample would depend largely on whether or not there were an incipient hot-spot in that 5 yards. The smoothness of the curve in Fig. 44 seems to negative this, but it would be of interest to know whether the curve represents a mean value of the results of many tests.

Mr. A. M. Taylor: The author's statement in reference to intersheaths on page 122 and in connection with Fig. 51, viz. that the intersheaths reduce the risk of breakdown, interests me very much. I am glad to find that he agrees with me as to the advantage afforded by intersheaths in this respect, which I have long maintained. There is another advantage which is not so fully appreciated, viz. that intersheaths tend very

materially to stop the puckering of the paper when the cable is bent; or, conversely, permit of a greater depth of insulation for equal puckering. I am surprised that some recent super-tension cables, to be used in America, have apparently been designed in total disregard of this factor. A very great authority on cable manufacture told me three years ago that it was impracticable, on account of this puckering of the paper, to *make* single-core paper cables if the depth of insulation exceeded a certain amount. No puckering occurs until after the second intersheath has been reached, a distance from the centre of the cable of quite 50 per cent in excess of that indicated by the authority referred to above. This result has no doubt been obtained by the use of intersheaths. It will be noted that the puckering is in parts so severe as virtually to form radial paths on the line of cleavage of the insulation, thereby greatly weakening the dielectric strength at this part. It ought to be mentioned that this puckering will be prevented on future cables, but at any rate the fact has been established that the intersheaths have this very valuable property. Another advantage of intersheaths, and a very important

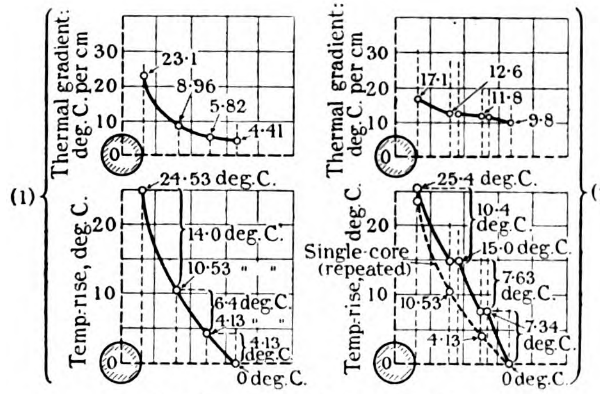

FIG. F.—Thermal characteristics.

(1) Single-core cable for 41 000 kW.
(2) 3-core concentric cable for 104 000 kW.

one, is that the thermal gradient across the innermost dielectric, due to the load current, may be controlled and greatly reduced below what it would be if there were no intersheaths, resulting in a considerably increased carrying capacity. For instance, in Fig. F it will be noticed that there are only 10·4 deg. C. across the innermost dielectric in a 0·15 sq. in. triple-concentric cable transmitting 104 000 kW; whilst there are no less than 14 deg. C. across a corresponding thickness on the single-core cable transmitting only 41 000 kW, both cables having the same overall diameter. If the load on the right-hand cable were reduced to 41 000 kW there would be only 1·61 deg. C. across the innermost dielectric, as compared with 14 deg. C. across the corresponding slice of the single-core cable. The importance of this control over the temperature of the innermost parts of the cable, only needs to be pointed out to be appreciated. One more advantage of intersheath cables is of considerable importance, viz. that each section of the cable can be tested separately. This feature enabled me to discover that there was insufficient impregnation in my intermediate insulation, a defect which will be easily remediable in future cables. With reference to my earlier remark, I would call attention to the author's statement on page 121, viz. "The charred condition is restricted neither to the proximity of the conductor nor to that of the lead," which agrees with the tendency to pucker (even before bending) that undoubtedly exists where there is a considerable depth of insulation without any intersheath. It may be also that the results observed by Mr. Fernie, viz. that the dielectric was in some cases weakest at the circumference, may have been due to the same cause.

Mr. H. C. Silver: I am most interested in the Section dealing with the resistance of the cable, and I should like to ask the author whether he thinks more attention should not be devoted to the subject of resistance, so that by this means we might eliminate the testing of cables for breakdown pressure. Further, I suggest that the progress of our knowledge of dielectrics would be greater if we devoted more attention to the measurement of resistance and less to the determination of what is known as "electric strength." The author has suggested a theory of cable breakdown, and I should like his views on the following: It is known that chemical action cannot take place unless moisture is present, and it is believed that this must be in the form of an electrolyte. Is electrical breakdown a chemical action and merely the result of passing current through the dielectric, thereby converting it into a conductor?

Mr. G. L. Addenbrooke: Dielectrics are one thing and dielectrics made up into cable are to some extent a different thing. Certain conditions which necessarily occur in cables are not present when dielectrics are tested in perfectly even fields. That is a point which very greatly complicates any question of finding final explanations. I wish to speak chiefly on the question of explanations or theories of dielectrics. Some years ago I discussed with the late Sir James Dewar the question of what could be done to investigate the fundamental problems of dielectrics, when he said: "Experiments on dielectrics will be worthless unless they are made on some perfectly definite chemical substance." There is a great deal in that point of view. Every substance behaves in certain definite ways in electric fields and if two substances are mixed together the action on each of those may be different, and a compound result is obtained. I feel that that is to some extent an explanation of the dip in the curve to which the author devotes a good deal of attention. In some lectures I gave six years ago I showed a curve of that description, which was originally obtained in Glover's works in 1906, but at that time it seemed so curious that we thought there was a mistake in our readings, and therefore I did not deal with it or publish anything about it until the time of my lectures, when the British Insulated Wire Co. supplied me with some cable data in which that curve occurred. I asked them if they had any explanation of it, and they replied that they thought it was due to increase of pressure in the cable as it became heated. Mineral oils, of course, expand very considerably on heating, and the lead does not expand so much, so that the heating would be less on the outside. At the same time, they said they were not altogether

satisfied with the explanation, and asked if I could suggest any other. I did think of another explanation, which I discussed with the late Bertram Blount, the chemist. This explanation is based on some results which I gave in those lectures to which I have referred, and which I repeated in *Nature* about 18 months ago. My experiments were in drying a dielectric, taking its electrical properties and then allowing small weighed percentages of moisture to diffuse into the dielectric. I then ascertained the effects of those extra percentages of moisture. I found that when the amount of moisture is very small the losses go up very nearly as the percentage of moisture increases, but after a certain point the curve begins to rise rapidly, that is to say, the losses are greater than the proportionate increase in the moisture. What appears to happen in drying is that the drying tends to draw the moisture out of the material and, on the other hand, the material tries to retain the moisture. The result is a certain equilibrium. There may be one equilibrium for oil and another for paper, which has a very large surface. The paper can be dried to a very great extent by passing dry air through it, heating it and so on. The hot paper is brought into contact with the oil, and they both cool together. There is a certain vapour pressure in each, and the question is whether the vapour pressure is equal in both or whether there is a tendency for the moisture in one to get absorbed into the other. I am under the impression that in those circumstances a good deal of the moisture which is in the oil when it is warm will go into and settle down in the paper as the oil cools, and that will cause the paper and the cable as a whole to have a heavier loss than it would have if the moisture were equally diffused. When the current is switched on and the cable starts to heat up, the paper gives up its moisture and it diffuses into the oil and the losses are reduced up to a point. I do not say that is the whole of the explanation, but I think that it is part of it. It is also the case, I think, that with increased pressure the losses would be diminished. That is a matter which, at any rate for submarine cables, was studied very carefully as long ago as 1860. It was found that putting a pressure of 3 tons per sq. in. on cables increased the resistance six times at the same temperature, but the capacity was not appreciably altered. I believe those tests have been carried out again within the last year or two and have been confirmed, but they are not mentioned in textbooks and the fact that pressure has a great effect on resistance and not on capacity is overlooked. I have no doubt it has also an effect on the alternating losses, but very little on capacity, though I know of no experiments which so far have been tried. That, I think, is one of the points which lead to the belief that absorption losses are due to the presence of moisture or electrolyte and not to a property of the material. The author has spoken a great deal about resistances and capacities in series or parallel. Many years ago I spent time on this subject, but I believe that Curtis of the Bureau of Standards has shown that, if extended, similar results do not agree with what is actually found in practice. Again, supposing the actions are imitated by means of resistance and capacity, what progress has been made? What we want is a real physical explanation, and the explanation referred to above only substitutes one incomprehensible idea for another which is really more incomprehensible.

Mr. W. D. Owen: The author has explained how he has been led by Schweidler, Granier, and others, to a conception of a.c. power loss as a joulean loss due to absorption current and normal conduction current flowing in a Maxwell network of capacities and resistances. This conception does not account for the distortion of wave-form which takes place with some dielectrics, such as glass.* Can a modified quantitative theory be formulated on the lines of the author's argument which may include distortion? The author's statement on page 119, that: "This time effect is quite a new phenomenon and so far very little has been published on the subject," calls for some comment. My own work on this subject [see Appendix II (26)] is based on the laws published by Peek as far back as 1915, and there can be little doubt that Peek adopted the same method of extrapolating to "infinite time," although there does not appear to be any evidence that the significance of the resulting conclusions is even now fully appreciated. Whatever criticisms may be levelled against methods which make it possible to extrapolate to infinite time on the assumption that the law holds, there can be no denying the value of the revelation that the rate of decrease of electric strength with time is not constant for all materials but differs appreciably. Two materials A and B have similar breakdown values when tested in accordance with present-day accepted standards, but one falls off with time at a greater rate than the other. Presumably the watt loss per unit volume is greater, or its thermal resistance is higher and the influence of the pent-up heat is cumulative. Whatever the reason may be, the "endurance" of the two differs, and a stress such as one can withstand satisfactorily for many years may conceivably rupture the other in a few days. Factors of safety based on a comparison of the 1-minute breakdown values of dielectrics cease to apply after 1 minute has elapsed. What, then, is meant by the term "factor of safety" in relation to dielectrics? Many electrical engineers interpret it as the ratio between the short-time strength and the long-time stress thus: An insulator having a 1-minute breakdown value of 100 kV is put in service on a 20-kV system and is said to have a factor of 100/20, i.e. 5. Herein lies the explanation of "the failure of super-tension cables many months after installation" (p. 119). The same, of course, applies to insulation other than that on cables that suddenly "sits down" on the job after spectacular tests before assembly and possibly after many months of service. The author's frank admissions relative to the past are the finest possible guarantees for the future, and his example is one that might well be followed by others.

Mr. E. A. Beavis (*communicated*): The efficacy of d.c. tests of prolonged duration and periodic reversals at a constant potential of 1 000 volts or so, has long been proved in dealing with gutta-percha cables; undoubtedly it is the most useful method of showing up incipient faults in the dielectric. Extreme care and concentration is essential in such tests over the whole period, and it is

* W. M. Thornton: *Proceedings of the Physical Society of London*, 1911–12 vol. 24 p. 301.

insufficient merely to note readings at 1-minute intervals since defective insulation may only create in the first instance a slight irregularity or temporary holding up of the gradually falling deflection—possibly only for a few seconds—which may pass unnoticed unless attentive watch is kept throughout. It would seem that there is scope for a similar procedure for high-voltage cables; the usual 1-minute d.c. results are useless except for commercial comparison and record purposes, and there is urgent need for factory tests that will discover such potential faults as appear to be impervious to the initial high-voltage a.c. pressures. The use of the "Kenotron" apparatus for obtaining high-voltage electrification curves as a means of discovering incipient faults in power networks has proved successful to some extent, and suggests the possibility that the solution of the problem lies in some form of prolonged steady-potential test. In dealing with the question of power factor and voltage the author has suggested that the true power factor will be equivalent to the low-voltage value obtained from the d.c. index n, plus some allowance for ionization. Now the latter appears to be a very indeterminate factor depending upon variable conditions of manufacture, and as such will alter with different cables and most probably with different lengths of the same cable. It does not seem possible, therefore, that any definite relation for general application between power factor and voltage can exist, i.e. each cable length must apparently be treated on its merits. Under these circumstances the equation obtained for $\cos \theta$ at low voltages cannot very well be applied to the variable high-voltage conditions that obtain. There is also another point to be considered. May not partial ionization also take place in the oil or compound at these higher voltages? This has been suggested as the cause of dielectric resistance decreasing at high voltages, apart from any question of occluded air, and if so it tends to complicate the matter still further. The author has indicated the variations in power factor that can be caused by overloading the cable; other investigators have found similar results, but in many cases these were of a temporary nature, the cable returning to its original condition after the lapse of some weeks. It would be interesting to know what happened in the example cited, i.e. whether the deterioration was permanent. With reference to this phenomenon a case that came under my observation may be of interest inasmuch as the effects were dissimilar to those generally experienced. It was discovered more by luck than design, and occurred to a cable sample that had been in the hot tank undergoing loss/temperature tests. The cable in special circumstances had to be removed from the tank when at a temperature of 180° F., and forthwith placed in a cold tank. The normal power factor was much improved by this drastic treatment and remained so for some days; the original value, however, was regained on slowly cooling from the high temperature about a week later. The curves of power factor and voltage for this particular sample are shown in Fig. G. Such results are possibly not of much value save for the purpose of noting the variability of the power factor at normal temperatures and its dependence on extraneous conditions. At higher temperatures the ionization, although no doubt present, does not seem to be so apparent, and results show more stability. There is also another variable in the power-factor equation and this appears to be "time," since in many cases value increases with prolonged voltage application. On the basis of the "V" curve, supposing a reasonable temperature-rise owing to the duration of the test, there should rather be a tendency for the power factor to decrease; here, presumably, is another effect due to ionization. A solution to the enigma of power factor and voltage holds most probably the key to the problems of high-voltage dielectrics. In relation to the variation of dielectric resistance with temperature, it has been stated that the temperature coefficient is not constant over the temperature range for any one time-interval. The author has given two coefficients in each case for the lower and higher temperatures respectively. It is of interest to know whether the change of value is continuous over the whole

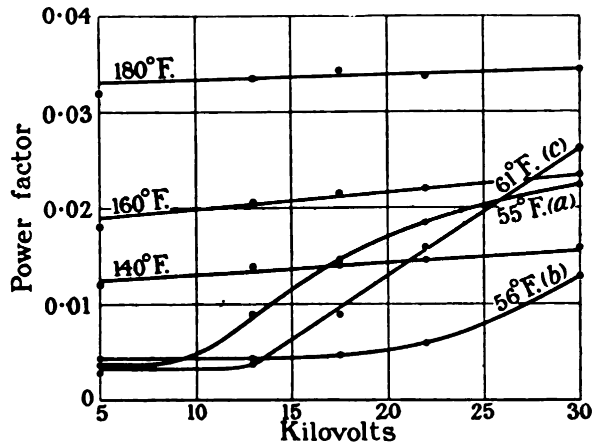

FIG. G.—Variation of power factor with voltage at various temperatures.

(a) Initial test as manufactured.

(c) After gradual cooling from 180° F.

range, or whether (as seems probable) it takes place at or about the region of transition, i.e. the melting point of the cable compound. In the latter case the two coefficients can be applied fairly accurately within their respective limits. Any further information that the author can furnish on this point will be welcome.

Mr. R. M. Wilmotte (*communicated*): The paper marks an important stride forward on the subject of dielectric losses, not only for the very valuable data and theories which it gives, but also in making manufacturers realize that to solve the problem and obtain a material improvement in design it is necessary to go down to the fundamental reasons and not so much by collecting a vast array of unconnected data as by scientific thinking. In this respect Mr. Addenbrooke's remarks on experimenting on pure substances are of interest. From his list of references the author has omitted a recent paper by L. Hartshorn * in which a theory of dielectric loss is put forward and leads to a representation by three shunted condensers, similar to those shown in Fig. 6. In this theory the main effect

* *Proceedings of the Physical Society of London*, 1925, vol. 37, p. 215.

is supposed to be due to a contact resistance between the electrodes and the dielectric. This effect appears to have been fairly well established in the case of semi-conductors by the work of Barlow. A further evidence would appear to be given by the effect of pressure on dielectrics. With increased pressure one would expect better contact between the dielectric and the electrodes. This would reduce the shunting resistance of the two outside condensers and thus increase the dielectric loss and reduce the d.c. resistance, and this effect is known to occur. Mr. Hartshorn gives a good deal of other qualitative evidence for his theory, to which might also be added the recent theories on crystal rectification, which are based upon considerable experimental evidence on contact effects. I am not quite clear about the author's explanation of the "V" curve. On page 107 he says: "Each of these imaginary circuits has a distinct power factor ranging from zero with I_1 to unity with I_n (all resistances in series)." Why should the power factor be represented by a resistance in series with a condenser? If the resistance is due to electrolytic action a parallel resistance would appear to give a better physical representation. I should like to suggest the following explanation of the "V" curve. As the temperature rises, the insulation presses against the lead sheath and also on the copper cores. On Hartshorn's theory better contact is obtained and the dielectric loss becomes greater. On cooling, the paper insulation contracts over the copper core, and it is probable that the improved contact on the copper core more than balances the decrease of pressure on the lead sheath, so that the dielectric loss increases on cooling. On further cooling, however, the contact at the lead sheath would become so bad that the dielectric would improve again. If a minimum occurs at about 40° C. it probably means that the paper is exerting about an equal pressure on the copper core and lead sheath at that temperature. Mr. Emanueli's curves, showing how the "V" curves reach a maximum at about 0° C. and then decrease, seem to give good evidence in favour of this explanation. I should like to hear the author's opinion on these points.

[**Mr. C. J. Beaver** also took part in this discussion. The substance of his remarks will be found on page 138 in connection with the discussion before the North-Western Centre.]

[The author's reply to this discussion will be found on page 144.]

North-Eastern Centre, at Newcastle, 9 November, 1925.

Prof. W. M. Thornton: From time to time papers have been read before the Institution that may be called stepping-stones, like Mr. Evershed's recent paper on "Magnets," and that are valuable, not only for the direct information they contain, but for what they point out as unknown. The first step in research is to realize a gap in the subject. The present paper is of value for both reasons. The author shows us the present state of the science and art of cable-making and, further, where this is still imperfect. As I read it, what is still lacking is a connected theory of dielectrics by which certain practical measurements may be co-ordinated, such, for example, as power factor, and the direct- and alternating-current resistances, resistance and the slow change of capacity under direct electrification, breakdown strength and voltage, dielectric loss and voltage, the relation of breakdown strength to frequency, and so on. Several of these may be connected and all of them explained if we regard the rate of change of polarization as the current, and its resistance to motion not in the least resembling the resistance of conductors, which is due to absorption of energy of molecular vibrators from electrons driven by the field colliding with them, but, as the earliest thinkers saw, an "elastic afterworking" due to attraction of polarized molecules, a slow readjustment of electron structure and position after initial polarization. Thus it can be shown that the true resistivity of a dielectric is $\rho = 4\pi v^2/(dk/dt) \times 10^9$ ohms per cm^3,* where v is the velocity of light and k the dielectric constant. Again, in a condenser of capacity c we have $Q = cv$, $I = dQ/dt = c(dv/dt) + V(dc/dt)$. When the voltage is constant $\partial V/dt = 0$ and $I = V(dc/dt)$, so that $dc/dt = 1/R$, the apparent unidirectional resistance of the cable.

Again $W = VI \cos\phi = V^2(dc/dt)$,

or $\cos\phi = (V/I)\ (dc/dt) = r_0/r$

where r_0 is the alternating-current resistance and r the direct-current resistance. The latter in constant when the rate of change of the capacity is uniform, and I have shown that this is characteristic of dielectric polarization in steady fields of force over a long time.* In the above W varies as V^2 when dc/dt is constant, so that the author's result—that the dielectric loss varies as the square of the applied voltage—is an indication that the mean rate of change of the dielectric coefficient with time is independent of the field. I found that the polarization of a rod of insulating material hung in a field approaches the same value whatever the intensity of the field may be.* The expression quoted by the author as given by many investigators for the absorption current is $I_t = I + At^{-n}$. This might well be replaced by one of the form $I_t = I/(1 - \epsilon^{-at})$. At the start when t is small, I is very large. Later it falls to the steady value I.† This has the advantage of using the exponential term directly instead of through Granier's analysis, and no expression in which the index is variable can be regarded as a law unless an expression for the law of variation itself is given. I agree with the author that all the losses can be cast in the form I^2R, but this resistance is not, I think, electrolytic or anything but that due to the internal molecular attraction found equally well in crystalline or fibrous insulators. A

flat-sided hysteresis loop leads to the same law.* The change of loss with temperature is interesting, and the author's results are very valuable. There can be no doubt from the shape of the "V" curves that the author's analysis into two components in Fig. 23 is substantially correct, for no other explanation would seem to fit the curves of Fig. 24, for example. On the polarized molecular basis the argument would seem to be as follows: At moderate temperature there is a certain inter-attraction, and since as the temperature rises the molecules vibrate sideways and in all directions, the poles can be imagined to be shaken a little out of range, and so the loss will be less. At higher temperatures they are driven in the line of the field nearer together for a part of their motion and, since the law of attraction is the inverse square, they then stick together more and cause more energy loss in separation. When they are all driven into contact to form an electrostatic chain, if one electron slips from an atom they slip all along the line and the material breaks down. The nature of cable breakdown discussed in Section (IX) is of the first interest, but I might call attention to the remarkable law—first, I believe, worked out by Kapp but given by me later,† viz. Breakdown thickness $= AV + BV^2$. This fits most dielectrics so closely that it clearly contains the reason for dielectric failure. I regard it as (i) high initial polarization proportional to V, (ii) attraction of polarized molecules according to the square law. One term is purely elastic; the other contains the cause of energy loss and residual charge. There are many other points of interest in the paper. One must admire the method of classifying cables by models, especially if the physical properties of the insulation are varied so that the change due to any component can be seen by the lateral growth of the curves. The problem of thermal conductivity is a further question. We are all indebted to the author for placing this side of the subject before us in so clear and useful a manner.

Mr. C. Vernier: As pointed out by our Chairman in his recent Address, it is quite correct to say that cables lag behind other apparatus as a unit of load capacity, and that the call for higher-voltage cables is becoming more and more insistent. It is pleasing, however, to record that we have in this district carried out much of the pioneer work on high-voltage cables on a commercial scale. It was in 1906 that the first large network comprising some 40 miles of 20 000-volt cables was laid down here. Those cables are still working to-day and have given the very best service during all those years. More recently, some years ago, we adopted reduced thicknesses of dielectric which we believe are not in use anywhere else, the thickness of insulation on 20 000-volt cables being that specified in the B.E.S.A. tables for 11 000-volt working, resulting in a very considerable saving in capital cost. These cables also have given every satisfaction, and are now standard with us for this voltage. A good deal of 66 000-volt cable (both 3-core and single-core) has been laid down and operated during the past 18 months, and whilst it is too early to say that these cables will prove satisfactory, and it is also perhaps an open secret that the first cables operated at this pressure did not come up to expectations, later cables (both 3-core and single-core) have now operated quite satisfactorily for some months under severe conditions. I fully endorse the author's remarks on page 98 regarding the need for improved tests which, while not damaging the cable, will enable the user to discriminate between a cable that will fail within a few months under ordinary conditions of service and one that will continue to stand up satisfactorily over many years. It is unfortunate to have to admit that not one of the present known tests which can be practically applied to very high-voltage cables (say 33 000 volts and over) will reveal serious defects, and users of such cables therefore welcome the author's efforts in his search for one or more such tests. The tests now usually employed comprise: (1) Insulation resistance measurements; (2) measurement of dielectric losses; (3) ionization tests; and (4) breakdown tests and prolonged pressure tests. The futility of the test for insulation resistance as usually performed has been well shown by the author in the first part of the paper, and, in my experience, although such tests are carried out on all cables the results always show great variations between different drums of cables of the same design and manufacture, and no special importance is usually attached to them beyond seeing that the minimum insulation resistance is of a high order. Dielectric-loss tests and breakdown tests have during recent years been the principal tests which have been relied upon to determine the quality of very high-voltage cables. High values for breakdown tests over 15-minute periods are easily attained and cables seldom fail to pass this test notwithstanding that they may later fail and even fail rapidly in service. Dielectric-loss tests are complicated by the sensitiveness of the instruments required for their measurement, the small values of the losses and the highly scientific methods necessary for their correct determination. The buyer or inspector must usually accept a good deal for granted, and, were it not for the very high commercial reputation of our British cable firms, he could place but little reliance upon the results. No independent authority has hitherto been available for checking these results in this country, but I believe that the National Physical Laboratory will shortly be fully equipped for this purpose, if it is not already in a position to carry out such tests. Dielectric-loss tests have the disadvantage that they only give the average loss in the length under test, whereas what is required is the maximum loss at any point. Local defects, as, for example, patchy and imperfect impregnation, may escape detection entirely if confined to a small proportion of the total length under test. The ionization test, on the other hand, is difficult to carry out on very high-voltage cables, as it necessitates the carrying out of dielectric-loss tests up to several times the normal working pressure of the cable and the difficulty is self-evident when dealing with cables for working pressures of 66 000 volts and upwards. Evidence of ionization is only too often revealed in a comparatively short time, varying from a few weeks or months after the cable has been put into service. This usually takes the form of free carbon spots, tree-like markings as depicted by the author in Fig. 47, and the

* "Dielectric Hysteresis at Low Frequencies," *Proceedings of the Physical Society of London*, 1912, vol. 24, p. 301.
† *Philosophical Magazine*, 1915, vol. 30, p. 124.

formation of a substance like wax between the layers of paper and usually in the gap between the edges of adjacent paper wrappings. For want of a better practical test it has recently been necessary to seek this evidence by a rule-of-thumb method consisting in applying a pressure of approximately 50 per cent above the normal working pressure to the cable at the works for days and subsequently carrying out a detailed dissection and inspection of a sample of the cable for evidence of ionization such as described. This, it should be noted, is a check test, as it is obviously impracticable to subject every drum or cable to pressure at the works for such a long period. From these remarks it will be evident how urgent is the need for a test which can be easily and quickly carried out on every drum of cable to indicate its suitability for a long life. The rise of power factor with voltage attributed to ionization by Proos and others is a phenomenon well worth further investigation in view of its importance, and more especially in its connection with the previous history of the loading of the cable. I believe this will prove a fundamental characteristic affecting the design of very high-voltage cables. For example, the reinforcement of the lead sheath by armouring will be essential to prevent its expansion, and the use of a fluid impregnating compound and the provision of oil ducts in the cable will ensure that no voids can form on heating and cooling. Opinion is at present divided on this question among the leading manufacturers, but personally I think that a solution of the very high-voltage cable problem will be found along these lines and by employing methods of filling or re-filling or impregnating the cable after it is completely laid in situ. In no other way does it seem possible completely to eliminate the voids formed on bending the cable and the loosening of the lead sheath and of the paper insulation on heating and subsequent cooling. I consider that it will also be necessary to maintain a constant and definite pressure on the oil in the ducts of the cable, as by maintaining a pressure on the insulation in this way the ionization potential can be increased. Further, the pressure of oil ensures that within a limited time during which it may be necessary to operate the cable at a lower voltage the voids themselves become filled with oil. Means are, of course, provided for expansion and contraction of the oil and insulation on heating and cooling. This is readily done by fixing expansion chambers at joints and terminal boxes. These methods are already being tried out by at least two important manufacturers here and abroad with, so far, excellent results. It would be of great value in connection with the ionization theory if the author could indicate whether he has carried out any tests on the constituent parts of high-voltage cables, viz. impregnated paper and impregnating oils or compounds separately, to determine whether the power factor on these varies strictly as the square of the voltage. There is a certain amount of indirect confirmation of this theory in its relation to the previous loading of the cable in the fact that breakdowns of 33 000-volt and higher-voltage cables have been observed to occur in many cases during the night or at week-ends at periods of light load. Section (VIII) of the paper dealing with the time/voltage relationship is of great importance, but I am not prepared to accept *in extenso* the author's general statement that pressure-rises and high-pressure tests may seriously affect the life of the cable. My experience on a very large system of cables up to 20 000 volts for nearly 20 years does not bear this out in the slightest degree, yet, as I have already mentioned, we use reduced thicknesses of dielectric and deliberately insert cables in series with extra-high-pressure overhead lines at terminal points in order to absorb switching surges and protect the substation plant against lightning. These cables must have withstood many hundreds of thousands of such surges and pressure-rises over many years, yet breakdowns of such cables are extremely rare, whilst they fulfil their intended function admirably in a district which, however, is not subject to very frequent or severe lightning storms. I am of opinion that the author's statement can only apply, if at all, to cables of 33 000 volts and upwards, and for these cables I quite agree that frequent and prolonged pressure tests, whether d.c. or a.c., are strongly to be deprecated. Such cables, if not actually operated above the potential gradient which can produce ionization in voids or gaseous films within the insulation at the normal working pressure, certainly incur this condition under pressure tests, with consequent burning and damage of the papers (see Fig. 47). Whether the usual surges or pressure-rises on a large system can produce the same effect even on these cables I am not in a position to say, but I should think it unlikely because of their extremely short duration. Unless, however, the cable insulation can be completely filled and air and gas films thoroughly excluded, the risk cannot be ignored. Dr. Klein * published an interesting series of tests carried out on very similar lines to the author's, which showed that cables which had been overstressed gave reduction of breakdown strength of approximately 10 per cent if broken down immediately, but that if allowed to rest for several weeks before being broken down the breakdown voltage was actually somewhat higher than on cable which had never been previously stressed. He concludes that there is no permanent deterioration, such as ageing, but a kind of fatigue from which the cable can completely recover if allowed to rest. It would doubtless throw some light on this important question if these tests were repeated by applying an intermittent increased stress to a cable operating at normal working pressure to simulate surges, and if, instead of allowing the cable to rest without stress, it were kept under normal working pressure for some hours, days or weeks before breaking it down. I find no difficulty in accepting the tangential-stress theory in 3-core cables referred to in Section (IX), or the pyro-electric theory, or the I^2R theory of dielectric losses. Each and all undoubtedly play their part in the breakdown of cables. Breakdowns on the tangential-stress theory are easily explained, quite apart from the imperfect contact which may exist between the core papers and the wormings on account of the potential difference which exists at the surface of the core insulation between a point on a line joining the centres of the conductors of a 3-core cable and another point on a line joining the centre of each conductor with the centre of the cable. The fact that this by no means negligible

* *Elektrotechnische Zeitschrift*, 1923, vol. 44, p. 233.

potential difference acts in a tangential direction between these two points, accentuates any tendency to burning due to imperfect oil filling, not only between the core papers and the wormings but also between the layers of paper on the core itself in a diminishing degree as the centre of the core insulation is approached. This is in accordance with what occurs in practice where one usually finds burning or charring diminishing from the outside of the core insulation towards the centre on unwrapping, as mentioned by the author on page 121. The difficulty of ensuring perfect contact and oil filling between the core insulation and the centre worming and the different material often used for such wormings, are contributory causes which no doubt accentuate the charring. It is worthy of note, however, that although these two factors also hold for the outside wormings, yet charring is seldom (I think I can say never) encountered on the points of contact with the outer wormings. In considering these theories we must allow for the higher maximum stresses at which high-voltage cables (over 20 000 volts) operate, and recognize that above these voltages we are encountering new conditions. I have never found any burning on 20 000-volt or lower-voltage 3-core cables, and I have no reason to doubt that these cables, if allowed to cool down after prolonged high-voltage tests, do recover and suffer no damage.

Mr. W. T. Maccall: In Fig. 46 is there any particular virtue in the inverse fourth root? That is to say, would not plotting against the inverse fifth root or the inverse cube root give equally reliable values for the breakdown voltage with infinite time? The application of the author's second method (Appendix 1) to the gutta-percha cable (Fig. 11) gives for the 1-, 2- and 4-minute values $I = 0 \cdot 72$ and $n = 0 \cdot 37$; and from the 2-, 4- and 8-minute values, $I = 0 \cdot 69$ and $n = 0 \cdot 33$. It would be interesting to know whether these agree with any values obtained by the slope method, and if so at what times they correspond. I suggest that measurements of the power lost (or of the quantities of charge and discharge) when a cable is charged at a steady pressure and then allowed to discharge would throw light on the probable variation of the component capacities in the model dielectric (Fig 6). In connection with the author's very interesting suggestion of extending his solid models to fill up gaps in our knowledge, it may be worth noting that the power factor is not unity even with a steady pressure, since part of the energy is stored up and is given out again partially on discharge. It may give a better perspective to consider the periodic time rather than the frequency; I do not suggest making the models in this way, since for the scale used for the change from 50 cycles to 25 cycles they would then be some miles long if extended to the steady-pressure cases. What are the author's ideas as to the source of the variation of capacity required by the model dielectric of Fig. 6? In a homogeneous dielectric the resistance of each part $= (1/C) \times$ a constant, if the temperature is the same throughout. Does he consider the resistances to be real resistances, or only equivalent resistances representing the losses in the dielectric due to hysteresis as well as real resistance losses? To use an analogy, the iron losses in a choking coil may be represented by an equivalent resistance; but if the conditions, e.g. frequency, current, etc., are varied this equivalent resistance will change in a different way from the ohmic resistance. I think the case of the dielectric is similar to this, and Dr. Thornton's remarks seem to support this view, but the paper tends to the implication that the resistances are ohmic, and I should like to know the author's opinion on this point. I think that further light would be thrown on this point by comparing the loss tests (or the charging currents) on the same cable (*a*) heated by water, giving sufficient time for the dielectric to reach a uniform temperature; and (*b*) heated by current, but while still on the drum (cf. page 127), so that there is a temperature gradient in the dielectric. This will alter the ohmic resistances of successive layers in different ratios, and so should have a large effect on the losses due to ohmic resistance. Finally, is there any likelihood that the criterion of breakdown in an insulated cable is similar to that for the start of corona on overhead wires? That is to say, does breakdown occur, not when the maximum voltage gradient reaches a certain value, nor, as Fernie suggests, when the minimum stress reaches a certain value, but when the gradient at an intermediate point reaches a certain value, this intermediate point's distance from the core varying with the size of the cable, though not in direct proportion?

Mr. F. H. Williams: From the point of view of the distribution engineer, his requirements in super-tension cables can be stated quite simply. He requires a cable which, once laid, will give no trouble, and he requires a series of tests which he can apply to the cable during manufacture, which tests having successfully been applied he can rest assured that, apart from mechanical damage, the cable will work satisfactorily. When we raised our distribution voltages from 11 000 to 20 000 I do not think that many of us realized that in one step we had actually reached the limit of the particular design of paper-insulated lead-covered cables that we were using, and that future developments could not be met by using the same compound and merely increasing the thickness of dielectric or reducing the potential stress. That, however, was what had happened. The cable maker found that on designing a super-tension cable on the same lines as heretofore the cable tended to heat up when made alive without load, and this heating was traced to losses in the dielectric. To deal with this a different type of impregnating medium had to be sought and a new series of tests discovered. As can be gathered from the paper, the final solution of both of these requirements has still to be obtained, although many miles of three-phase cables for voltages over 20 kV have been laid and are actually in operation to-day. It is a great pity that, the demand having overtaken the development work in the way it has, manufacturers did not realize that they could only deal with an unprecedented situation by heroic measures. One feels that through the Cable Makers' Association or the Electrical Research Association some general pooling of information could have been arranged and a great deal of waste of effort and trouble avoided. Is it too late to hope that something of the kind may still take place? As I have already stated, there are two problems: (1) To manufacture commercially a cable which will operate satis-

factorily at voltages over 20 kV, and (2) to develop a new series of tests to prove that such cables will be satisfactory in operation. The problem of the design of the satisfactory cable is one with which only the cable maker and his research department can deal, but in considering the paper one or two queries naturally arise and I should like to ask the author whether he can show us comparative " V " curves for, say, either a 20-kV cable of the old design or a cable for a higher voltage using the same design and the old type of compound, compared with a cable using the newer type of compound. I should also like to ask him whether he has any data of the losses and behaviour of a Höchstädter 3-core cable. Arising out of the author's theory as to the cause of the " V " curves, has he any data as to the " hydraulic " pressures set up in a cable due either to dielectric loss or to load-current heating when steps have been taken to prevent the expansion of the lead sheath ? The point I have in mind here is that one explanation of the " V " curve, as the author mentions, is that it is partly the result of viscosity, partly the result of expansion and partly the result of ionization. In other words, as the cable warms up the compound becomes less viscous and expands, causing a partial closing of the vacuous spaces, and the dielectric loss falls until ionization of the vacuous spaces takes place, when the curve begins to rise again. A further factor is that there are certain minute air spaces which expand as the cable warms up, and the ionization in these spaces increases and with it the dielectric loss. I think it would be very instructive to plot on one of these " V " curves a curve showing the variation of viscosity with temperatures and the variation of " hydraulic " pressure with temperature. With regard to the testing of super-tension cables I do not like the method approved by the author of heating the cable under test by immersing it in hot water. This gives a heat flow the reverse of that which takes place under ordinary working conditions, and however satisfactory it may be from a research point of view, it is unsatisfactory from the user's point of view as it does not reproduce the conditions of the cable under operating conditions. Further, due to the fact that the lead is hotter than the copper, one would expect the dielectric loss to be increased due to the reduction of the pressure exerted by the lead allowing the formation or enlargement of vacuous spaces. Some tests which I had made with the cable heated (1) externally by water and (2) internally by a circulating current, confirmed this and actually gave, for the cable under consideration, an increased loss of about 50 per cent at 180° F. The difference at a lower temperature was less (as was expected) and was only about 20 per cent. With regard to the testing of super-tension cables, in addition to the standard form of high-pressure test, i.e. " x times normal pressure for 15 minutes," it is customary to measure directly the dielectric loss. Usually this is done while the cable is alive at normal voltage, and in addition to the difficulty of measuring accurately a comparatively small loss practically 90 degrees out of phase with the applied pressure there is the complication of the cable being alive and, usually, of the voltage coil of the wattmeter requiring a resistance which will stand the full voltage. The inspecting engineer responsible for passing such cable is in a very unfortunate position, as he has practically no means of checking the results obtained. There are hardly any published data on the subject; no two manufacturers carry out the tests in exactly the same way with the same apparatus. Further, there is no outside authority to whom he can appeal so as to get the results of various manufacturers reduced to a common basis. It is to be hoped that at an early date the National Physical Laboratory will be in a position to carry out such work and that a method of measuring dielectric losses will be standardized so that the purchasers can make a direct comparison of the results obtained by different makes. As the author points out, however, this dielectric-loss measurement has a distinct limitation in that it only measures the average loss and does not enable us to detect a short, badly-impregnated patch of a cable which has passed the high-pressure tests but will probably cause breakdown in time. A test which will enable faulty impregnation to be detected is an urgent necessity.

Mr. J. Schuil: I should like the author to give his opinion in regard to high-voltage d.c.tests, i.e. whether such tests are detrimental to the cables. Up to about a year ago a steady increase in d.c. cable testing was noticed, but at that time several supply undertakings found that their 33 000-volt cables broke down at the ordinary pressure a few hours or days after the " Delon " test had been carried out. This gave a set-back to d.c. testing for a time, but now with the " Kenotron " method it is forging ahead again. It seems to me that the d.c. test is more piercing than the a.c. test, it penetrates deeper in the insulating layer and therefore finds defeats which sooner or later would have given trouble, and accentuates them. The result will be of great benefit to the industry.

Mr. N. Elkington (*communicated*): The principal fact arising from the paper is how very empirical the manufacture of high-voltage cables is. This is the natural condition of a branch of the industry that has been of financial urgency for only a few years; and I have no doubt that, as usual, there is available among physicists sufficient knowledge, were the facts and needs brought before them, for a scientific explanation of most of the phenomena. There are at least two facts not mentioned by the author that might explain the charring of the dielectric at points where, at first sight, the maximum potential gradient does not occur. In the first place, the dielectric constant is a function of temperature. Hence the incidence of electric force will vary from point to point of the dielectric when the core is heated and the sheath is at a different temperature. I have seen figures for this temperature variation, but cannot recollect where; and I should be pleased if the author would, in his reply, devote a few words to the subject and give any reference he may have seen. In the second place, the actual charring of the paper is due to oxidation of, or similar chemical action on, the less inert constituents. So that if a cable were about to break down along the heated path of an ohmic leak the charring would not necessarily occur at the point of maximum electric stress, or even of maximum temperature, but at the point of most conductive gas. Besides

considering entrapped air in this connection, it would be interesting to know what gases would be liberated from the impregnating fluid into the vacuous space occasioned by the separating of layers of paper during the handling of the cable.

Mr. L. C. Grant (*communicated*) : The author appears to be of the opinion that ionization in the dielectric and relatively high-frequency surging account for many of our cable troubles. If the design of the dielectric is right, ionization is usually due to non-uniformity, and entrapped air is often blamed for troubles of this nature. Inspection of extra-high-tension cable faults appears in many ways to confirm this view and much good could, no doubt, be done by improved methods of wrapping and impregnation so that air and impurities in the oil and paper are excluded. Manufacturers are working on these lines and are probably best competent to deal with this aspect of the problem. Cable troubles at 10 000 volts working pressure will come as a surprise to many of us, but the fact that the troubles were eliminated by the use of surge-absorbing appliances is none the less interesting. The method of handling surges is important, and it is difficult to see how any apparatus employing resistance or spark-gaps alone or in combination can be effective. Spark-gap and resistance devices work by connecting the affected line to earth and thus reducing the potential, but it is possible to prove by simple mathematics that effective protection cannot be obtained in this manner. To be effective, the resistance must prevent the oscillations building up and to achieve this the resistance should be at least twice the surge impedance of the line. Greater values of resistance are usually employed. With such an arrangement it is possible to limit the extent of a pressure-rise, but it is not possible to prevent some rise taking place. To put it briefly, there are two limits : On the one hand the resistance must be kept high to prevent oscillations building up, but on the other hand it must be low enough to prevent a dangerous voltage-rise. Normally, resistances used in this way are capable only of limiting the voltage-rise to something like 70–80 per cent of the maximum possible value. Spark-gap devices are of doubtful value, first because they must be set at some voltage above the line voltage before they will operate, and, secondly, because a spark-gap tends to promote oscillations on its own account in much the same way as in Tesla and wireless apparatus. To overcome these troubles the surge-dissipating device should be of a non-oscillatory form and should contain no spark-gaps. The "Campos" device and the surge-absorber described by Captain Ferranti at the Paris Conference operate by dissipating the energy of the surge in the form of heat. In the "Campos" arrangement, inductance shunted by resistance is employed to localize the pressure-rise and to dissipate it in the form of heat. One of the objections to this arrangement is that it is difficult to build and insulate a resistance capable of handling sufficient energy to give efficient protection. The other arrangement overcomes this trouble by utilizing a step-down effect so that the dissipator is able to handle large amounts of energy, whilst the insulation required is of an ordinary character. Condenser devices and inductance coils, no matter of what form, are alone quite incapable of dissipating the surge energy : in fact, they tend to set up and maintain surges. Properly embodied, however, their characteristics can be usefully employed in surge dissipators where they have a definite duty to perform, but that duty can never be the actual dissipation of the energy in a surge.

Mr. E. B. Nixon (*communicated*) : What is the author's opinion of graded dielectrics for super-pressure cables ? Such dielectrics would appear to solve the troubles at present experienced with impregnated paper. This point is linked up with the requirements of many speakers in the discussion, i.e. new methods of testing to localize incipient cable faults. The suggestion is made that graded dielectrics would nullify this demand. It should be possible to give, within reasonable limits, the testing voltage a cable will withstand, and also the puncture voltage. These tests would be carried out on test-lengths only, and the final test on the cable when laid would be a d.c. test of a voltage suitable to prove that the laying and connecting have been well done. From the testing voltage can be derived the safety factor, if this is desired, i.e. safety factor = (testing voltage for a period of, say, 1 hour)/(line pressure). I think that the author will agree with these principles, for there is no doubt that, as he states on page 121, high-voltage tests may damage the insulation, and after all they do not prove that the cable will be satisfactory.

[The author's reply to this discussion will be found on page 144.]

NORTH-WESTERN CENTRE, AT MANCHESTER, 17 NOVEMBER, 1925.

Mr. C. J. Beaver : Like the majority of papers which deal with electric cables, this paper is chiefly concerned with the electrical aspect of the subject ; it usually seems to happen that very little account is taken of the physical or chemical aspects, and one is rather liable to lose the proper perspective of the whole thing. There is perhaps too much inclination to deal with the subject on a mathematical basis, and to ignore factors which are not susceptible to mathematical treatment, such as the heterogeneous structure of the material and its chemical stability or instability. There is much in this paper which is known in a general way but, like a lot of those things which we think we know, a great deal more reveals itself when we come to look thoroughly into the subject and analyse it completely. For example, the electrification and the time/voltage relationship to which the author has referred is an everyday matter to those who have to test electric cables in the factory. Variations of it in analysing anything suspicious are used as almost a matter of everyday occurrence. Taking a general survey of the paper, the author seems to have vacillated somewhat before reaching his I^2R loss conception, and to have accepted as the whole story what most authorities on

the subject agree is a substantial part. We have to remember that, whatever conception we may have of it, it all comes down to a common end. The penultimate stage results in the dielectric becoming more or less conductive, and the ultimate breakdown is simply a matter of sufficient energy per unit volume of the dielectric being liberated in it, after that state has been reached. In other words, this common end of the mechanism of breakdown—whatever the intermediate processes may be—is accountable for by what the author has referred to as the pyro-electric theory. The claims for his theory, as stated on page 122 under six headings, refer to points which really have been quite convincingly explained by other theories—such as the ionization theory—although the points do not strictly come into line. To take the first—"the presence of the charred patches in isolated places after prolonged test"—I think, for the reasons I have just stated, that this cannot be claimed to support the I^2R loss theory. It is a pyro-electric effect. The second one—"the peculiar designs assumed by the charring"—is much more characteristic of ionization in air or gas spaces than of simple charring effects. They are the sort of tree-formation appearances which one would associate with static discharge, the charring or burning being an advanced stage of it. Next, the time/voltage relationship and the overloading to which the author refers seem to me to amount to this, that when we either overload the cable or overstress it we do something which leads to a disturbance of the physical state of the chemical composition, and we cannot expect to get the same result after we have set up the incipient conditions for the process of breakdown. The shape of the burnt-out path through the dielectric is simply determined by the path which we have more or less rendered conductive. It may be radial in direction, or curved or angular in relation to the axis of the cable, according to the imperfections or impurities which have determined the path in the earlier stages of its development. The author's last point—"the difficulty in employing the logarithmic formula connecting dielectric stress, dimensions and breakdown voltage"—has, I think, no relation to his claims. The difficulty has been very thoroughly discussed by various writers, and one need only look at it from this point of view, that these theoretical formulæ assume an isotropic or, at least, homogeneous dielectric which does not exist in actual practice. The kind and degree of heterogeneity vary in different dielectrics. For example, a varnished-cambric cable dielectric is very coarsely heterogeneous, consisting of cellular parts composed of woven fabric interspaced with varnish films. Further, the cellular parts cannot be perfectly freed from air and moisture, so that the mass as a whole is far removed from homogeneity. Yet this type of dielectric is often referred to in accounts of experiments bearing on the proof of theoretical formulæ. The author's reference to the intersheath form of cable is rather interesting to me because I was, in 1914, the apostle of intersheath cables; and the interesting part is that the author says exactly the opposite to what all my critics said in 1914. They said that if there were any weaknesses in the layers of dielectric the intersheaths would line them up and the cable would break down; whereas the author says that the intersheaths will, according to his I^2R theory, strengthen the dielectric simply by their presence. On page 120 the author has referred to a matter of extreme importance regarding the protection of high-voltage cables in use. I know that there will be a lot of disagreement as to the necessity of it, but the article by Mr. Partridge of the London Electric Supply Corporation referred to in Appendix II (36) showed some very remarkable and significant results. The subject is worthy of very close attention and should not be lightly dismissed. There is a good deal more in it than the author's brief reference indicates, and I recommend its careful perusal. The author's reference on page 122 to statements I have made regarding losses in paddings or wormings in 3-core cables relates, I take it, to a lantern slide which I showed here about 9 months ago; and as unimpregnated wormings were not referred to, and, further, as the bearing of the whole matter had

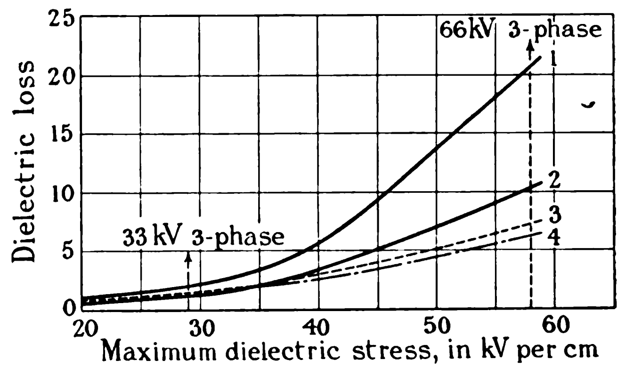

FIG. H.—Comparison of types of padding. Variation of dielectric loss with dielectric stress. Tests at air temperature.

Cable 1.—Cable with ordinary impregnated paper padding.
Cable 2.—As Cable 1, but padding filled with compound under pressure.
Cable 3.—Cores as Cable 1, but padding of homogeneous non-fibrous material.
Cable 4.—Theoretical curve for Cable 3, assuming constant power factor.

reference to the elimination of air from padding spaces and its effect on losses which were clearly due to ionization, I should like to show the slide again. According to my notes, I quoted a statement by Mr. Tracey of Messrs. Johnson and Phillips, at an Informal Discussion in London on the wattmeter method of measuring dielectric losses, to the effect that if the losses in a multicore cable could be segregated and analysed, 75 per cent of them would be found to occur in the filler spaces. I showed the slide in question (Fig. H) to illustrate my experimental confirmation of what Mr. Tracey had predicted. The loss/stress curves in Fig. H relate to three cables, the cores of which are identical. In the first case the cores were laid up with ordinary impregnated-paper padding. The second cable was identical with the first, but the padding was filled with compound under pressure. In the third cable the padding was made of a homogeneous non-fibrous air-free material. It will be seen that the losses are of the same general order in all three cables at stresses between 20 and 30 kV per cm, but there is a very considerable difference between them at stresses

of the order of 50 to 60 kV per cm, i.e. at stresses at which ionization in air spaces can freely occur. Comparing curves 1 and 2 at 60 kV per cm, it will be seen that in the latter curve the total losses under three-phase test conditions have been reduced by 50 per cent, as the result of filling the impregnated paper padding with the compound under pressure in situ, whilst the substitution of the ordinary impregnated paper padding by the homogeneous air-free material

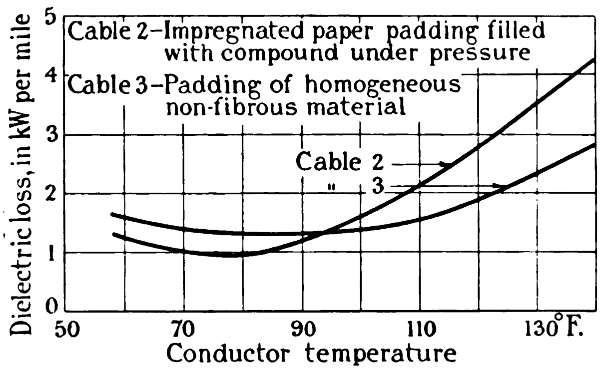

FIG. J.—Comparison of types of padding. Variation of dielectric loss with conductor temperature.

reduces the losses by 60 to 70 per cent. The theoretical curve (4), plotted on the assumption of constant power factor, lies very close to curve 3, showing the very marked effect of eliminating occluded air and gases from the padding spaces. This does not, however, necessarily reduce the power factor. It is well known that at stresses below those at which ionization occurs

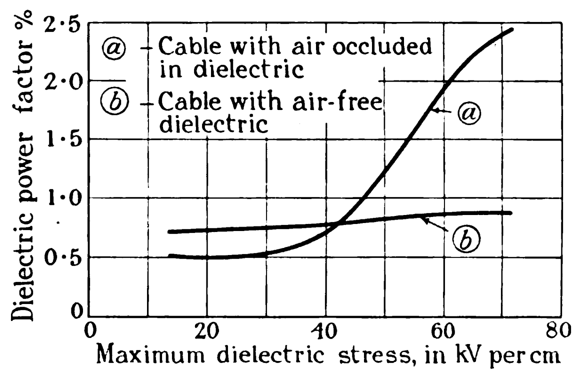

FIG. K.—Variation of dielectric power factor with dielectric stress. Test on single-core cables.

a dielectric containing appreciable proportions of air may have a lower power factor than an air-free dielectric. Fig. J shows the loss/temperature curves for cables 2 and 3, from which it will be seen that, owing to the different shapes of the curves, the values over the lower portion of the temperature range are lower for cable 2, containing air in the padding spaces, than for cable 3, containing practically none. The point is further illustrated in Fig. K, which shows the power-factor/stress characteristics of two single-core cables of similar dimensions, cable (*a*) containing air and (*b*) being free from air. It will be seen that (*b*) has a higher power factor than (*a*), but the power factor remains approximately constant over the whole range of dielectric stress, whilst (*a*), as a result of containing air, shows a fairly rapid increase in power factor at stresses exceeding that at which ionization commences. It will be clear that all this evidence is more in accord with the ionization theory than with the author's I^2R theory. A further point in this connection is that the partially solidified impregnating material which is frequently found in conjunction with the charred tree-like formations in an overstressed dielectric has been proved to be an oxidation product, which clearly indicates the presence of air. In conclusion I should like to refer to one or two of the author's statements regarding the hypothetical fault illustrated in Fig. 51. I consider he is not entitled to say that an effect which he finds to occur on the surface of freely exposed impregnated paper will also occur in the interior of a cable dielectric. So far as dispersal of compound around the test-electrodes is concerned, the phenomenon is quite familiar. I have always attributed it to electrostatic repulsion between free particles of material. Similar conditions do not exist inside a cable dielectric, except in an actual cavity, and although the presumed travel of compound is not inconceivable I have never found any evidence of it in practice.

Mr. H. Hawkins: I intend to confine my remarks more particularly to the question of design, because I feel sure that the selection of a suitable design would carry with it the solution of some of the problems which the author has described. From my experiences of 33 000-volt three-phase cables I have become a convert to Höchstädter—to his type of cable and to his theories—and I suggest that his cable, or one of a fundamentally similar type, would provide a solution of many of our difficulties. The Höchstädter cable differs essentially from the type of cable under consideration in the paper, i.e. the standard 33 000-volt cable in use to-day. In the Höchstädter cable the belt or girdle of insulation encircling the grouped cores is absent, a proportionate amount being added to the insulation of each individual core; and each of the three cores has finally its own copper sheath in contact with the lead sheathing. From my experience I should perhaps feel inclined to add to such a cable a brass, or copper, constricting band encircling the three cores, as it would keep the core sheathings in intimate contact throughout the life of the cable and would also tend to localize the effects of faults. Incidentally, it may be presumed that such a cable would be less liable to faults between phases than one of the "belted type." I am aware that such a constricting band was used on a beltless super-tension cable which has, I understand, been in successful operation at 55 kV for some years, and in that cable the band has a more essential duty to perform. The author would appear to support me in my contention that such a cable merits attention. I refer to his article (No. 31 in Appendix II) in the *Electrician*, where he alludes to a three-phase cable made by his company. He states that such a cable, known as the "S.L. type" (which if not of the exact Höchstädter pattern is at least beltless, when used for pressures above 33 kV), offers

"enormous advantages." This statement brings me back to Höchstädter's theory of "limiting voltages," governed by the fact, he affirms, that above approximately 15 000 volts to earth and 25 000 volts between phases the quadratic law of dielectric loss is no longer true for three-phase cables (of the belted type), and the loss is proportional to higher powers. I would, however, supplement this by a further quotation from the author's article previously referred to: "Where pressures exceeding 22 kV are under consideration quite a new range of phenomena enter into cable manufacture and operation." Now, if I accept this theory of "limiting pressures," I am driven to the conclusion that there should logically be but one type of three-phase cable for all pressures above 22 kV and that one the Höchstädter, or one of the allied beltless types, which should offer some if not all of the advantages claimed for the original. The chief of these advantages is perhaps the elimination of those "annoying tangential stresses," owing to the fact that the whole of the outer surface of the dielectric of each core is kept at earth potential by its metallic sheathing, inside which there is uniform stress in every direction. If such a standard type, as I suggest, had already been in existence and generally adopted, the somewhat anomalous position in which users of 33-kV three-phase cables at the present time appear to be would have been avoided, as we are now told that other types offer "enormous advantages" for pressures above 33 kV, which leaves us in this dilemma. Are we to lower our working pressure below 22 kV in order to escape from the implied disadvantages under which we suffer, or are we to change the type of cable and raise our voltage? If it is not denied that improved types of cable are capable of giving satisfactory service at pressures of 44 kV and above, it must surely be agreed that such a type if used at 33 kV would at least give a greater "factor of safety," and, further, that its users could, without excessive increase in their original outlay, have the opportunity, which they have not hitherto enjoyed, of being able to raise their working pressure at some future date. I feel that perhaps I owe the author an apology for the above remarks, inasmuch as they may not be accepted as strictly germane to the points at issue, but I consider that a fundamental alteration in the present type of cable would offer a solution of many of the problems mentioned in the paper. In conclusion I would ask the author, placing his own valuation on the great advantages of the type of cable he has advocated for pressures above 33 kV, would not the improved "factor of safety," if such cable were used at a lower pressure, relieve users of some of their anxieties in regard to the phenomena mentioned in the paper, and further, would it not provide an answer to some of the questions which require settling as between maker and user?

Mr. H. M. Crellin: I do not agree with the author's I^2R theory as an explanation of either dielectric absorption or alternating-current losses, or as the primary cause of dielectric breakdown. With regard to Figs. 4 and 6, I think that it is quite legitimate, for the purpose of mathematical analysis or to facilitate calculation, to represent an absorption condenser as equivalent to a combination of a pure (or no-loss) condenser shunted by a resistance, but I am quite convinced that such an arrangement does not represent the true physical action in an absorptive condenser. Consider the application of a d.c. voltage across the condensers and resistances shown in Figs. 4 and 6, e.g. when connected across a battery. If now the connection between the condensers and the battery be broken those condensers would all be immediately discharged through the resistances in parallel with them. This does not happen, however, in an actual cable. Even if one endeavours to conceive the values of the resistances to be so high as to allow the condensers to discharge extremely slowly, the resistances would have too high a value to carry the comparatively instantaneous and large current necessary for the absorption component. Take another instance bearing on the same point. In Fig. 24 the dielectric loss for a 30-yard length of 0·1 sq. inch cable is given as roughly 0·002 watt at, say, 100 volts. This figure corresponds to an "effective" or, shall we say, equivalent (mathematically) resistance of 5 megohms for that length, or 0·085 megohm per mile of cable. I cannot accept this figure as representing a real physical resistance, because a condenser shunted by such a low resistance would not hold (as a real cable will) the charge from a low-voltage battery when testing the electrostatic capacity by the direct-deflection method. From pages 121 and 122 the author's contention, apparently, is that all breakdowns are preceded by some charring through heating caused by displacement currents. In my opinion this is incorrect. I cannot conceive that in the case of a cable or other dielectric subjected suddenly to a pressure so much above its breakdown strength as to cause instantaneous rupture that the breakdown is preceded, or caused, by charring due to displacement currents. I agree that on tests with pressures lower than the instantaneous breakdown values, applied for comparatively long periods on cables or dielectrics containing defects, some charring due to internal discharges across such defects may precede and accelerate breakdown, but such action does not to my mind represent the true physical nature of breakdown under electric stress any more than would a theory that the invariable cause of failure of metals under tensile or compressive stress is entirely due to defects in the metal.

Mr. A. Philip: On page 121 the author states that "paper fibres . . . no doubt have tiny quantities of moisture," and I should therefore like to have his opinion as to the extent to which moisture is allowable in cable paper. We find that in the paper of most high-tension cables which we have examined moisture is present to the extent of from 1 to 2 per cent, and I should like to know if the author considers these values to be excessive. In my opinion the absorption equation $I_t = I + At^{-n}$ is not at all satisfactory, because (1) it is based on a study of gutta-percha cables and thereafter applied to paper cables, and (2) the so-called constants are really variable. It is not quite clear from the paper whether Granier actually uses this equation in his treatment of the subject, and I should like to know if the author has calculated the a.c. losses from Granier's expression and the index n for any

particular cable for low voltages where the question of ionization does not arise. The absorption curves given in the paper commence usually at a value $t = \frac{1}{4}$ minute or $t = 1$ minute, whereas under a.c. conditions the times involved are very small fractions of a second, so that it is difficult to connect the d.c. index n with Granier's n. It would also be interesting to know how the absorption equation "constants" vary with the voltage.

Mr. B. G. Churcher: The need for a theory connecting d.c. with a.c. dielectric phenomena has long been realized and I think the present paper is a valuable one in that direction. It has long been known that the a.c. losses are not generally merely a matter of simple conduction. That is to say, the loss is not equal to E^2/R, where E is the applied P.D. and R the insulation resistance measured with direct current. However, there is actually one case where the a.c. loss is equal to E^2/R. This occurs in very poor-class insulating materials, such as slate, in which a power factor of unity may be obtained. These materials behave like conductors. The resistance is invariable with the frequency and the d.c. resistance is equal to the a.c. resistance. Another speaker has already raised a question in regard to the curve connecting the absorption index with the power factor (Fig. 22). I should like to know whether the author has taken a cable, measured the capacity of the cable with direct current and from the absorption index calculated the power factor; then for a given a.c. voltage and frequency applied to the same cable has calculated what the dielectric loss should be, checking the value so obtained by a wattmeter measurement. That would seem to be a crucial test of the theory. I should imagine that the different values of n at different times during the charging period would make it difficult to get an accurate check. The deduction on page 109 regarding the variation of power factor with frequency is interesting. I have looked up the ratios of the power factors at 25 and 50 cycles for two materials. In a sample of rather low-grade bakelite with a power factor of 0·17 the ratio was found to be 1·22, and for ebonite with a power factor of 0·016 the ratio was 1·05. These values tend to confirm the author's deduction. In connection with the theory of parallel condensers and resistances, it is perhaps rather necessary to point out that although we may make a sort of model the performance of which fits the observed behaviour of the dielectric very well, it cannot be argued that because the transformation of electrical energy into heat energy takes place according to the I^2R law in the model, that therefore the same thing happens in a cable. Models of that kind, or equivalent circuits, can be made to represent many electrical phenomena, but they do not indicate what is actually happening inside the apparatus which the model represents. I do not wish in any way to depreciate the value of the model for purposes of calculation, but I think it is necessary to bear in mind this limitation. With regard to the "V" curves given on pages 110 and 111, I have not, on any materials of which I have had experience, found the power factor to decrease with an increase in temperature in the region of 20° to 30° or 40° C. I am speaking, of course, of materials which are used in the insulation of electrical machinery and not in cables. These materials give a roughly constant power factor from about 20° to 30° C., after which the power factor increases. I should like to know whether the "V" curve is a peculiarity of the materials used in cables or whether it arises from the way in which the insulation is applied in the manufacture of a cable. The figures in Table 5 showing the relation between the d.c. and a.c. losses are very interesting. Although the power factors are not given, the tests were made, of course, under conditions of increasing power factor, as the power factor increases in general with temperature. It is shown that the ratio of d.c. to a.c. losses comes nearer to unity as the temperature is increased. I take it that if one could heat the cable sufficiently without damaging it, unity power factor would be reached and the d.c. loss would be equal to the a.c. loss. With regard to the effect of stress on power factor, has the author considered the rise of the average temperature of the dielectric in a cable, due to dielectric loss? Taking some figures given in the paper, I have worked out a case where one can get quite an appreciable temperature-rise for a voltage of 70 kV and a thickness of insulation of 1 cm. For instance, taking the permittivity of the insulation as 4, the thermal resistivity for oil-soaked paper as 250, and the frequency as 50; then taking the curve in Fig. 25 the power factor at 50° C. is 0·02, which gives a loss of about 0·011 watt per cm^3. Assuming that the testing voltage were kept on for a sufficient time for thermal equilibrium to be attained, the dielectric loss would give an excess of temperature on the inside of the insulation over that on the outside of about 1·4 degrees. If the cable is heated up to 70° C. the curve shows that the power factor will be about 0·09, which will give 0·048 watt per cm^3, and a temperature difference between the inside and outside of the insulation of about 7 degrees. Looking at the power-factor curve, it can be seen that at 70° C. the curve is very steep and an increase of 2 to 3 degrees in the average temperature of the insulation would increase the apparent power factor quite appreciably. Of course there is little doubt that a great deal of the increase in power factor with stress, observed by the author, is due to discharge across air inclusions, but I should like to ask him whether he thinks that the increase of power factor due to heating by dielectric loss is negligible. In testing specimens of material where there is little or no chance of air inclusions one usually assumes that an increase of power factor with stress is due to internal heating. The magnitude of the effect is usually consistent with this view.

Mr. E. L. Davey: Maxwell explained d.c. absorption and residual charge on the basis of a heterogeneous dielectric, and the author has endeavoured to apply this to a.c. conditions, explaining the a.c. losses as being due to the absorbed charge currents flowing through resistances and discarding the idea of a dielectric hysteresis. It is interesting to note that Del

Mar and Hanson * showed that the effect of the composite structure of insulation was to increase the loss under a.c. conditions due to the fact that the voltage was capacity distributed, whilst under d.c. conditions this distribution was in proportion to the resistances and a minimum energy loss was involved. This conception is much clearer than that of a current flowing through a resistance to supply an internal or absorbed charge, since it is difficult to visualize an absorbed charge under a.c. conditions. Del Mar and Hanson stated that the increasing of the loss would be independent of frequency, i.e. the behaviour of the loss of a composite dielectric would be governed by the behaviour of the losses in the materials used in building up the dielectric. The dielectric hysteresis idea has a physical basis and is appreciated by virtue of this, whereas the conception presented by the author has no such basis. The hypothesis of a condenser and series resistance for a dielectric under a.c. conditions at low temperatures is quite unsatisfactory for several reasons. In the first place the dielectric power factor at low temperatures is independent of the frequency, whilst that of the condenser arrangement is governed by the relation $\cos\,\theta = \omega CR/\sqrt{(\omega^2C^2R^2 + 1)}$ into which the frequency enters appreciably unless R is very large. The approach of independence of $\cos\theta$ with respect to frequency is simultaneous with $\cos\theta$ approaching unity, and this is not in accord with the low values of power factor met with in practice. For a reasonable value of power factor we must have a very low value of series resistance, but this is contrary to the values of resistance met in connection with dielectric work, and also under these conditions $\cos\theta$ approximates to a value ωCR, i.e. it is dependent upon the frequency. In the I^2R explanation of the "V" curve of dielectric loss it becomes necessary to revert from the series arrangement of resistance to a parallel arrangement. This is purely a mathematical artifice and can by no means be called an explanation of the "V" curve, a true explanation of which connects up the electrical behaviour with the physical changes that take place as a result of the heating. Höchstädter and Pungs have pointed out the great similarity between the behaviour of the a.c. losses of the impregnating compound and the losses in the actual cable with respect to frequency and temperature. The close coincidence of the minimum-loss point with the melting point of the impregnating compound also merits great attention, whilst the work of the physicists such as Decombre, Jaffé, Malclès, etc., on ionic motion in dielectrics cannot be lightly passed over. As a result of the Granier relationship betwen the a.c. power factor and the d.c. absorption index n, the author states that so far as absorption losses are concerned the perfect cable dielectric is one which in the index n equals unity, giving zero power factor and hence no absorption losses. This is not in agreement with the equation $I_t = I + At^{-n}$, where At^{-n} represents the current supplying the absorbed charge, since the latter is not zero when n equals unity but only when A equals zero, as can be shown by a study of the absorptive condenser of Fig. 4. The value of the index n for a paper-insulated cable falls from about unity to 0·5 as the temperature is raised from 10° C. to, say, 60° C., and according to the Granier formula the power factor should rise with increase of temperature to an extremely large value, such as is never met with in practice. Also, until n equals zero the loss depends upon the frequency to some extent, but in practice it is independent of the frequency for temperatures above 50° C. No explanation of the minimum-loss point can be given on the basis of absorption since, as shown above, the absorption losses increase steadily with temperature. In connection with the tests on celluloid conditioned at various humidities, it is interesting to note that Du Bois gave an explanation of dielectric loss based on the mechanical action of moisture in a dielectric field and supported his theory by experimental results on a cable which had been given less drying than usual. Marbury has also recently shown that the effect of moisture is greatly to increase the d.c. absorbed charge, but with well-dried cables this effect should be negligible. It is stated from a consideration of Fig. 34 that it is evident that by far the greater part of the losses round 80° C. are cyclical, but judging by the 150° F. line of Fig. 36 this would not seem to be the case since the loss is independent of the frequency from about 5 cycles per second upwards. The capacity voltage-distribution theory will give a very reasonable explanation of this. This point also illustrates the drawback of endeavouring to connect up the d.c. losses with a.c. losses at 25 and 50 cycles. At very low frequencies the loss curve rises suddenly with respect to frequency and no explanation of this can be advanced on the basis of the I^2R theory. The author's explanation of the minimum-loss point refutes his main theory, as he states on page 114 that the absorption losses seem to have in them two components to produce the dipping curve. We only have to specify that the decreasing component varies as the frequency, and we have arrived at the Höchstädter explanation. The effect upon its ionization characteristic of heating and cooling a cable is well known and can be explained by the action of the draining of the impregnating compound and also the lowering of the pressure of the entrapped air due to the compound solidifying under pressure. Thus curve A in Fig. 39 represents a cable having occluded air present in the dielectric, this air being uniformly distributed, and curve C represents a much less uniform state. As would be expected, this effect is practically absent in a thoroughly impregnated dielectric. Owen's method of plotting breakdown voltage against the inverse fourth root of time has been used in a very arbitrary manner, and the conclusion that a cable would support indefinitely voltages below a certain value is unwarranted. The maximum time taken in the breakdown tests is of the order of 60 hours, and the author has assumed that the straight line variation of breakdown voltage with the inverse fourth root of time holds for time values of the order of a number of years, irrespective of the variation of the rate of deterioration of a cable with time. The outcome of the study of the nature of cable breakdown seems to suggest that the utmost

* *Transactions of the American Institute of Electrical Engineers*, 1922, vol. 41, p. 563.

care should be taken thoroughly to impregnate a cable dielectric and to exclude air. The I^2R theory does not explain the increase of dielectric loss at low voltages with better impregnation of the dielectric. This experimental fact supports the ionization theory, as air has practically no loss when stressed electrically until it becomes ionized, and then the loss increases at a very rapid rate. The author's explanation of the motion of the impregnating compound near a weak patch in a cable dielectric is opposed to a fundamental law of the dielectric circuit, namely that a material of high specific inductive capacity is urged towards the strongest part of the field from weaker parts until a maximum amount of energy is being stored in the dielectric field. Steinmetz and Hayden based their breakdown theory of liquid dielectrics upon this law and it can be illustrated experimentally by dropping water, etc., into an oil gap. Clark and Shanklin are referred to as having given an explanation of the " V " curve on the ionization basis, but in their actual tests in 1917 they found that the dielectric loss for all their cables increased steadily with temperature throughout the temperature range. If the stress is high enough and air is occluded within a dielectric the " V " curve is made more prominent due to the losses being increased by the ionization losses at low temperatures, whilst at high temperatures the pressure of the occluded air is sufficiently high to prevent ionization. The heating of a cable for dielectric-loss tests by placing it in water has the drawback that the whole of the dielectric is at a uniform temperature and the effects of the temperature gradient on the dielectric loss are missed.

Mr. J. L. Carr: The phenomenon of dielectric absorption has been explained by an arrangement of condensers in cascade, with resistances in parallel, and I think that this theory received support from Steinmetz himself some two years ago. In my opinion it seems to provide a reasonable explanation of what occurs in charging and discharging an electric cable. I am rather disappointed that the author has devoted so little space to the question of the design of, and the development of breakdown in, electric cables. These considerations would, I think, be of greater interest to the majority of electrical engineers at this time than the question of dielectric absorption. In this connection there are one or two points which I should like to raise. On page 121 there is a statement attributed to Fernie, that the breakdown of a high-voltage cable takes place at the point of minimum stress. To my mind this is an absurdity. A chain is no stronger than its weakest link, and it is not reasonable to assume that a cable will break down at the point of least stress. It is a fact, however, that cables do break down at a point adjacent to the position of minimum stress calculated according to the logarithmic formula, but this is largely due to the fact that the stresses in a 3-core cable are not uniform; and, quite apart from the tangential stress described by Höchstädter, there are other stresses which lie along the individual layers of paper rather than across them, and, given certain other conditions, this results in a discharge taking place at this point. In this connection, it is a matter of easy verification that in the presence of air and moisture it is comparatively much easier to produce a flash over the surface of an insulating material than to puncture it. In the case of paper impregnated with cable compound, a flash-over in the presence of air and moisture takes place very easily. I am speaking of cables subjected to a pressure far beyond that at which the cable is intended to work, provided that the insulation is sufficiently good, and the cable well impregnated, without considerable air spaces. During these tests, discharges become apparent after a time, and if in the early stages the interior of the cable be examined, the effect of the discharge is seen to lie in the compound on the surface of the paper without actually damaging the fibres, so far as can be seen under the microscope. If the test be extended over a considerable period, the paper itself becomes charred. This, I think, rather supports the view that the initial discharge which occurs on the surface of the paper is due to the presence of air or moisture. As soon as a discharge takes place, the presence of carbonaceous matter in the cable itself tends still further to disturb the stresses and produce still greater discharge. As far as my experience goes in carrying out tests on short lengths of single-core cable, in the majority of cases the cable shows signs of breakdown first at, or near, the point of calculated maximum stress, that is, near the conductor, although it is fairly easy to understand that there may possibly be signs of discharge at other points.

[**Mr. H. A. Ratcliff** also took part in this discussion. The substance of his remarks will be found on page 127 in connection with the discussion before the Institution.]

The Author's Reply to the Discussions at London, Newcastle and Manchester.

Mr. P. Dunsheath (*in reply*): In presenting the paper I expressed a hope that, whether or not the paper itself added to our common stock of knowledge, at least good would come from the subsequent discussion. The wide field covered by the many valuable contributions to the discussion, and the kind appreciatory comments on my ideas by acknowledged authorities, make me feel that in both respects the paper has been worth while.

In connection with the relationship between d.c. conduction and a.c. loss in a cable at its higher temperature, Mr. Melsom refers to the important investigations of Mr. Evershed, but I have carefully studied Mr. Evershed's paper and can find nothing that carries us very far in this matter. The most useful prior publications are those of Dr. Fleming and Mr. Dyke, and Mr. Addenbrooke, referred to in the paper. I fully agree with Mr. Melsom that the Section on assessment of cable quality could be amplified with advantage, and perhaps one day we may have an Institution paper on the subject. It is worth an entire paper to itself. As Mr. Melsom does not say in what respect he dis-

agrees with what I have said in this Section, it is not possible to reply very usefully.

Mr. Emanueli's support of my experimental results demonstrating the existence of the "V" curve at low voltage is very gratifying, but he brings out a new and valuable fact in showing the existence of a maximum point at about 0° C. I have not carried out tests at these low temperatures, and without further investigation it is difficult to explain with certainty this maximum point. The value of the temperature at which it occurs, however, suggests some connection with the freezing of moisture particles or filaments. Although I had not thought of it before seeing Mr. Emanueli's curves, the results are consistent with the theory of the "V" curve which I have advanced at the bottom of page 109, col. 1. As the temperature falls the values of the series resistances may only continue to rise down to the freezing-point of water, and if at this point the negative temperature coefficient disappears, as is quite probable, the falling part of the "V" characteristic will reach a limit here and the curves will be explained. The nature of the variation of power factor at the higher temperatures in Mr. Emanueli's Fig. A is consistent with that shown in my Fig. 43, but I cannot understand the increase with frequency in his tests between 0° and 20° C. The shifting of the minimum point by alteration of compound, referred to by the same speaker, is also illustrated in my Fig. 41, and I can confirm his statement that the addition of rosin moves the point to the right. With the rest of Mr. Emanueli's remarks on the various questions of inspection of cables, undesirable reductions of dielectric losses, methods of heating cables for loss tests, etc., I am in entire agreement.

Mr. Ratcliff questions the application of the well-proved time-voltage relationship to explain the breakdown of cables months after installation. If he accepts the nature of the curve—and there is sufficient evidence to make this necessary—then I cannot see why he should decline to accept the application. He also raises the vexed question of factor of safety, and bases his requirements on a 25-year life. If, now, we could determine the 15-minute test voltage which is equivalent to 25 years at the working voltage, it would be necessary to obtain only a small percentage increase on the test value in order to extend the life of the cable by a second 25 years, presuming, of course, identical conditions in both cases. The reason for this is that after a long time the time/voltage curve is very nearly flat and a slight change in the height is accompanied by an enormous change in the time. The really important fact that we must face is that different dielectrics and, therefore, different cables have different time-voltage curves, and the fact that two cables have the same factor of safety on a short-time test is no criterion that they will have the same factor of safety over years of service. Mr. Ratcliff's remarks as a cable user on the desirability of installing protective gear are of considerable interest, although in the light of the results obtained by another cable user quoted in the paper, and of views expressed by other members in the discussion, for example, Mr. Beaver and Mr. Grant, it does not appear that the last word has been said on the subject. He expresses the opinion that the cables themselves are the most effective absorbers of transient high-frequency disturbance on a system, but we must bear in mind that this is not the prime function of a cable, nor are cables designed with a view to make them efficient shock absorbers. I think it must be admitted that if a system is subject to pressure-rises and the engineer does not wish, for various reasons, to install protective devices, then the cable must be designed more generously than if all precautions were taken to prevent the voltage exceeding the normal working value. I am in agreement with Mr. Ratcliff on the relative reliability of three-core and single-core cables, and I refer to the matter below in replying to the points raised by Mr. Hawkins.

I see that Mr. Ratcliff and I are not in agreement over the method of heating a length of cable for dielectric-loss tests. He claims that where a cable is heated by current the temperature gradient in the dielectric and the electromagnetic effects arising from the circulating current so obtained—features not obtained where water-heating is adopted—have an important bearing on the behaviour of the dielectric. The temperature gradient certainly is an important factor, but I can scarcely believe that the electromagnetic forces between conductors carrying normal currents are of any importance at all compared with the mechanical force due to bending a cable. And what can be the advantage from the user's point of view in testing his cable with only a part of the dielectric heated to a known temperature, over testing with the temperature of the whole dielectric absolutely controlled? If there were any electrical weakness introduced by having a temperature which falls off in value from the conductor to the lead, there might be some reason for accepting the other disadvantages of this test, but I have never seen any evidence of such weakness. In case it may appear that my opinion is influenced from the manufacturer's standpoint, I may say that a cable always shows up better on dielectric-loss tests when tested by Mr. Ratcliff's method than when tested in water, for the simple reason that in the latter method all the dielectric is hot and not merely that part near the conductor.

Mr. Allen explained the method of analysis described by Steinmetz to demonstrate how a more exact expression than $I+At^{-n}$ could be obtained for the charging current of a cable dielectric. He produced some interesting curves and there is no doubt that Steinmetz's analysis of a charging-current curve into a series of exponential curves has all in its favour from a mathematical point of view. It does not at present, however, help us in co-ordinating the work of those investigators who have used the index n in the d.c. formula adopted in the paper for analysis of the a.c. conditions. Mr. Allen's remarks on the effect of light and heavy oils and finely divided air are valuable, but the examination of any such theory as he advances to explain the "V" curve would involve consideration of the various expansion coefficients of the different components of the cable, the oil, paper, air and enclosing envelope. This would be well worth following up. Mr. Allen also raised the question of the

effect of hot spots on the smoothness of the time-voltage curve. It is the author's experience that with 5-yard samples of a well-made cable with well-made pot ends the points generally do not depart far from a smooth curve.

Mr. Taylor's observations on the effect of intersheaths on puckering of papers in a single-core cable are of considerable interest, as, of course, anything which makes for compactness is an advantage from the electrical point of view.

In reply to Mr. Silver, I do not consider that tests of dielectric resistance can at present replace pressure tests. There are certain possible defects in high-voltage cables which, while causing failure in use, would not show up on a resistance test. For instance, imperfect impregnation may result in a high value for dielectric resistance, but the heating under alternating voltage would quickly produce failure. In reply to Mr. Silver's second query it is my belief that electrical breakdown is certainly a chemical action. Whether or not it always follows the conversion of the dielectric into a conductor by the passage of a current I should not like to say, but most decidedly it sometimes works that way, as can be easily seen by dissecting and examining a cable on which a prolonged test has been interrupted before actual failure.

Mr. Addenbrooke has put his finger on a very important point in showing how the subject of cable dielectrics is complicated by the fact that the conditions under which the dielectric works when made up into a cable are quite different from those holding when the dielectric is tested in a uniform field. I myself, as well as many other investigators, have appreciated this fact and am very chary of accepting results obtained on samples of material until they are confirmed on actual cables made with those materials. Mr. Addenbrooke's suggestion for explaining the " V " curve by an unstable equilibrium of moisture between the paper and oil is new to me, and is very interesting. I feel with Mr. Addenbrooke, however, that this is not the whole story, because some of my experiments show that the curve is not always entirely reversible. Repeating the loss tests at, say, 20° C. after a series of tests up to 60° C. does not necessarily give a repeat of the former 20° C. figure. The effect of pressure on resistance, Mr. Addenbrooke's second suggestion, would, I think, fit in better with these facts. The mechanical pressure generated during heating may cause some physical displacement which is not restored during cooling.

In reply to Mr. Owen, I am afraid that the scope of the paper, wide as it is, does not include glass dielectrics, but the subject of wave distortion in this material should, of course, be considered in any attempt at a complete theory, if we ever arrive at such a desirable end. In his second point, too, Mr. Owen has, I think, overlooked the title of the paper. Whilst there is nothing new in the time effect in the study of dielectrics in general, my contention that the phenomena has not been appreciated in connection with cables is fully supported, if further evidence is necessary, by the remarks of some of the leading cable users in this same direction. In replying to Mr. Ratcliff I have gone over very much the same ground as covered by Mr. Owen in the latter part of his remarks.

Mr. Beavis has contributed some interesting observations on the use of high-voltage d.c. testing for the detection of incipient faults, but in spite of the present popularity of " Delon " and " Kenotron " testing there is a good deal to be learned about the relative effects of high-voltage direct current and alternating current.

Mr. Schuil raised the same point and, in reply to him, I should say that a test of this kind should not be detrimental to a well-made cable. This speaker claims that the d.c. test penetrates deeper into the insulating layer than does alternating current. Well, I do not know about this, but I think that a certain form of deterioration leading to failure which accompanies a.c. testing is not found with direct current. In reply to Mr. Beavis's query about the tests recorded in Fig. 39, the original conditions did not return with time. The experiment on the improvement of power factor of a hot cable by plunging into cold water, as described by this same speaker, is interesting and is no doubt connected with the mechanical contraction of the lead sheath causing a high hydrostatic pressure within the dielectric, which is still expanded by the heat retained. In reply to Mr. Beavis's last point, the curves plotted from the temperature test suggest that the coefficient changes uniformly throughout the range.

Mr. Willmotte refers to the recent suggestion made by Mr. L. Hartshorn, that the seat of dielectric loss and absorption phenomena is in the region of contact between the electrode and the dielectric material. I have been very interested in following the steps in Mr. Hartshorn's theory, but have had difficulty in seeing why in a dielectric like that found in a paper cable, for instance, there is any more reason for the contact resistance at the electrode being more responsible than that between different layers in the body of the dielectric. This same investigator accepts the absence of residual charge in liquid dielectrics. My own results disprove this. He also claims that the power loss in a liquid dielectric is independent of frequency; Mr. Emanueli's contribution to the present discussion shows that this is incorrect. These points, and others not relevant at this juncture, make one think that there must be loss in the dielectric itself quite apart from the contact with the electrodes. Mr. Willmotte's suggested explanation of the " V " curve is subject to the same criticism, and his reference to Mr. Emanueli's curves is covered by my answer to this speaker.

No worker has given more serious thought on the theoretical side to the questions discussed in the paper than Prof. Thornton, and it is therefore very gratifying that he has contributed to this discussion so useful a summary of his views, many of which have already been published. Generally speaking, I agree with all that he says, but with one reservation. I cannot follow under his banner when he treats a cable dielectric as a perfectly homogeneous material. I think that all that he says would apply to a true dielectric, but when we are considering a laminated mass of paper, impregnated, not always perfectly, with oil and, from a chemical point of view, by no means dry, then I am

afraid a connected theory, based on elastic afterworking only, will leave a good deal unexplained.

Mr. Vernier's remarks on the progress which is being made in the Newcastle district in the use of cables for higher voltages are very welcome, as are also his observations on the present types of test employed in the acceptance of cables. I am sorry that he has any qualms about the methods adopted for dielectric-loss measurement. They are certainly complicated, but the order of accuracy usually obtained is easily sufficient to show the difference between a good cable and a bad one. I agree with Mr. Vernier that we badly need a more satisfactory test than any at present available. If the theory of failure which I have advanced in the paper is along the right lines, it is possible that a good ageing test could be obtained by employing a high frequency. If the deterioration is due to a local conduction current which flows to and from the local position through more perfect parts of the dielectric acting as condensers, then the rate of energy dissipation in the conducting portions will be proportional to the frequency, and possibly the effect of a year's life at 50 cycles may be imitated by a few hours on the same voltage at, say, 100 000 cycles per second. With reference to the work of Dr. Klein, quoted by Mr. Vernier, there does seem to be a certain amount of evidence for two types of deterioration, one which is temporary and one from the effects of which the cable never recovers, and the investigation suggested by this speaker would be a profitable line for study. As regards the tangential-stress theory of Höchstädter, far from decrying this I believe it to be right, but it is not the whole story. As advanced by the proposer, this theory does not explain, as mine does, why we can find tree-burning in the centre of the mass of dielectric on a single-core cable. I think that my theory on this point, taken in conjunction with Höchstädter's, brings us somewhere near the truth.

I have introduced into the text of the paper a few explanatory notes suggested by Mr. Maccall and would say that in adopting the inverse fourth root for the time-voltage curves, I have followed Peek. As the scale was convenient I have not troubled to search for an alternative. Probably there is a better one. As Prof. Thornton reminded us in the Newcastle discussion, the measurement of loss during a complete charge and discharge cycle has been done by Dr. Ashton. I cannot trace the application in the direction suggested, however. As to whether I consider the resistances to be real resistances, I see no reason why they should not be. Under the condition I have postulated in discussing breakdown (see Fig. 51), the resistance is a very definite entity. I have tested the relative effect of current- and water-heating on the "V" curve of loss and temperature, but never for the purpose suggested by Mr. Maccall. It might prove a profitable line of research. I have not considered that there is a very close connection between the methods of failure in a cable and an air-insulated wire, unless the correct insulation, impregnated paper, be partially replaced by air through imperfect manufacture, and then there may be a similarity.

Mr. Williams regrets that the cable manufacturers have not adopted sufficiently heroic measures in dealing with the difficulties of high-voltage cable dielectrics, and suggests a closer co-operation through the Cable Makers' Association and the Electrical Research Association to this end. I can assure Mr. Williams that although no claims are being made to the title "heroic," a very large amount of valuable research work is being done not only by the manufacturers individually, but also co-operatively through the C.M.A. and the E.R.A. Except in the case of out-of-date firms, there has been for some years considerable enthusiasm in investigating fully the problems of the dielectric, and up-to-date manufacturers need no urging either to investigate or to co-operate.

There have been several papers in the *Journal* of the American Institute giving the information asked for by Mr. Williams on the difference between the "V" curves obtained on the older and the modern types of compound. I cannot quote a set of figures which would give a simple answer to the question, but, generally speaking, the improvement consists in a flattening and a general lowering of the curve. I am sorry, too, that I cannot give any data relating to the "Höchstädter" type of cable which would be of use in a general discussion such as this. This form of construction is best discussed in connection with a particular proposition and compared with other standard types, as the question of cost enters very largely into the matter. The question of the connection between hydraulic pressures set up by loss and heating, and the nature of the "V" curve, is not an easy one on which to generalize. Variations due to the nature of the compound and the efficiency of the impregnating process make it impossible to draw any hard-and-fast conclusions at present. In my reply to Mr. Ratcliff I have referred to the method of heating a cable during the loss tests, but there is a further point calling for comment in Mr. Williams's remarks. My chief reason for supporting the water-tank method of heating, against the method of conductor heating, is that the whole of the cable is at one temperature. The lead is not hotter than the copper. On the other hand, under current heating it is absolutely impossible to state with certainty the temperature of any other part of the dielectric except that immediately in contact with the conductor, and then only an average value over the length of cable is possible. On the question of the reliability of loss tests, I would refer Mr. Williams to my reply on the same point raised by Mr. Vernier.

In reply to Mr. Elkington, some data on the distribution of temperature throughout the dielectric of a cable have been given recently by Mr. Beavis,* but I do not quite agree that the change of dielectric constant with temperature is of much consequence in explaining tree-burning. As is well known, the dielectric constant of a paper cable does not change to any marked extent over a temperature range of, say, 20° C. to 60° C. I agree with this speaker's last point that the position of tree-burning is probably settled as much by the nature of the gas in the space considered as by the temperature or stress, and that the kind of

* E. A. BEAVIS: "High-Voltage Cables," *Electrical Review*, 1925, vol. 97, p. 413.

impregnating fluid may have a marked influence in this respect.

Mr. Grant's observations on surges are of value in showing the type of protection that should be employed to ensure that under conditions of exceptional pressure-rise the energy is dissipated in the protective gear rather than in the cable dielectric. Possibly the antipathy shown by other speakers towards surge protection may be due to their having had experience of the unsatisfactory types referred to by Mr. Grant.

Mr. Nixon wants my opinion on graded dielectrics. I cannot speak for the future, but, so far, I have seen no really satisfactory evidence that grading a dielectric has ever increased its breakdown strength under service conditions, and I fail to see how grading can affect the problem of testing. I certainly agree that high-voltage tests may damage a cable dielectric, but I think that Mr. Nixon's definition of factor of safety is weak. Suppose, for instance, a piece of inferior cable to work at 33 kV stood 66 kV for one hour. Then Mr. Nixon would say that it had a factor of safety of 2. Now that same cable, if put on 33 kV, might fail in 100 hours. Could it then be claimed that such a cable had any factor of safety at all? As I have pointed out in replying to Mr. Ratcliff, a satisfactory definition of factor of safety is difficult, if not impossible.

Mr. Beaver implies a good deal of unexpressed criticism in the opening part of his remarks. I will accept the challenge on the relative importance of the physical, chemical and electrical properties of a cable, and will point out that, after all, it is the electrical properties which are of ultimate importance. A study of the chemical and physical properties is the best path along which to travel in improving the quality; but the effects of alteration in design, material and workmanship should all be traced right through to the electrical results, including, of course, those which allow for the effect of time. I think, too, that there can be little ground for any suggestion that I have gone too far on the mathematical side. Mr. Beaver criticizes at some length my suggestion to account for failure preceded by tree-burning, but his objections rather beg the question. In the first place, as stated clearly at the head of the list of phenomena on page 122, I am referring to the theory of breakdown explained on the same page, and not to the I^2R theory discussed earlier in the paper. On the second point, it is not really material to the operation of breakdown on the lines suggested, whether, once the lines of current flow are diverted from a radial to a tangential direction, they travel in the material or through conducting threads of ionized gas. The point which I have tried to make is that a certain current flows through the dielectric, shown in Fig. 51, between the conductor and the sheath and that this is at one part of the path purely a non-heating displacement current flowing radially, and at another part a heating current through having to flow circumferentially. This is most certainly not the pyro-electric theory of Wagner. In view of Mr. Beaver's remarks I think that I ought to amplify point (vi) on page 122. Accepting the long-employed logarithmic formula for maximum stress, the failure in a single-core cable should always be near the core. Add to this the fact that the losses cause the dielectric to be hottest near the conductor, then there should be no doubt that an interrupted prolonged pressure test should always show the deterioration to be at the parts subjected to maximum stress, i.e. near the conductor. What do we find in practice? The burning is anywhere and is by no means confined to the part of the dielectric around the conductor.

I am glad to have Mr. Beaver's support on the probable effect of an intersheath and the necessity for surge protection. We are also fortunate in having the results of this experiment, which are illustrated in Figs. H, J and K, now placed on record. He sums up this section by claiming that the evidence is more in accordance with the ionization theory than with mine. Personally, after examining the evidence in cold print, I find that there is not much to choose between the two, or, better, perhaps a combination of both theories may be the true explanation. Ionization of the air in the wormings only would certainly not account for what we find on dissecting a cable, tree-burning along the line of contact between cores on several papers down from the outside of the core. The suggestion which I have made would, however, do so.

Mr. Beaver's objection to migration of compound under stress, as postulated in the paper, is not easy to understand. It does seem reasonable, in view of experiments on electrodes and, what is more important, it has been actually observed in cables subjected to high-voltage tests.

Mr. Hawkins is rather afraid that his championing of the Höchstädter type of cable and discussion of the "S.L." type, on which I have published comments from time to time, may be considered to be irrelevant to the subject under discussion, but I think his observations are decidedly admissible. I can reply to the whole of his remarks very briefly by saying that I do consider that even for pressures as low as 33 kV, cables built on the "S.L." principle would have a greater reliability than the ordinary 3-core type.

Mr. Crellin has difficulty in seeing how a combination of resistances and condensers can represent the true physical action in an absorptive condenser, but I think he is overlooking the fact that I consider an infinite number of these units in combination, a mathematical abstraction certainly, but not an altogether impossible conception of the mass of a dielectric. The resistances with the high value are not those which carry the heavy current. This same speaker cannot accept the time function in breakdown; but here, I think, his difficulty is due to a loose interpretation of the word "instantaneous." I hope that one day somebody will investigate the time-voltage curve for very short time-intervals. I am certain that when this is done the present type of dielectric will still show the time effect. On the last point raised by Mr. Crellin, the suggestion I advanced to explain cable breakdown was never intended as a theory of the breakdown of pure and homogeneous dielectrics. That is a much more difficult field.

In reply to Mr. Philip's question on the allowable moisture in cable, I should say that no moisture is allowable, but as to how much gets in against the

regulations, I should not care to give a figure. It is certainly very much smaller than the figure which he quotes and is a most difficult quality to measure. On the use of the absorption index n, it is of no use applying the index obtained on long time-intervals for 50-cycle a.c. work. To obtain the calculation suggested, the index would need to be measured over time-intervals of the order of 1/100 second.

This answers a question put by Mr. Churcher, whose confirmation of the views advanced on change of power factor with frequency is very interesting. I think the reason that this speaker has not found the fall in power factor with rise of temperature, is because he has been working on a poorer class of dielectric, equivalent to the upper temperature range of impregnated paper where the "conduction" losses predominate. I agree with Mr. Churcher that the heating caused by dielectric loss may have a considerable effect on the power factor. This is shown very conclusively by recording the losses over a period of half an hour or so after switching on the voltage. They rise asymptotically to a maximum.

The points raised in the early part of Mr. Davey's remarks have been dealt with in replies to other speakers. His observations on the effect of frequency on power factor are a very useful contribution to the discussion and, in part at least, must be admitted. I think, however, that some of the specific objections raised are connected with the distribution of the vectors in Fig. 21. This is a real mathematical difficulty. In discussing the connection between the absorption index n and the a.c. power factor, it should be remembered that all the values which I have determined are for periods of time longer than 15 seconds. As previously explained in reply to another speaker, it would be necessary to obtain the values for very short time-intervals in order to use them for a.c. calculations. Mr. Davey claims that my explanation of the motion of the impregnating compound near a weak patch is opposed to a fundamental law of the dielectric circuit. I suggest that he should carry out the following experiment: Take two flat metal electrodes, a lower one 12 in. diameter and an upper one 3 in. diameter. Place a sheet of impregnated paper between them and apply a few thousand volts (a.c.). The impregnating compound will not move into the strong field between the electrodes, but will pile up all round the electrodes about an inch away, leaving the intermediate space dry.

I am glad to have Mr. Carr's confirmation of my own observations on incidence of tree-burning in the dielectric and on the difference in the nature of the discharge between that along a paper and through it. I would add, however, that papers which show the blackening described are still blackened after being thoroughly washed in naphtha, so that there is more than deterioration of compound. The analogy of a chain having a weak link, used by Mr. Carr, is a dangerous one when applied to a cable. One single broken link in a chain results in a broken chain and complete catastrophe. This is, however, not the case in a cable; a string of links joining the conductor to the lead must all fail before ultimate breakdown occurs, and this does not always follow immediately on the failure of one part.

REVIEWS OF PROGRESS.

The Council decided last Session to publish in the *Journal* periodical reviews of progress in electrical engineering, and for this purpose the subject has been divided into the following 13 sections :—

- *Electrical Plant and Machinery (including Marine Work).
- *Power Stations and their Equipment.
- Transmission and Distribution.
- Industrial and Domestic Applications (including Illumination).
- Electricity in Mining.
- Traction.
- Measuring Instruments (including Tariffs) and Sensitive Controlling Apparatus.
- *Telegraphy and Telephony.
- Radio-telegraphy and Radio-telephony.
- Electro-chemistry and Electro-metallurgy.
- *Electro-physics.
- *Research.
- *Standardization.

Whilst it is hoped eventually to publish each year reviews of all the sections, a beginning is made this year with the sections marked with an asterisk, and two appear below. A further selection will appear in 1927, and subsequent action will be based on the experience gained during the first two years.

These reviews have been prepared with a view to recording briefly recent advances, and they are intended, not so much for the information of experts in the particular subject under review, as for the information of those members of the Institution who wish to follow the trend of progress in branches of electrical engineering other than their own.

The Council will be glad if members will forward to the Secretary of the Institution any criticisms which they may wish to make on the present reviews, and also on the ground to be covered by those to be published in the future, more especially in regard to points of interest which come under their notice and on which they consider comment might usefully be made in the reviews.

ELECTRO-PHYSICS.†

By Prof. A. O. Rankine, D.Sc.

At the present time the appropriate, indeed the almost inevitable, starting-point for a report on progress in any branch of physics is the consideration of the constitution of atoms of matter. It is now generally accepted that atoms are electrical structures, and that their properties must be capable of being harmonized with electrical laws. This very fact makes it difficult to prescribe limits to the scope of a subject termed "Electro-physics." The position is being rapidly approached in which all physics must be regarded as electro-physics, and the interconnections between what have been historically distinct branches of the subject are already so numerous and important that they cannot be disregarded. In the present report an attempt will be made to confine attention to the phenomena associated with electricity in the sense generally understood in the past, digressions being followed only so far as the necessity for logical presentation demands. We begin, then, with a statement of the progress of atomic theory, and afterwards consider it in relation to some of the chief experimental facts of electricity and magnetism.

Structure of the atom.—The general outcome of recent research has been steadily to bring confirmation to the nuclear theory of the atom proposed some years ago by Rutherford, namely, that atoms consist of very small positively-charged central bodies surrounded by a number of electrons at relatively great distances. In a neutral atom the charge on this nucleus is equal to the sum of the charges of the electrons, each of which has an invariable charge of $-4 \cdot 77 \times 10^{-10}$ electrostatic C.G.S. units. The nucleus possesses practically the whole mass of the atom, the electrons contributing only a very small fraction.

The characteristic property of an atom is the electrical charge of its nucleus, or the number of electrons surrounding it in the neutral condition. This number is called the "atomic number" and determines the position of the element in question in the periodic classification previously arranged according to atomic weights. Thus the atomic number of hydrogen is *1*, of helium *2*, of lithium *3*, and so on up to the number *92* which belongs to uranium. In every case it is the factor which determines the chemical properties of the atom. Most of the atoms between *1* and *92* have been identified with known elements; only two or three gaps remain, one having been filled recently by the remarkable discovery of hafnium (atomic number *72*) referred to later. The possibility of the future discovery of atoms with higher atomic number than *92* is, of course, not excluded.

The outer part of the atomic edifice.—So far the theory of atomic structure finds general acceptance, but there persist two widely divergent views as to the condition of the electrons outside the nucleus. The application, initiated by Bohr, of the quantum theory to the nuclear atom demands that the electrons are describing orbits of specified characters round the nucleus, and that radiations visible or invisible occur only when electrons jump from one orbit to one possessing less energy. The development of this theory in the hands of Bohr and others has been so remarkably successful in accounting for the spectra emitted by excited atoms, besides other phenomena in the physical domain, that most physicists

† Reprints, in pamphlet form, price 2s. 6d. each, can be obtained from the Secretary of the Institution.

regard it as fundamentally true.* On the other hand, chemists have been attracted to the theory propounded by Lewis and Langmuir, which supposes the electrons in the atom to be stationary, or nearly so, because it has been serviceable in accounting for the chemical combinations into which atoms enter. A completely acceptable theory must account for all the facts, and for this we have still to look to the future.

The atomic nucleus.—Important progress has been made in the investigation of the structure of the atomic nucleus, mainly in the Cavendish Laboratory. As will be seen, the results lend further support to the view—now several years old—that the nuclei of atoms have common constituents—that they are, in fact, built up of electrons and their counterparts, the so-called "protons," closely packed together. The proton is identified with the nucleus of a hydrogen atom, and although its charge is equal and opposite to that of an electron, its mass is 1 800 times as great as the electron mass. According to this view, therefore, the atomic mass is determined almost entirely by the number of protons the nucleus contains, while the atomic number is equal to the *excess* of the number of protons over the number of electrons *in the nucleus*. The mechanism of the equilibrium of such systems of electrons and protons remains for the present unexplained.

Isotopes and Isobares.—The significance of this nuclear theory is of fundamental importance. It provides an explanation of the existence of so-called "isotopes," besides being in harmony with the facts of the disintegration and transformation of atoms, both natural and artificial. Isotopes are atoms of the same chemical properties, and therefore having the same atomic number, but with different masses or weights, and their discovery in the radio-active sequences of elements has been followed by proof of their existence in many non-radio-active elements also. The proton-electron theory of the atomic nucleus is in keeping with these results, for clearly an increase in the number of protons in the nucleus, accompanied by an equal increase in the number of electrons, does not change the atomic number. A further possibility suggested by the theory is the existence of atoms of the *same* mass, i.e. with equal numbers of protons in the nucleus, but with different atomic numbers, owing to the number of nuclear electrons not being the same. Such atoms would possess quite dissimilar chemical properties, and are already known in the radio-active series. They are called "isobares."

Much progress has been made during the past year or two in the investigation of isotopes and isobares, chiefly by the continued work of Aston on measurements of positive rays with the mass spectrograph. This method enables the masses of *individual* atoms to be measured (as distinct from the *average* mass obtainable by chemical means), and has proved indisputably that many elements are mixtures of isotopic atoms, and, moreover, that each individual atomic mass is a whole number of definite units, which theory identifies with protons. A recent list is given by Aston in the Royal Society 1925 Wembley publication "Phases of Modern Science," pp. 43 and 44, from which it appears that some elements, tin, for example, are mixtures of at least seven isotopes, and possibly more. The existence of isobares has also been definitely established, although the occurrence so far is relatively rare. A notable example is the case of argon and calcium, both of which consist of two isotopes. The principal constituent of each has a mass equal to 40 protons, while the atomic numbers, which determine the widely different properties, are 18 and 20 respectively.

Atomic disintegration and transformation.—Further evidence in favour of the proton-electron structure of the atomic nucleus is provided, as already mentioned, by both the natural and artificial transformation of atoms. The corpuscular radiation from the radio-active atoms during the process of spontaneous disintegration has long been known to originate in the nucleus. It consists of two distinct entities, the α particle and the β particle. Of these the β particle is a high-speed electron, and the α particle has been proved to be identical with the nucleus of the helium atom, possessing a positive charge equivalent to two electronic charges. The evidence of radio-activity thus proves that electrons are among the constituents of at least some atomic nuclei, and that the positive nuclear component is capable of splitting up into smaller parts. For definite proof that there are protons in atomic nuclei one must turn to the remarkable experiments of Rutherford and his collaborators on the controlled disintegration and transformation of atoms, recent accounts of which may be found in the *Proceedings of the Royal Institution*, 1923–25, vol. 24, p. 585, and in "Phases of Modern Science," pp. 30–36.

The experiments generally consist of observing the effects of bombarding materials with α particles from radio-active preparations—natural projectiles which in their combined speed and mass transcend in effectiveness anything obtainable by artificial means. These positively-charged projectiles are able to approach closely to the nuclei of the bombarded atoms in spite of the electric repulsion, and, in the case of atoms of small atomic number or small nuclear charge, to collide directly with the nucleus. Such collisions are, of course, very rare events, owing to the minuteness of both target and projectile, but when they do occur disruption may result, and a proton may be ejected from the nucleus with high speed. Rutherford has shown that all the elements between boron and potassium in the atomic classification, with the exceptions of carbon and oxygen, may be disintegrated by this means. Perhaps the most remarkable of all the results is the series of photographs Blackett (*Proceedings of the Royal Society*, A, 1925, vol. 107, p. 349) has obtained by an adaptation of the Wilson condensation ray-track apparatus, showing the tracks of particles in gaseous nitrogen. Over 400 000 such tracks were photographed, and of these eight displayed the track of a proton ejected from a nitrogen nucleus together with that of the recoiling nucleus itself. But no trace was found of the continued track of the original projectile—the α particle—and Blackett has concluded that it was captured in the collision. On the accepted nuclear theory

* Prof. Bohr, in an article just published (5th December) in the supplement to *Nature* (1925, vol. 116, p. 847), appears to anticipate that the developments of his theory will necessitate the abandonment of this view of atomic structure. He says: "In contrast to ordinary mechanics, the new quantum mechanics does not deal with a space-time description of the motion of atomic particles"; and again, "To the physicists it will at first seem deplorable that in atomic problems we have apparently met with such a limitation of our usual means of visualization." It is certainly disturbing, coming from such a source.

this would signify that the nitrogen atom has on the whole gained both in mass and in nuclear charge; for, while it has lost one proton and one positive charge, it has gained an α particle (which has the mass of 4 protons) and two positive charges. Its mass, originally 14 protons, has increased to 17 and its nuclear charge, originally 7, has increased to 8, which is the atomic number of oxygen. The nitrogen atom is thus regarded as having been transformed into an oxygen atom—an isotope of the usual variety.

Atomic energy and atomic transformation.—The possibility of changing one atom into another raises a question of great significance, namely, the equivalence of mass and energy as indicated by the theory of relativity. A mass m at rest may be regarded as energy of amount mc^2, c being the velocity of light. If in an atomic transformation the total mass becomes reduced, say to m', an amount of energy will be liberated, and presumably radiated, equal to $(m - m')c^2$. Aston's experiments show that the single proton which forms the whole nucleus of an atom of hydrogen has a mass 1·0077 times as great as that of protons in the nucleus of more complicated atoms. Thus if hydrogen became transformed into any other element, for example helium, the change would be accompanied by a reduction of mass and a liberation of energy which, although small in respect of each atom, would reach prodigious amounts for even 1 gramme of transformed substance. Such changes are believed by astronomers to be occurring in the stars and to be responsible for stellar radiation,* and although the question must still be treated with reserve, the possibility of the artificial liberation of atomic energy has to be contemplated for the future.

X-rays.—It is, however, in respect of the relations between radiation and the extra-nuclear electrons of atoms that progress has been most rapid in recent years. An atom radiates electromagnetic waves only when one of these electrons revolving round the nucleus suddenly jumps from one orbit to another. The mechanism of this transfer is not yet understood, but there appears to be no doubt that the frequency of the radiation is determined by the reduction of orbital energy associated with the transfer. This is, in fact, a statement of the quantum theory as applied to atoms; atomic radiation takes place, not continuously, but spasmodically and in definite amounts or quanta to which the frequency of the radiated energy is proportional. In the case of atoms of small atomic number, i.e. atoms with small nuclear charge and few orbital electrons, the energy changes in the possible orbital transfers are such that the radiation frequencies are in or near the visible region of the spectrum. So also are the radiations even for atoms of high atomic number if only electrons in outlying orbits are disturbed. Very great progress continues to be made in the examination and interpretation of ordinary spectra in relation to the theory here briefly indicated. It is now believed also that X-rays originate in the same way as ordinary visible spectral lines, except that the electrons which produce them are those occupying the inner orbits of atoms of sufficiently high atomic number. To measure the high frequencies and short wave-lengths of these rays, prisms and artificially-ruled diffraction gratings are too coarse, but the regular arrangement of atoms in crystals has fortunately provided natural diffraction gratings of sufficient fineness.

In order that an atom may radiate it is necessary that its electrons should be displaced from their normal orbits to more distant ones possessing greater energy, so that the energy may be re-emitted in the process of returning. The atom has, in fact, first to be excited. Excitation may be effected in a variety of ways, the chief of which is by means of bombardment by swiftly moving electrons such as, for example, the cathode stream in a vacuum tube. The extent of excitation depends on the speed and energy of the bombarding electron; it cannot produce an energy change in the bombarded atom greater than that which it itself possesses. With the high-speed electrons proceeding from the cathode in an X-ray tube subjected to high voltage the deep-seated orbital electrons in the atoms composing the anticathode are sufficiently disturbed, and, in returning to these inner orbits, they emit the characteristic X-rays of the element in question. These characteristic rays have frequencies depending, according to the Moseley law, on the atomic number, and they have been determined for most of the heavy atoms. A most remarkable achievement in this connection was the discovery of the new element hafnium by means of the characteristic X-rays which it produced when the preparation suspected of containing it was placed on the anticathode of a tube. The identification of this hitherto missing element of atomic number 72 was announced by Coster and Hevesy in 1923, and since then numerous other of its properties have been determined in Copenhagen. These are recorded in a monograph by Hevesy, entitled "Recherches sur les Propriétés du Hafnium." *

Ionization potentials.—The excitation of an atom may proceed to such an extent that one or more of its electrons are actually ejected completely from the atomic edifice; in such a case the atom is said to be ionized. If the agency of ionization is the bombardment by electrons, the electron energy must exceed a certain minimum, characteristic of the bombarded atom. The voltage through which the electron must fall in order to acquire this minimum speed is called the "ionization potential" of the atom thereby ionized. Much work has been done in measuring these potentials for different gases, the values being of great importance in connection with the theory of spectra.

Photo-electricity.—There is, besides, another agency for producing ionization, namely, radiation of suitable frequency. It is in this field that the quantum theory has derived some of its most convincing support. The photo-electric emission of electrons from atoms occurs only when the frequency of incident radiation reaches a minimum or "threshold" value. Thus if W is the

* In this connection reference must be made to the recent remarkable discovery by Millikan of high-frequency rays of cosmic origin described in *Nature*, 1925, vol. 116, p. 823. These rays, which are of far greater penetrating power than any hitherto known, are apparently reaching the earth's surface with equal intensity in all directions and at all times. The frequency of the hardest of them is probably 50 times that of the hardest γ rays from radio-active sources, and the wave-length correspondingly short, namely, 4×10^{-12} cm.

Millikan draws attention to the fact that the frequency of this part of the new radiation corresponds, according to the quantum theory, to the energy change in the hydrogen-helium transformation here referred to, and suggests this change as the possible origin of the rays in remote spiral nebulæ.

* Published by Det. Kgl. Danske Videnskabernes Selskab.

work necessary just to remove an electron from an atom (this depends, of course, on the nuclear charge and the particular orbit occupied by the electron) and the threshold radiation frequency is ν_0, the quantum relation $W = h\nu_0$ holds, h being Planck's universal constant. No electrons are emitted for frequencies less than ν_0, but when the incident frequency ν is in excess of ν_0, the balance of the energy $h\nu - W$ appears as kinetic energy of the ejected electron, so that

$$h\nu - W = \tfrac{1}{2}mv^2$$

m being the mass of the electron, and v the velocity after ejection.

This relation was first established for the atoms of the alkali metals, each of which has a loosely bound electron capable of ejection by the relatively low frequencies of visible radiation. Their photo-electric properties are now being extensively made use of in so-called photo-electric cells, which have numerous practical applications such as the telegraphic transmission of pictures. But all atoms have photo-electric properties. To eject deep-seated electrons, very high-frequency radiation is necessary, and important work has been done, chiefly by de Broglie, on the electron emission from atoms in consequence of irradiation by very high-frequency X-rays. The measurement, by deflection in a magnetic field, of the velocities of the various electrons extracted under these conditions from an atom has provided, in conjunction with the quantum theory, a most effective means of examining the so-called energy levels of the atomic electron orbits. In addition, a similar examination of the relations between the γ-rays and β particles emitted from the nuclei of radioactive atoms appears to point to the existence of minute electron orbits actually within the nucleus itself.

Conduction of electricity.—The way in which electricity is transported under the action of an applied voltage is a question of fundamental importance. From the point of view of atomic theory we can be said at present to be only at the beginning of its explanation. The mechanism of the process is quite clearly understood only in the special case in which free electrons in a complete vacuum themselves move and thereby constitute the current, as in the hard X-ray tube, or in the thermionic valve. Conduction in gases, liquids and solids must, of course, ultimately also be completely explainable in terms of the theory, but that has not yet been done.

Conduction in gases.—The mechanism of the motion of electricity in gases is believed to be that of ionization of the atoms or molecules by electronic bombardment, by suitable radiation or by such agencies as α particles. The applied voltage causes the ions to move in the appropriate directions, and the current consists of these streams of ions. With gases at low pressure, as in a discharge tube, cumulative ionization may occur, thus enhancing the current. In other words, an ion may be able to move freely under the action of the voltage gradient, and thus gather sufficient speed to ionize the atom with which it eventually collides. The process, of course, is complicated by the recombinations which are continually going on. In the discharge tube the electrons proceeding from the cathode must be able to traverse unimpeded a range corresponding to the ionization potential, and the positive ions then formed are driven towards the cathode, and through it if it is perforated, thus giving the positive rays which, by being subsequently deflected by known electric and magnetic fields, give the isotopic mass spectra of Aston. A valuable account of the general nature of conduction in gases at low pressure has recently been given by Whiddington (*Nature*, 1925, vol. 116, p. 506).

Conduction in electrolytes.—The laws of conduction in fused salts and in solutions of salts have long been known, and they are in close accord with the view that the carriers are ions, i.e. atoms or groups of atoms which have gained or lost one or more electrons. There is evidence from the X-ray analysis of crystals of the salts that these transfers of electrons have already taken place in the solid, fusion or solution merely separating the positive and negative parts. Quantatively, atomic theory is in satisfactory agreement with the experimental laws of electrolysis, but the mechanism of this type of ionization remains obscure.

Conduction in metals.—Although we now know with precision the number of atoms in a specified piece of any metal and the number of extra-nuclear electrons in each atom—and therefore the total number of such electrons—the majority of the phenomena of metallic conduction still await a quantitative explanation. It appears to be certain, since the metallic atoms themselves are not transported, that the carriers are the extra-nuclear electrons, which have, therefore, an average velocity in the direction opposite to the nominal current direction. This *average* velocity can obviously be easily calculated, but gives no clue as to the fraction of the total number of electrons actually taking part in the transfer at any given moment, or as to the mechanism of their release from or re-combination with the stationary atoms. Reference may be made in this connection to the illuminating account of the motion of electricity in metals, given by H. A. Lorentz in the recent Lecture (May, 1925) before the Institute of Metals, in which, among other things, he draws attention to the experiments of Tolman and Stewart on the currents produced by the acceleration of a conductor. The magnitude and direction of these currents are such as to prove that in metals electric currents do consist of the motion of negative electrons.

Magnetism.—The theory of the atom described earlier would appear to have the elements necessary for the explanation of magnetism. A circulating electron is a current producing a magnetic field in the direction of the axis. Further, the application of a magnetic field to an atom might be able to impart to electrons additional circulation which would give rise to an opposing magnetic field. The latter effect would correspond to dia-magnetism; the former, combined with inter-atomic collisions, to para-magnetism. But the remarkable experimental work of Stern and Gerlach on the behaviour in magnetic fields of isolated atoms of various metals renders it necessary to revise the earlier views of the origin of magnetism. Briefly, these experiments, commenced in 1922 and still in progress,* consist of observing the deflections of vaporized atoms of the

* See W. Gerlach, *Annalen der Physik*, 1925, vol. 76, p. 163.

metal shot out from a furnace into a vacuum, when a non-uniform magnetic field is applied perpendicular to the atomic tracks. Some atoms—lead, tin and, oddly enough, iron—are unaffected by the field, and must be presumed in this isolated condition to have no magnetic moment. Others—copper, silver and gold—are deflected, but in such a way as to indicate that the atoms can occupy only two definite positions in the applied field. For the bearing of this on atomic theory in relation to so-called space quantization, reference may be made to the original papers and to a recent Royal Institution lecture by C. G. Darwin.*

One other very surprising experimental result must be mentioned. Glaser † has measured for the three gases H_2, N_2 and CO_2 the diamagnetic susceptibility at pressures ranging from 0–900 mm of mercury. The curves in each case indicate a notable change of susceptibility with reduction of pressure. At low pressures the susceptibility is proportional to the pressure; above this range the proportionality ceases, and this is followed at higher pressures by a new proportionality, with, however, a constant only one-third of the original value. So far no adequate explanation of the phenomenon has been offered.

Conclusion.—A report like the present one, with prescribed limitations as to length, obviously cannot be exhaustive. What has been done is to select for description certain outstanding recent advances in the subject. The omission of reference to many phenomena such as thermionics, thermo-electricity, piezo- and pyro-electricity, to mention some only, is due to the reporter being unaware of specially notable recent progress in these branches of electro-physics.

TELEGRAPHY AND TELEPHONY.‡

By W. CRUICKSHANK, Member.

INTRODUCTION.

In this, the first, review of the progress of telegraphy and telephony published in the *Journal* it may not be amiss to furnish a record to date of the magnitude of the undertakings under those headings controlled by the Postmaster-General in this country (which does not include the Irish Free State) so as to provide a basis for comparison in succeeding reports. The figures quoted, it should be understood, apply to the State industry only, and do not cover the railway systems or the innumerable private-wire installations erected and maintained by large industrial concerns.

Total single-wire mileage (working and spare) as at 31st March, 1925	5 222 424
Telegraph mileage (working)	273 010
Telephone mileage (working)	4 387 324
Telephone mileage, trunk lines (working)	669 753
Telephone mileage, local exchange lines (working)	3 717 571

The lines may be further subdivided into three broad classes—aerial, underground and submarine—the figures for which are as follows:—

Aerial wire mileage	1 106 375
Underground mileage	4 095 591
Submarine mileage	20 458
Total	5 222 424

The P.O. Engineering Department has developed methods of ascertaining construction and maintenance costs, extending over all districts and covering all classes of plant, and expresses the results in multiples of the man-hour unit.

The financial results of the working of the plant can be obtained from the Commercial Accounts published annually.

TELEGRAPHY.

Developments in this country.—A scheme of reconstruction is taking place in the Central Telegraph Office—which incidentally has squeezed out the Engineer-in-Chief and his staff from the G.P.O. West—and old telegraph men will have difficulty in finding their way through the galleries. The intercommunication switchboard, which provided direct switching between out-offices, is being replaced by lamp-signalling concentration switchboards, and by direct communication in the case of offices which have sufficient traffic to warrant junction lines. Additional lamp-signalling concentrators have been installed at Manchester and Edinburgh and a trial has been made of automatic concentration working, in which a calling line searches for a disengaged working set.

The method of superposing telegraphs on telephone lines, known as compositing, has been working satisfactorily on the circuits London to Penzance, and London to Chester, while the same system has been applied successfully to the telephone circuits working in the London–Brighton cable. The arrangement is a development of the original Van Rysselberghe method of introducing inductance in the direct telegraph lead, with a capacity shunt to earth, with the object of rounding-off the square fronts of the battery-derived telegraph signals and so preventing "morse thump" and disturbance on the telephone lines. The introduction of properly designed filters has resulted in the production of circuits which can carry both telegraph and telephone communications without serious interference with each other. The system is being used extensively in the United States.

An interesting example of the better-known method of superposing circuit on circuit has been introduced on the London–Penzance cable, where seven duplex high-speed telegraph loop-circuits are obtained on eight wires. Four loop-circuits are worked on the four physical pairs; one phantom circuit is superposed on pairs 1 and 2, another on pairs 3 and 4, while a third, which is known as the double plus, is superposed on the two phantoms.

When the telegraph circuits were first brought underground to avoid interruption from storms, working speeds were reduced owing to the greater capacity and resistance of the cable. Single-wire and earth-return circuits produced inductive disturbance, even when each

* *Proceedings of the Royal Institution*, 1925, vol. 24, p. 626.
† *Annalen der Physik*, 1924, vol. 75, p. 459.
‡ Reprints, in pamphlet form, price 2s. 6d. each, can be obtained from the Secretary of the Institution.

circuit was electrostatically screened from its neighbours by a copper tape, earth connected. Loop working was then resorted to, but as cable-balancing had not reached its present efficiency it was found necessary to use separate batteries not earthed in the centre, as in the case of the P.O. standard voltages for double-current working. Speed was increased by the use of a vibrating relay (based on the Gulstad principle) on the line, the auxiliary windings of which caused the armature to vibrate at approximately the speed of the incoming signals. Exhaustive trials are now being made with the standard batteries using a modified form of relay which, in addition to its auxiliary windings, is fitted with a double set of differential line windings. The relay is connected in the circuit, which is made up of the two wires of a cable pair, so that in a duplex circuit the compensation or artificial-line portion is connected between the two windings which are not joined to the line. The A and B wires, being joined to two equal windings, will—when subjected to external inductive interference—affect the relay equally and thus cancel out the trouble. To secure accurate balancing, double differential galvanometers are used in conjunction with the relays.

A similar circuit has been developed in the United States, where it is known as the polar duplex. A striking feature in the American circuit is the type of relay used. Permalloy is employed in the yoke, pole-pieces and armature. The last-mentioned is securely clamped at one end and passes through the hollow centre of the coil windings. The nickel-iron alloy is magnetized by a permanent magnet in such a manner that the ends of the armature are at equal magnetic potentials. The operating ampere-turns upset this balance and cause the free end to move in the required direction, its momentum increasing as it travels towards the local contact. To prevent rebound and chatter, the free end of the armature is fitted with flexible contacts which ensure a certain amount of rubbing contact without breaking. Two types of the relay have been devised, one fitted with auxiliary vibrating windings and one with double differential coils only. Extreme sensitiveness is claimed for the type, which enables the circuits to be worked with small voltages and correspondingly weak currents with minimum inductive effects on adjacent pairs. The circuits are worked on loops, and where telephone repeaters are fitted on all pairs by-pass channels are provided for the telegraph signals.

Progress of machine telegraphy.—Continued progress has been made in the direction of the supersession of morse-operated circuits by machine telegraphs. During the past two years the following Baudot circuits have been introduced :—

One quadruplex simplex, TSF—Boulogne and Lille.
One duplex 3-station, Leeds–Edinburgh–Belfast.
Eight duplex 2-station circuits converted to 3-station duplex.

In connection with the 3-station circuits, a new distributor table has been designed for re-transmitters and is being introduced at all intermediate stations on 3-station duplex circuits.

During the same period 22 duplex Morkrum teletype tape printers and 12 simplex sets have been installed. Eight of the latter have been fitted on private wires.

A second equipment of the Kleinschmidt column printer has been installed on the TS—Savings Bank lines.

Voice-frequency telegraphs.—Carrier-wave telephony —or wired wireless, as it has been called—has been operating successfully in this country for some time on selected trunk lines, but up to the present no working trial of the telegraph system based on the use of alternating currents of voice frequencies—say 200 to 2 000 periods—has taken place on actual lines, although successful trials have been made on artificial lines and spare pairs in the cables. The continual conversion from open line to underground working for other reasons is, however, turning the attention of the authorities towards the more economical utilization of underground networks, and it is probable that voice-frequency telegraphs will play a large part in the near future. The characteristics of valves as oscillators, amplifiers and rectifiers, and the application of filters for selective purposes have been fully investigated by the Department.

Two practical working systems have been devised, one in the States and the other in Germany. Both are worked on a multiplex simplex basis, two pairs of wires being utilized for working in two directions, one pair for sending and the other for receiving. Existing forms of telegraph apparatus can be utilized, and as far as the telegraphists are concerned they may each be working on direct physical lines. The sending and receiving apparatus of each arm can be assembled adjacent on the table, so that repetitions can be asked for exactly as on a duplex set, but no compensation circuit will be required.

In the American system, 10 frequencies, each a multiple of 85, beginning with 425 (approximately 2 670 radians per second) and going up by steps of 170, are utilized, the frequencies being produced by 10 small inductor alternators mounted on a common shaft and with a common field. Each of the 10 frequencies is controlled by a key or other sender and furnishes one arm of the multiplex. The frequency is first carried through a band filter, which eliminates or suppresses any harmonics that may exist, and is then passed on to common leads where it mingles, as it were, with the other 9 frequencies, each of which had been filtered in the same way. The common leads are terminated on the input winding of a valve-amplifier transformer, the output of which is joined to the sending line. At the receiving end the line terminates on an amplifier, the output of which is connected to common leads. From these common leads 10 receiving band filters select their own particular frequencies. Each frequency is then amplified, rectified, and operates its receiving relay. There are many special features employed which require too much room to describe.

The system devised by Messrs. Siemens and Halske is based on the same general principles. The main differences lie in the method of producing the oscillations and in the fact that the individual sending arm outputs are not filtered before combination. Oscillating valves

are used which are of the 3-electrode type; the combiner and amplifying valve has two grids, one of which is charged from an 80-volt tap off the 220-volt anode voltage, and the other primed negatively to approximately 6 volts. The common amplifying valve and the rectifying valves in each arm at the receiving end are also of the 4-electrode type.

The system has been tried experimentally on an artificial line and on a length of loaded underground cable at the G.P.O., and on each of the six arms with which the sets were equipped Wheatstone apparatus attained satisfactory working speeds of 100 words per minute. The frequencies used are 2 500, 4 000, 5 500, 7 000, 8 500 and 10 000 radians per second. These values can be regulated within certain limits by an adjustable iron plunger, which can be made to penetrate more or less deeply into the hollow core of each oscillating transformer.

The great advantage of the voice-frequency telegraph is that it can be used on underground telephone networks. The voltage impressed on the line is of the same order as that of telephone speech currents; hence inductive disturbances on adjacent circuits are minimized. Further, standard 4-wire repeaters can be employed on the circuits; uniformity of construction of cables can be secured and any pair can be taken indiscriminately for either telegraph or telephone purposes, due regard being paid of course to efficient balancing of the pairs in the cable.

Speeding up the telegraphs.—It is not surprising that proposals have been made to eliminate the comparatively highly-paid telegraphist by the process of short-circuiting him, the function of the public office being then merely to switch lines together. Mr. Donald Murray's paper on "Speeding up the Telegraphs" read before the Institution on the 18th December, 1924, advocated the introduction of teletype exchanges, which would afford the same facilities to start-stop telegraph-printer subscribers as telephone subscribers now enjoy. The paper opened up a fascinating vista, and the scheme cannot be thrown aside without the fullest consideration being given to its proposals. It may be that demands will come along in sufficient numbers to warrant mass-production, and the "Ford car of telegraphy" may then take its position as an essential part of the furnishing of every business-man's office.

Submarine telegraphs.—In this particular branch of telegraphy the past two years have presented a more drastic development perhaps than in any other. Karl Willy Wagner, in the October 1924 issue of *Elektrische Nachrichtentechnik*, describes the advent of wireless telegraphy as the Siegfried who wakened the dragon Fafnir guarding the Rhinegold of submarine telegraphy. Fafnir's dictum—"I lie and I possess; let me sleep"—is not strictly true when applied to the cable administrations, but the competition of wireless has certainly roused them to a keener sense of the need for faster methods of communication over the deep-sea routes. The introduction of Heurtley, Oerling, Sullivan and valve amplifiers, combined with the use of correcting networks to improve the incoming wave-front and to reduce distortion, increased the speed of working appreciably, but the recent development of continuous loading has so increased the capabilities of the cable itself that the line speed has now outstripped the receiving powers of the terminal apparatus.

Towards the end of 1923 the Western Union cable-ship "Lord Kelvin" sailed from Greenwich with a 120-mile length of permalloy-loaded cable, which she laid in 2 500 fathoms in a loop from Devonshire Bay, Bermuda. Both ends were landed, and a long series of experiments began. The trials were successful and, as a result, an order was placed with the Telegraph Construction and Maintenance Co. for a cable of similar construction, 2 400 miles long, to be laid between New York and the Azores. This cable was laid last year and the speed attained has exceeded even the most optimistic hopes. The permalloy tape with which the stranded copper conductor is wound is made of an alloy of 78·5 per cent nickel and 21·5 per cent iron. The tape is 6 mils thick and ⅛ inch wide, and is wrapped round the copper in a close helix, giving a uniform inductance of 54 millihenrys per nautical mile. The initial permeability of the tape is such that, if it were replaced by a continuous sleeve of the same thickness, μ would have a value of 2 300. A speed of 1 920 letters per minute was attained between Fayal and New York, after specially designed high-speed recorders had been devised to receive the signals legibly.

Before these results were made possible, a vast amount of patient research work had to be done. The difficulty of annealing the iron without injury to the copper had to be surmounted, after the best combination of nickel–iron had been determined to secure a minimum loss from hysteresis and eddy currents. Even after the cable had been laid, many problems arose. The question of the most efficient sea-earth, its length and relation to the depth of the cable at both ends to avoid extraneous interference and, above all, the best method of operating the cable with its high-speed possibilities, had to be considered. Most cables are worked duplex, but in this case the make-up, combined with the comparatively low propagation speed—which is not the same thing as the signalling speed—makes the balancing problem a most difficult one. Mr. Oliver E. Buckley, in the August issue of the *Journal* of the American Institute, discusses this point and says that to realize the full commercial advantages from the cable it should be worked on a multi-channel basis, say with a Baudot code, on a simplex up-and-down basis. There are reports that the cable will be ultimately operated sextuple multiplex, with re-transmitters or repeaters at the Azores, two arms New York–England, two New York–Germany, one New York–Italy, and one New York–Spain. Be these as they may, the fact remains that the permalloy-loaded cable has scored a distinct success and, it is understood, both the Pacific Cable Board and the Eastern Extension Co. have contracts for cables of similar construction in hand for operating on their America–Australian routes.

Although the Western Electric Co.'s engineers have been successful with permalloy, researches are being continued with other alloys, and it is understood that very good results are being obtained in this country with an alloy in which some 4 per cent copper is used, in addition to nickel and iron.

TELEPHONY.

In spite of the state of depression affecting certain sections of industry, the number of telephone stations in this country is ever increasing. If inter-communicating private sets were included, the number of telephones operating would be near the 2 millions mark; the number of stations, including exchange, private wire, call office and service lines, on the Post Office system amounted to 1 317 522 at the end of August, of which 462 007 were in the London telephone area and 855 515 in the provinces.

Colonel Purves, in his paper on "The Post Office and Automatic Telephones," read before the Institution on the 5th March last,* gave a complete statement of the automatic position in Great Britain. In Appendix 2 of the paper, a list of towns scheduled for automatic equipment is given; since the paper was read a start has been made with the manufacture or installation of such large equipments as those for Bedford, Burnley, Chesterfield, Coventry, Edinburgh (some 15 000 lines in four exchanges), Exeter, Kirkcaldy (completed), Sheffield Central (6 300 lines) and Southport. The whole of the Leeds area is now automatic, since the opening of Roundhay, Chapeltown and Headingley exchanges; Torquay and Paignton have also changed over to the new system, with through-dialling between the two towns. A number of orders are also in hand for extensions to existing automatic exchanges. The popularity of the private automatic branch exchange is evidenced by the fact that well over 70 separate installations of this type have been fitted or are on order in the last 12 months for large industrial and commercial firms. Many new manual exchanges and extensions to existing manual exchanges are in progress where economic necessities demand the continuance of hand operating. An elaborate scheme of direct dialling between automatic and automatic exchanges and between automatic and manual exchanges in non-director areas has been devised and is being introduced as opportunity and occasion require.

To provide for cable distribution from Wood-street, in the heart of the London area, where at least three 10 000-line exchanges are to be installed, a tunnel has been run under Wood-street from Gresham-street to London-wall and along London-wall to Moorgate-street, a distance of 660 yards. The depth of the tunnel is approximately 40 ft. and the diameter 6 ft. clear. Owing to the congested condition of the street, both above and below ground, and its situation in the danger area, there was considerable objection to the usual method of opening-up from above; in fact, there was no room in the subsoil for the large number of ducts required. At the exchange end the tunnel, which is lined with cast-iron segments similar to those used in tube-railway construction, is approached by an incline 8 ft. in diameter, making 35° with the horizontal, and three shafts approximately 4 ft. 5 in. in diameter are sunk at intervals along its length. The tube will be completed with a concrete floor, and bearers capable of taking 80 3-in. cables are fitted along both sides.

Position of automatic systems in the U.S.A.—The following details of the position of automatic development in the States (supplied by Mr. G. H. Nash of the Standard Telephones and Cables, Ltd.) may be of interest. It would appear that the policy is to install the panel system in the large areas, and step-by-step systems in the smaller. The figures dealing with the panel cover the period January, 1919, to September, 1925; step-by-step from January, 1903, to September, 1925.

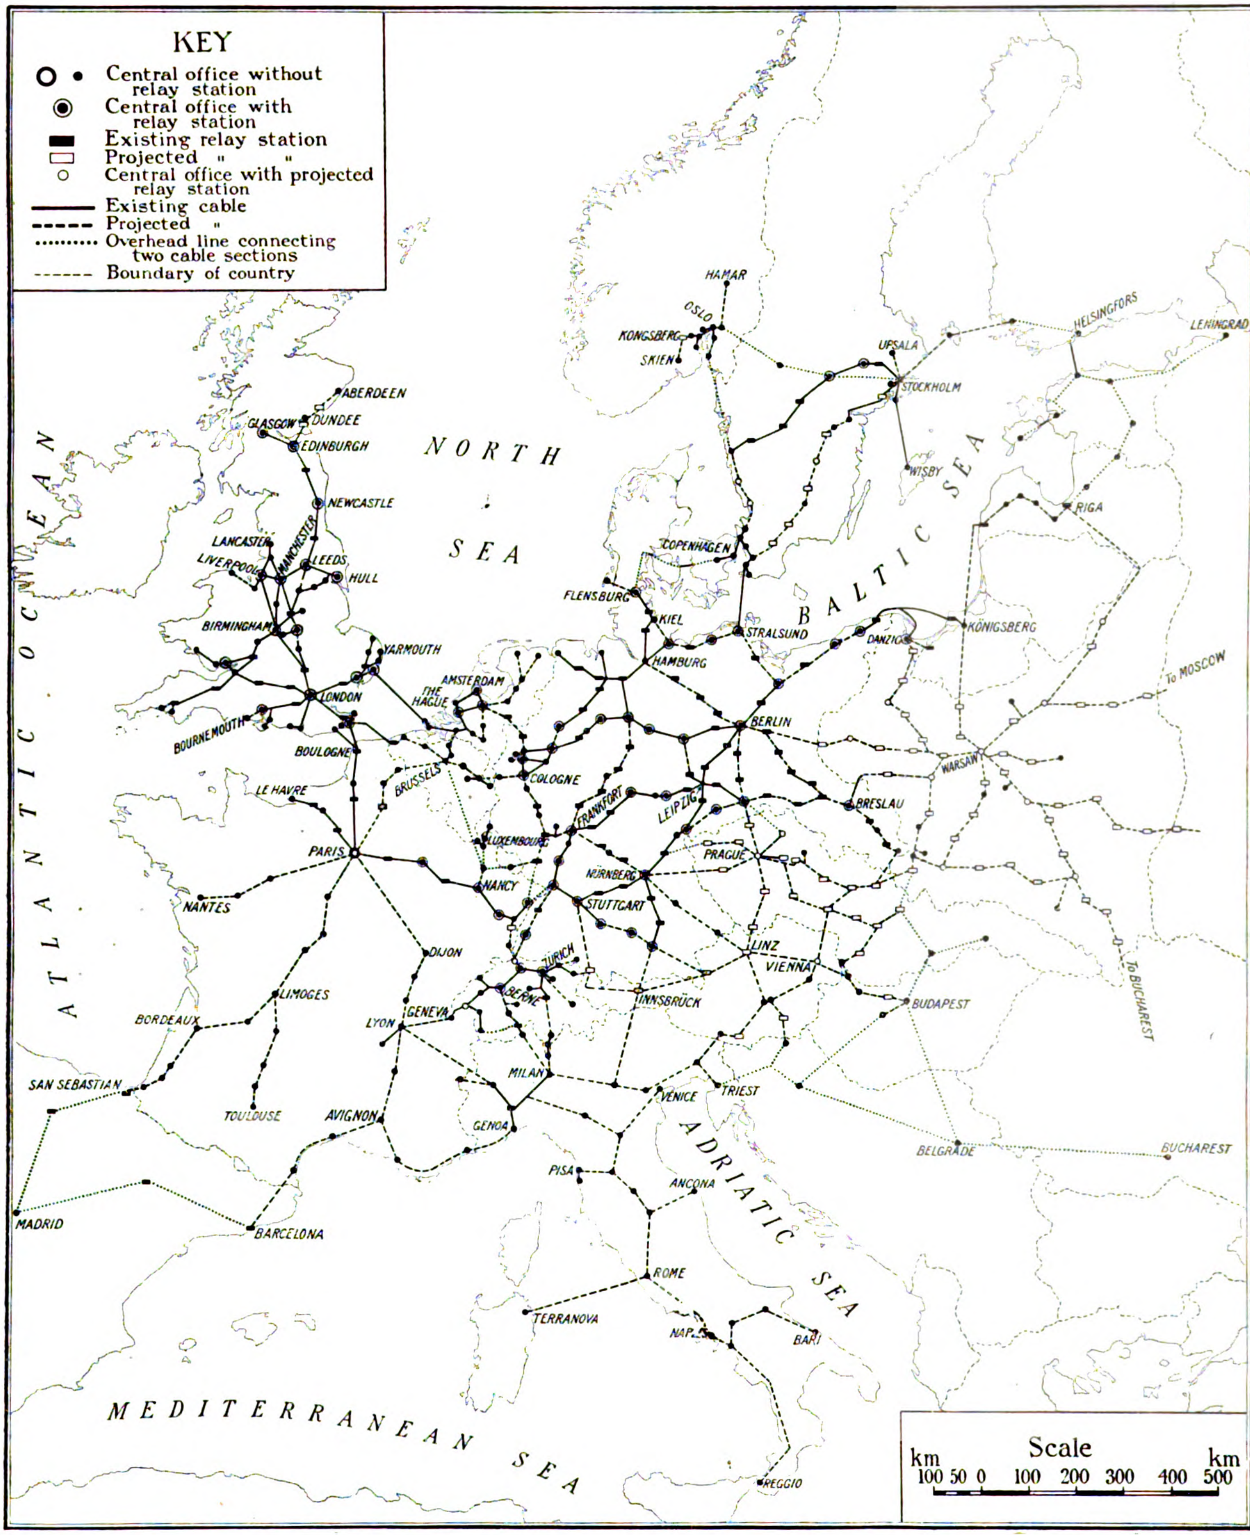
The position in Europe.—In Mr. F. Gill's presidential address to the Institution in 1922, he urged the development of intercommunication and the organized erection of trans-European trunk lines. On the 12th March, 1923, the first meeting of the Preliminary Technical Committee of representatives from Belgium, Spain, France, Italy, Switzerland and Great Britain, was held in Paris for the purpose of considering from the technical point of view the study of the problem of long-distance telephones in Europe. In May of the following year the International Advisory Committee, composed of representatives from Germany, Austria, Denmark, Finland, Hungary, Lettland, Luxemburg, Norway, Holland, Poland, Serbia, Croatia and Slavonia, Sweden and Czecho-Slovakia, as well as those from the original consulting countries, considered and adopted bases relating to the following questions:—

Transmission questions, traffic questions, maintenance and survey of lines. Since then, standard specifications for the supply of international cables and apparatus have been drafted, methods of measurements have been agreed upon, and dispositions relating to the

* *Journal I.E.E.*, 1925, vol. 63, p. 617.



Map showing International Telephone System of Europe.

measures required for the protection of telephonic lines from interference by power systems have been set out. Some controversy arose as to the best method of stating the efficiency of lines and apparatus, and the transmission unit has not been agreed upon at the time of writing.

The various units used or proposed from time to time may be stated as follows :—

(*a*) A mile of standard cable. The standard cable in this country is an air-space paper-core cable with the following constants per loop mile: resistance 88 ohms, inductance 0·001 henry, leakance 10^{-6} mho, capacity 0·054 microfarad.

(*b*) The 800-cycle mile. This unit has an attenuation equal to that of a standard cable mile at a frequency of 800 per second.

(*c*) The attenuation constant β. The natural unit based on the physical characteristics of a long uniform line and used in all theoretical calculation work on line-transmission problems.

(*d*) The decie. A tenth of β and suggested as a more convenient dimension.

(*e*) The transmission unit of "T.U." adopted in America. The transmission loss is 1 unit when the ratio of the power being transmitted between two points in the circuit is equal to $10^{0 \cdot 1}$. The main opposition to the use of this unit arises from the necessity of using a factor to convert logarithms from the natural base *e* to the base 10. America has been asked to send representatives to the next conference, and they will submit arguments in favour of the adoption of the "T.U." as the international standard.*

The accompanying map, showing the present position of the layout of the main European trunk routes, will give an indication of the progress made towards the linking-up of international communications and the extent of the programme. Conversations have been carried out successfully between London–Rome and London–Stockholm, but reliable service of commercial quality over these distances has not yet been attained. The London-Stockholm line, it will be observed, includes two lengths of submarine cable.

The French Administration has adopted a standard subscriber's telephone set with a view to securing a higher grade of transmission from the sending end than has hitherto been possible.

Underground cable problems.—The provision of underground networks on main trunk routes, fitted at regular intervals throughout their length with repeaters, has produced many new problems which were undreamt of when substantial copper wires widely spaced on the poles were the only means of communication. These problems have received careful study in the P.O. Research Section, and a résumé of the conclusions may be interesting.

First of all, the greatest care must be taken in the factory and on the road to secure uniformity of mutual capacity along a cable, so that a simple yet accurate balance (to simulate the line over the audio-frequency range) may be obtained at the repeater.

Secondly, lighter loading (i.e. a smaller amount of added inductance per mile) is desirable on longer circuits, for the following reasons :—

(*a*) To reduce the propagation time and so prevent echo effects. (Incidentally a very successful form of echo suppressor has been devised for 4-wire circuits. On long uniform overhead lines an echo is produced only by terminal reflection, and the transmission time is so short that the echo is merged in the main speech wave. Out-of-balance conditions at repeaters, inequalities in circuit characteristics and similar reflecting sources produce "echoes," and their interference on a loaded line degrades the articulation, a result liable to be amplified in the repeater. In the echo suppressor mentioned, an amplifier-rectifier valve in the "go" line is made to impress a quenching voltage on the grid of the amplifying valve in the "return" line, so as to reduce its efficiency and thereby cut off the echo.)

(*b*) To reduce transient disturbances and limit the distortion of the higher frequencies. Distortion is caused by the wave-length and amplitude of higher frequencies varying at a different rate from those of lower frequencies. The extent to which distortion can be reduced is limited by a number of conflicting considerations.

(*c*) To raise the cut-off frequency. The latter is that point on the curve of the attenuation constant plotted against frequency where the attenuation rises very rapidly and corresponds to a value of $\omega = 2/\sqrt{(LC)}$, where ω is the frequency in radians per second, L is the inductance per coil, and C the capacity per loading-coil section. Since loading has the effect of reducing the cut-off point, it is desirable, in order to preserve the essential qualities of speech, on longer lines involving many amplifications to cut off at higher frequencies than on shorter lines, even at the expense of an increased attenuation constant per mile.

The twisting of wires in pairs and the twisting of pairs should be carefully carried out to reduce unbalance and cross-talk, which would be amplified at repeater stations.

The relative advantages of twin, multiple-twin and star-quad formation may be summed up, for the types of cables used up to the present, as follows: More pairs for a given size of sheath and loop capacity can be placed in a multiple-twin than in a twin cable, and more still in a star-quad, the relative number of pairs being approximately, taking 100 in a twin as a basis, 113 in a multiple-twin and 135 in a star-quad. The disadvantage of the two latter types lies in the fact that the two pairs in a core run adjacent all the way and it is necessary to keep down unbalance between them. The capacity of a phantom circuit in a multiple-twin is 1·62 times that of the loop capacity, but as its resistance is only half that of the loop the phantom is more efficient than the side or physical circuit. In the case of a star-quad core the capacity of the phantom is 2·65 times that of the loop, and consequently the phantom is less efficient than the loop. The star-quad, which is used extensively in Germany, is made up of cores of 4 wires twisted uniformly together, a method formerly practised in this country, and will probably be used again, on account of its economy in space, in cases where phantom circuits are not likely to be required.

* At the December conference in Paris the U.S.A. representatives were present, but after full discussion the "T.U." was turned down by 5 countries to 3. Great Britain voted for "T.U."

Submarine cables.—The last two years have witnessed a considerable advance in the methods of manufacture of submarine telephone cable in this country. In August 1924 the first British-made lead-sheathed paper-insulated cross-sea cable was laid between Aldeburgh (Suffolk) and Domburg (Holland), and since then it has given excellent and continuous service, except for a breakdown last November, due, it is thought, to the fouling of a ship's anchor. The cable contains four quads—8 telephone loops—each conductor of which is made up of a centre copper wire, 76 mils diameter, surrounded by three copper strips 10 mils thick, and over these are wound two layers of 8 mils iron wire. A double lead sheath is fitted over the insulation to an external diameter of 1·52 in., and the cable is armoured with 24 No. 4 S.W.G., galvanized-iron wires. The overall diameter of the cable is 2·42 in.; its weight per nautical mile is 24·5 tons, and the total length is a little over 82 nautical miles. With a testing current of 1 mA, at a frequency of 5 000 radians per second, the attenuation constant per nautical mile came out at from 0·02001 to 0·02008 for the physical circuits and from 0·02365 to 0·02375 for the phantoms. The corresponding characteristic impedances varied from 410 $/\overline{6^\circ\ 22\frac{1}{4}'}$ to 418 $/\overline{6^\circ\ 15\frac{1}{2}'}$ vector ohms in the case of the loops and from 169·3 $/\overline{5^\circ\ 17\frac{1}{4}'}$ to 170·4 $/\overline{6^\circ\ 23'}$ for the phantoms. Cross-talk values ranged from 100- to 160-millionths of the impressed current from side-circuit to side-circuit, and from 800- to 2 000-millionths from side to phantom. The a.c. capacity was 0·097 μF and the insulation resistance 9 460–11 510 megohms per nautical mile.

Although this was the first type of paper-core, continuously-loaded lead cable laid in the North Sea, it is but fair to mention that the German Administration had laid similarly constructed cables in the Baltic about two years earlier, two to Sweden, two from Pomerania to East Prussia and one from Pomerania to Dantzig. The last-mentioned cable included four telegraph loops in addition to 8 telephone loops, and is about the same length as the Anglo-Dutch cable.

A 4-wire core, continuously-loaded, balata-insulated cable has just been completed for the New Zealand Government which will be laid between the North and South Islands to connect up the trunk system already existing there. The overall length is a little over 50 nautical miles. Under the same testing conditions as given above, the two pairs and phantom characteristics were as follows :—

	Attenuation constant per naut loop	Characteristic impedance in vector ohms
Pair 1	0·02726	252·7 $/\overline{6^\circ\ 1'}$
Pair 2	0·02733	251·2 $/\overline{6^\circ\ 13'}$
Phantom ..	0·02695	121·7 $/\overline{5^\circ\ 30'}$

Cross-talk tests gave 40-millionths side-circuit to side-circuit and 350- to 1 700-millionths side-circuit to phantom. The a.c. capacity was 0·17 μF per naut.

A more ambitious effort is being made in connection with a new cable, now in course of construction, which will be laid next year from Dumpton Gap, near Broadstairs, to La Panne, Belgium, a distance of some 50 nautical miles. The cable will contain 7 quad cores—14 telephone loops—and will be continuously loaded with iron wire. Paper insulation is being used, and there are two lead sheaths fitted, as in the Anglo-Dutch cable. The copper is much lighter, however, the weight being 118 lb. per naut, as against 165 in the latter. The attenuation constant must not exceed 0·030 per naut and the characteristic impedance 369 $/\overline{9^\circ\ 36'}$ vector ohms (ω = 5 000 radians per sec., 1 mA testing current) for the loop circuits, and 0·036 and 148 $/\overline{10^\circ\ 9'}$ for the phantoms. The overall diameter is 2·58 in. and the weight per nautical mile 26·5 tons.

The comparatively small inductance—from 10 to 20 per naut obtained by continuously loading the copper with iron wire on the Krarup principle—limits its effect in increasing the distance over which speech is possible, especially if the pairs are squeezed up close to increase their number, since the capacity is relatively increased.

It had been known for some time that the German Administration was very anxious for a direct telephone cable to this country, but the distance, some 285 miles, with light Krarup loading appears to be prohibitive. Two lengths of approximately 9 nautical miles each of coil-loaded, paper-insulated lead-covered cable, were this year manufactured by two German firms, each length containing 7 quads, with seven loading points spaced about 1¼ nauts apart. The 14 coils serving the 14 telephone loops were spread inside a "blob" 12 ft. long in one case and 15·75 ft. in the other, the largest diameter being 4·72 inches in the first and 5·5 inches in the second cable. The inductance per coil reached about 40 mH, with an a.c. resistance (at a frequency of 5 000 radians per second) of from 3 to 4 ohms. The effect of the additional inductance gave an attenuation constant of 0·01465 for No. 1 cable and 0·01484 for No. 2 cable, and a characteristic impedance of 615 ohms for the first and 570 ohms for the second. The copper conductors in No. 1 cable were 164·5, and in No. 2, 218 lb. per naut. The trials on these cables, which were made before laying, in position and after recovery, were carried out in the North Sea on the 27th–30th July, by the Reichpost authorities and were quite successful, apart from a fault developing in each length; neither fault, however, was of a very serious nature. These trials show that: (1) A cable of this type appears to maintain satisfactorily during laying and recovery the circuit electrical characteristics as regards transmission efficiency, distortion and freedom from inductive disturbance; (2) a cable of this type can be laid and recovered satisfactorily, provided the sea bottom is not too deeply sanded, by a cable-ship properly equipped for the purpose. The provision of a direct telephone cable from England to Germany is therefore a problem which awaits financial and traffic considerations only.

PERMISSIBLE CURRENT LOADING OF BRITISH STANDARD IMPREGNATED PAPER-INSULATED ELECTRIC CABLES.

SUPPLEMENT TO SECOND REPORT (REF. F/T12)* ON THE RESEARCH ON THE HEATING OF BURIED CABLES.

[REPORT (REF. F/T15) RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION.]

APPENDIX X.

Calculation of the Temperature-Rise of Electric Cables Buried in Groups.

In Technical Report Ref. F/T12 it was shown by Messrs. S. W. Melsom and H. C. Booth that the heating of cables buried in a group in the same horizontal plane, so that each influences the temperature-rise of the others, may be calculated by a superposition method. This is based upon a method originally suggested by Kennelly.† A general solution is now given applicable to cables buried at the same or at different depths.

The method is only an approximate one, but the accuracy of the result obtained is probably amply sufficient for the conditions encountered in practice. In view of the local variations in the moisture content of the soil, it is impracticable to estimate the heating of a single cable over its whole length with a high degree of accuracy, and therefore the approximate method described herein is justified when dealing with the more complicated subject of grouped cables. When it is necessary to determine the heating of grouped cables with great accuracy, it will be found more advantageous to give attention to the nature and condition of the soil than to further elaboration of the calculations.

The superposition method may be briefly stated thus: It is found experimentally that the temperature-rise of each cable may be determined by adding to the rise proper of the cable taken singly the temperature-rises which would be caused at the point where it is situated by each of the several neighbouring cables taken separately.

Referring to Fig. 1, it is then necessary to calculate the temperature-rise t_x at any point P at which a cable may be situated due to any other cable A, the depths and horizontal distance between the centres being as indicated in Fig. 1.

The temperature-rise t_4 at the surface of cable A (i.e. at radius r_6) is first ascertained by the method shown in Technical Report Ref. F/T12.‡ The temperature-rise t_x may then be calculated by the following formula,§ which is the general solution applicable to cables buried at the same or at different depths, referred to above :—

$$\frac{t_x}{t_4} = \frac{\log \dfrac{(L + L_1)^2 + x^2}{(L - L_1)^2 + x^2}}{2 \log \dfrac{2L}{r_6}}$$

* See *Journal I.E.E.*, 1923, vol. 61, p. 517.

† *Electrical World*, 1893, vol. 22, p. 183.

‡ For convenience the values of the thermal resistance S of the cable per cm length required in this calculation have been computed and issued in this supplement, for all the British Standard cables referred to in Ref. F/T12.

§ For proof of this formula see page 164.

The temperature-rise t_x is to be added to that proper to the cable at P, and if there are other neighbouring cables the temperature-rise due to each must be calculated and superposed in a similar manner. It is important to note that the temperature-rises to be taken in making the above calculation are those due to each cable taken singly as though laid alone, and not the higher values which result from the influence of neighbouring cables.

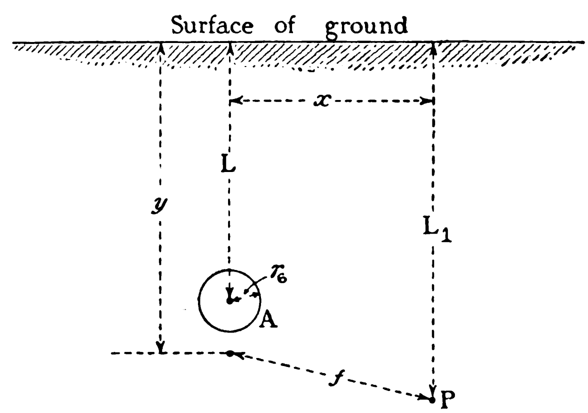


Fig. 1.

P = Point where a cable is situated, the temperature-rise of which is affected by a neighbouring cable A.
A = Cable causing temperature-rise at P.
L = Depth to centre of cable A, in inches.
L_1 = Depth of point P, in inches.
x = Horizontal distance between A and P, in inches.
r_6 = Radius of outer surface of cable A, in inches.
f = Radius of isothermal passing through point P, in inches.
y = Depth below surface of ground of centre of isothermal passing through point P, in inches.
t_4 = Temperature of outer surface of cable A.
t_x = Temperature-rise at point P due to A.

$$\frac{t_x}{t_4} = \frac{\log \dfrac{(L + L_1)^2 + x^2}{(L - L_1)^2 + x^2}}{2 \log \dfrac{2L}{r_6}}$$

Use of curves.

The estimation of t_x from t_4 may generally be made with sufficient accuracy by the use of the curves in Fig. 2. These are not derived from the formula given above but are based on the assumption of concentric isothermals. In Fig. 2, d is the radial distance from

the centre of cable A to the centre of the cable at P (Fig. 1). In most practical cases the values derived from the curves will agree with those derived from the formula to within $\pm$ 10 per cent.

The methods represented above are based on the work of Messrs. C. E. R. Bruce, W. P. Fuller, W. Bevan Whitney and the Director of Research.

Equating the two expressions for f^2 we obtain—

$$y = \frac{x^2 + L^2 + L_1^2}{2L_1}$$

hence by (39)—

$$\frac{B^2 + 1}{B^2 - 1} = \frac{x^2 + L^2 + L_1^2}{2LL_1}$$

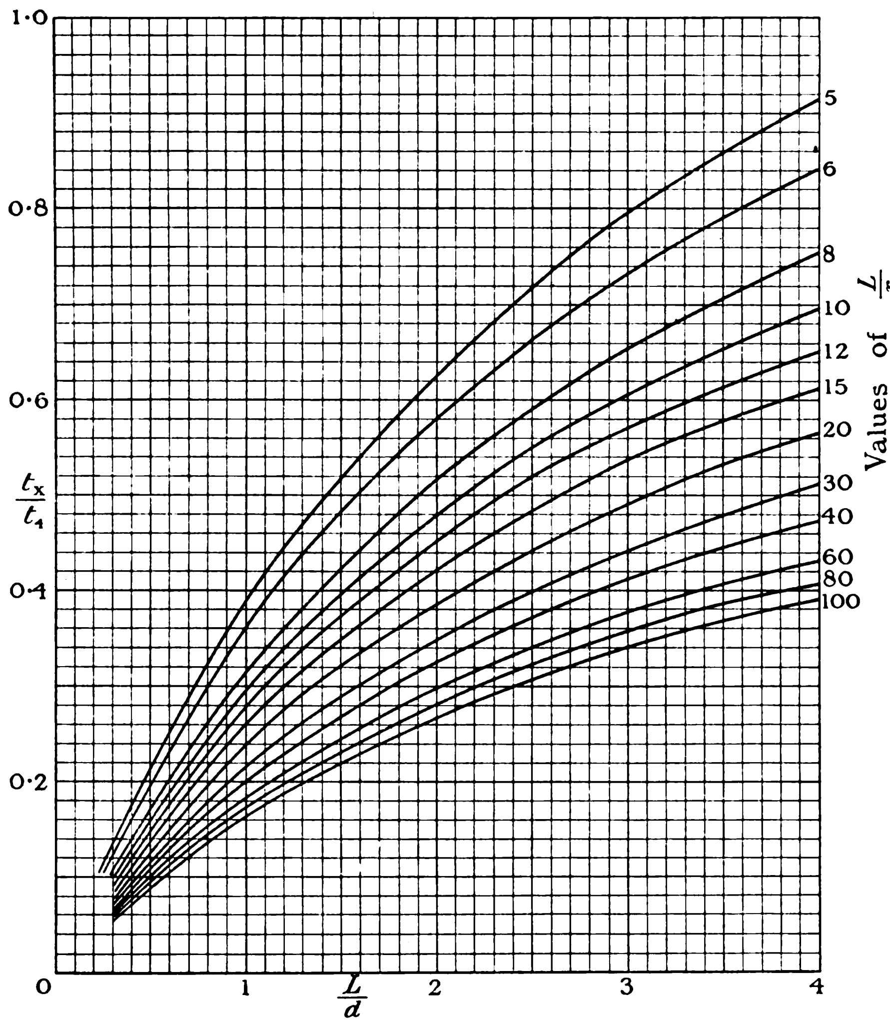

FIG. 2.—Curves for the evaluation of t_x.

Mathematical proof of the formula given on page 161.

Starting with the formulæ (39), (40), (41) in Technical Report Ref. F/T12 we have from (40)—

$$f^2 = \frac{4L^2B^2}{(B^2 - 1)^2}$$

$$= L^2 \frac{(B^2 + 1)^2 - (B^2 - 1)^2}{(B^2 - 1)^2}$$

substituting for y from (39)—

$$= y^2 - L^2$$

also $$f^2 = L_1^2 - 2L_1y + y^2 + x^2$$

or $$B^2 = \frac{x^2 + (L + L_1)^2}{x^2 + (L - L_1)^2}$$

Hence $$B = \sqrt{\left(\frac{(L + L_1)^2 + x^2}{(L - L_1)^2 + x^2}\right)}$$

$$= [M + \sqrt{(M^2 - 1)}]^{\delta} \text{ from (41).}$$

Hence $$\delta = \frac{\log B}{\log [M + \sqrt{(M^2 - 1)}]}$$

$$= \frac{\log \dfrac{(L + L_1)^2 + x^2}{(L - L_1)^2 + x^2}}{2 \log [M + \sqrt{(M^2 - 1)}]}$$

or taking the approximate value $2M$ for $M + \sqrt{(M^2 - 1)}$ and remembering that

$$M = \frac{L}{r_6}$$

we obtain
$$\delta = \frac{\log \dfrac{(L + L_1)^2 + x^2}{(L - L_1)^2 + x^2}}{2 \log (2M)}$$

Notes on the superposition method.

At first sight it would appear that the method of superposition cannot be correct, as in fact under working conditions the cables influencing each other are both loaded and therefore both running above the temperature taken in the calculation. It might be supposed that after evaluating the extra temperature-rise due to proximity by the formulæ given, the newly corrected figures should be used again for a closer approximation. This is not so, and if it were done it would be found that each successive approximation so made would give an increasingly higher result and without limit.

Examination of the basis of the formulæ employed shows that they are correct only provided that the cables be either mathematical points or material having the same thermal resistivity as the surrounding soil. If a cable were surrounded by a continuous ring of cables of infinitely high thermal resistance the heat could not escape at all and the temperature-rise would be unlimited, even though the surrounding cables carried no load. In a typical case, however, in which there are, say, two cables 2 in. diameter laid 10 in. apart, it will be seen that at the radius of 10 in. each cable occupies less than one-thirtieth of the cross-section of soil through which the heat of the other cable is escaping, and thus can have but a negligible influence whatever its thermal resistivity may be.

Under working conditions the thermal resistivity of one cable considered as part of the path of heat-flow from another cable is not greatly different from that of the surrounding soil, its dielectric of relatively high resistivity being surrounded by lead or armouring of relatively low resistivity, and doubtless in many cases its presence would actually improve the conditions.

It is not easy to picture how it is that the superposition principle can apply to several hot cables near together and with the dissipation of their heat taking place along the same path, but a rough calculation of an extreme case which admits of ready solution may be reassuring.

Let there be two cables represented by solid copper rods of relatively high thermal conductivity, of the same diameter and equally loaded. Now if these be brought nearer and nearer together it might be thought the superposition principle would give too low a value in an increasing degree. Take then the extreme case and assume the two rods can be superposed. They now occupy the same space and have to share the surrounding soil which now carries twice the heat-flow that it did before. This then results in doubling the temperature-rise, but the superposition principle gives precisely this answer. In actual practice ignoring any drying effect on the soil, the superposition method would give results erring on the high side for copper rods in near proximity, as their presence in the soil would improve the general conductivity.

APPENDIX XI.

Thermal Resistance of British Standard Impregnated Paper-Insulated Armoured Cables.

In Technical Report Ref. F/T12, it is shown that the heat emission of a cable can be deduced from the following formula :—

$$H = t/(S + G)$$

From the information given in Ref. F/T12, G can be computed without difficulty, but the value of S varies with the type and size of the cable under consideration.

The values of the thermal resistance per cm length, S, of the impregnated paper-insulated armoured cables given in British Standard Specification No. 7 have been computed by Messrs. S. W. Melsom and H. C. Booth and are shown below.

By the insertion of the appropriate value of S in the formula given above, an engineer is enabled to compute the temperature which will be reached in a British standard cable under service loading conditions for any method of laying and in any kind of soil.

TENTATIVE DIRECTIONS FOR THE DETERMINATION OF THE ELECTRIC STRENGTH OF SOLID DIELECTRICS.*

[REPORT (REF. L/S2) RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION.]

CONTENTS.

CONTENTS—*continued.*

PREFACE.

Since the publication (see *Journal I.E.E.*, 1922, vol. 60, p. 794), of its "Directions for Determining the Electric Strength of Fibrous Insulating Materials," Ref. A/S2, the Association has had under consideration the extension of these directions to other classes of solid dielectrics. It is now generally known that the results obtained in electric strength tests of solid dielectrics depend largely on the method of test employed. If different observers are to obtain strictly comparative results on insulating materials, it is essential that the method of test employed be standardized.

The standardization of a method of test which shall be applicable to formed and moulded pieces as well as to sheet material has presented many difficulties and further experimental investigation is required before the methods herein recommended can be extended to cover all classes of solid dielectrics. Sufficient progress has, however, been made to enable the Association to issue directions in a form specifying methods for the determination of the electric strength of the various classes of commercial insulating materials which are now under examination and which cover a wide and important field.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

The researches undertaken preparatory to the preparation of this document have thrown much new light on the subject and will shortly be made the subject of a technical report. Further work is required to obtain an explanation of the results obtained which may lead to the development of new and improved methods of testing. The recommendations herein are therefore tentative and subject to revision.

It should be specially noted that the directions contained in this publication are intended to apply to tests to destruction and are not therefore applicable to tests on finished machines, as for such tests precautions would have to be taken to avoid accidental damage to the apparatus under test.

It is hoped also that the issue of the directions in this manner will prompt members and others to furnish comments on the methods suggested, and the Director will be pleased to hear from anyone who may have occasion to use them.

Part I. RESEARCH TESTS ON ELECTRIC STRENGTH.

The following methods for the determination of the electric strength are recommended when the characteristics of the material are not known, and when a thorough investigation is required to ascertain the electric strength of the material under probable service conditions.

1. General.

It is of primary importance in the case of insulating materials that the recognized electric strength be that of the material when hot and under long-continued stress.

It is desirable to test materials at temperatures appreciably above their intended working temperature.

2. Forms in which the Material may be Tested.

The directions given in this document for the study of electric strength of dielectrics provide for the specimens being in one of the following forms :—*

(*a*) Flat sheets and boards.
(*b*) Small tubes.
(*c*) Large tubes.
(*d*) Insulation built up on conductors.
(*e*) Moulded compositions.

3. Preparation of Material Previous to Test.

The ability of a material to withstand a damp atmosphere may be due to :—

(*a*) The material itself being non-absorptive.
(*b*) Additional protection given by a surface layer either developed during manufacture or added subsequently.

In the latter case the specimens shall be prepared for test in the following manner :—

(i) When the specimen is in the final form in which it will be used commercially, the protective surface layers of (*b*) above shall be retained.

(ii) When determining the properties of the material itself it is necessary to exclude the additional protection afforded by the natural layer, by making tests upon sections cut from the material having the surface layers removed at all points.

The results should state in each case how the specimen had been prepared for test.

4. Conditioning the Material Previous to Test.

As the electric strength of most insulating materials is largely influenced by their moisture content, it is desirable that the characteristic curves referred to later should be obtained for as many as possible of the conditions indicated for the class of dielectric under investigation (see Appendix I).

When a specimen is moved to an atmosphere of different relative humidity or different temperature, change of moisture content may take place very rapidly. It is, therefore, essential that the electric strength test should be made as soon as possible after the specimen has been removed from the conditioning chamber.

When it is necessary to curtail the number of tests, preference should be given to those which will give the lowest electric strength with due regard to the purposes for which the material may be used. In such cases the abridged tests given in Part II shall be employed.

5. Method of Heating or Cooling the Specimen After Conditioning and Previous to Carrying Out the Electric Strength Test.

(*a*) *Tests in Air.*

When it is desired to carry out the electric strength test at a different temperature from that at which the specimen has been conditioned the following method shall be employed.

Previous to the removal of the specimen from the conditioning chamber the test chamber and two blocks of hard brass each **3** inches diameter by 1 inch thick shall be brought to the temperature at which it is desired to determine the electric strength, also the top electrode specified in Clause 13.

The specimen shall be rapidly transferred from the conditioning chamber to the test chamber, where it shall be immediately placed between the brass blocks for the period stated in Appendix II.

At the expiration of this period the upper brass block shall be removed and the top electrode specified in Clause 13 substituted. The bottom brass block shall be retained as the bottom electrode, and the electric stress applied as soon as possible after changing the top block.

After conditioning the specimen must not be exposed, except momentarily, to either the air of the laboratory or the air of the test chamber, as this may largely eliminate the effect of the conditioning.

(*b*) *Tests in Oil.*

When the test is made in oil the latter may retard change of moisture content of the specimen during the time its temperature is being brought to that required for the electric strength test. In this case, therefore, the electric strength is not so liable to be influenced by the period which elapses between the removal of the specimen from the conditioning chamber and the application of electric stress. Previous to the removal of the specimen from the conditioning chamber, the electrodes specified

* Methods of tests for compounds normally solid at room temperature, but liquid when hot, are under consideration.

in Clause 13 and the oil bath shall be brought to the temperature at which it is desired to determine the electric strength. When removed from the conditioning chamber the specimen shall be placed immediately between the electrodes and immersed in the oil bath. Electric stress shall be applied after the period specified in Appendix II.

6. Tests in Air or Oil.

It is often more convenient to immerse the sample under oil whilst the electric strength test is carried out. Under certain conditions the breakdown voltage obtained when the material is tested in oil is not the same as the breakdown voltage which would be obtained if the material were tested in air.

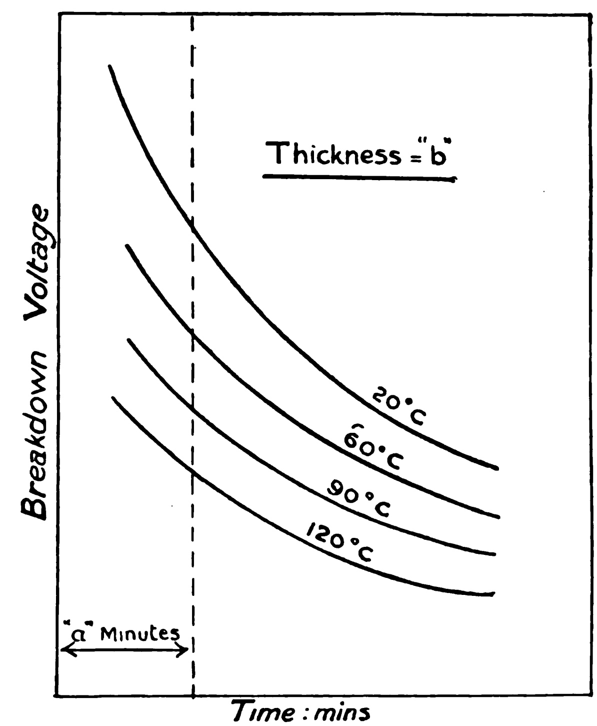

Fig. 1.—Time-voltage curves at various temperatures.

Unless the material is intended for use in oil-immersed apparatus, tests under oil are not permitted if, during the immersion under test conditions, the oil is liable to change the properties of the material in any way.

When testing materials which are intended for use in air and also in oil-immersed apparatus, it is desirable that the effect of conditioning in a damp atmosphere (Appendix I) should be ascertained both in air and in oil.

A schedule suggesting the mode of test which might be used for various classes of the more commonly employed insulating materials is given in Appendix III.

7. Method of Expressing Electric Strength.

A single value for the electric strength of most materials is misleading unless the condition of the material, the thickness, the time of application of the voltage and the temperature are either stated or clearly indicated.

Values obtained on a rapidly applied test are usually very high, being out of all proportion to the electric strength obtained by the sustained conditions of practice.

The electric strength shall be given in the form of a series of curves in which the actual breakdown voltage, R.M.S. value (0·707 of the maximum value) is plotted against time and temperature as shown in Figs. 1 and 2 respectively and in volts per mil against thickness as shown in Fig. 3.

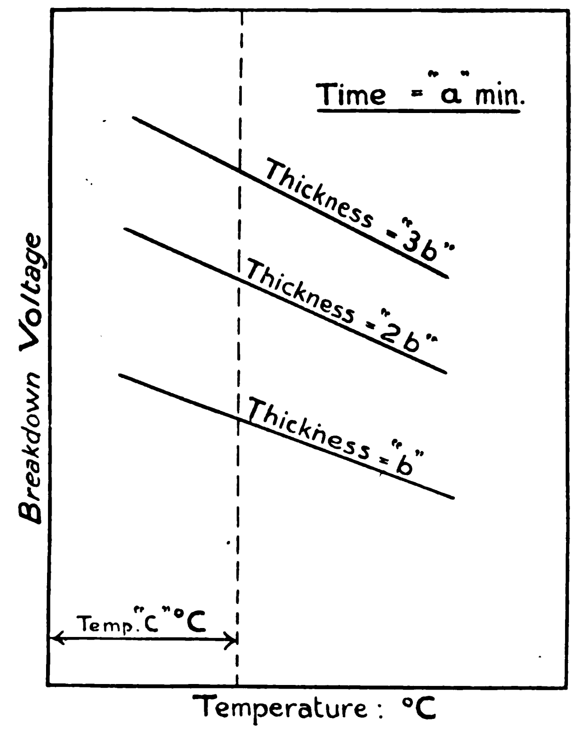

Fig. 2.—Temperature-voltage curves for various thicknesses.

Note. The temperature-voltage characteristic is not always a straight line

In calculating the electric strength in volts per mil the mean voltage gradient shall be employed, i.e. the breakdown voltage divided by the thickness of the dielectric. If in the case of tubes, or special shapes, it is desired to calculate the electric strength from the highest voltage gradient, the method given in Appendix IV may be employed.

When a spark-gap or other method for determining the peak value is used, the peak value shall be given and also the equivalent R.M.S. value (i.e. 0·707 of the peak value). [See Clause 12 (*d*).]

8. Time-Voltage Tests.

(*a*) In carrying out electric strength tests it is important to obtain time-voltage curves,* Fig. 1 showing the breakdown voltage over the time range from 0·5

* Details of an abridged method for the determination of time-voltage curves is given in Clause 10.

minute to the time * required for the breakdown voltage to become approximately independent of the time.

(*b*) In special cases transient voltage tests may be desirable.†

9. Temperature-Voltage Tests.

It is desirable that time-voltage tests (see Fig. 1) should be carried out at the temperatures indicated in Appendix III for the class of material under investigation.

For one minute and a selected number of other time values on the time-voltage curves, a temperature-voltage curve should be drawn similar to Fig. 2.

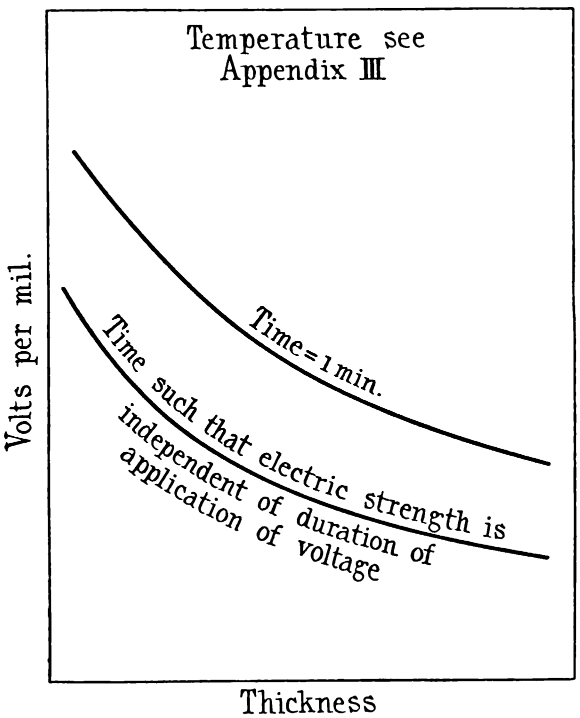

Fig. 3.—Curves showing variation of electric strength with thickness

10. Thickness-Voltage Tests.

When the material is supplied in more than one thickness it is further desirable that sufficient of the foregoing temperature-voltage curves, Fig. 2, should be obtained to enable the thickness-voltage curve to be plotted for definite time and temperature conditions, as in Fig. 3.

One of the thickness-voltage curves should be plotted from the one-minute values and another from the values obtained when the breakdown voltage is sufficiently independent of the time during which the voltage is applied (see curves in Fig. 3).

When it is desired to limit the study of these curves to one temperature, the temperature to be employed shall be the one indicated in Appendix III for the material under investigation.

To minimize the work required for the construction of a thickness-voltage curve the number of thicknesses tested may be reduced to three. Two thicknesses are not sufficient, as a knowledge of the shape of the curve is important.

Note.—In plotting thickness-voltage curves the values on the vertical axis should be in terms of volts per mil, and not in terms of breakdown voltages.

11. Calculation of Electric Strength.

(*a*) *Diagrams.*

For drawing the time-voltage curves sufficient tests shall be made to enable fair curves to be drawn over the time range under investigation.

In order that some idea may be formed of the uniformity of the material, all the experimental values are to be indicated, and when considerable variation is found, this fact should be specially mentioned.

As the temperature-voltage curves are taken from the mean curves drawn through the values obtained on the time-voltage tests, the experimental points cannot be indicated on these or on the thickness-voltage curve.

(*b*) *Measurement of Thickness.*

The thickness of the dielectric shall be measured by means of a micrometer or other suitable method.

12. Test Equipment for Power Frequency Tests.

(*a*) *Output of Testing Set.*

The output of the testing set shall be sufficient to maintain on the sample under test the necessary voltage for the maximum period required.

(*b*) *Frequency.*

The frequency of the supply voltage shall be approximately 50 cycles, and, if different, its value shall be recorded.

(*c*) *Application and Regulation of Voltage.*

It is essential that the voltage be applied without shock and in some tests, such as time-voltage tests, that the required voltage should be reached as rapidly as possible.

Methods which could be used for this purpose are given below, and their relative suitability indicated.

(i) *Separate Alternator.*

Undoubtedly the best method is to have a separate alternator for the testing transformer. When this is feasible the H.T. voltage should be controlled by means of a resistance in series with the alternator field. In cases where rapid application of a definite voltage is desired, the field rheostat should be adjusted to give the required voltage before the specimen is inserted, and after inserting the specimen the voltage should be applied by closing a switch in series with the alternator field, or by short circuiting an additional resistance temporarily added.

* When some dielectrics, such as the commonly used fibrous materials, are tested hot, the time required for the breakdown to become sufficiently independent of the time of application of the voltage may be about ten minutes. When, however, the tests are carried out at air temperature (about 20° C.) the time may be considerably longer.

† Methods for carrying out transient voltage tests are under consideration.

The generator supply must be disconnected from the testing transformer before the specimen is inserted.

(ii) *Induction Regulator.*

The use of an induction regulator designed to enable the voltage to be increased smoothly is the best method to employ when a separate alternator is not available.

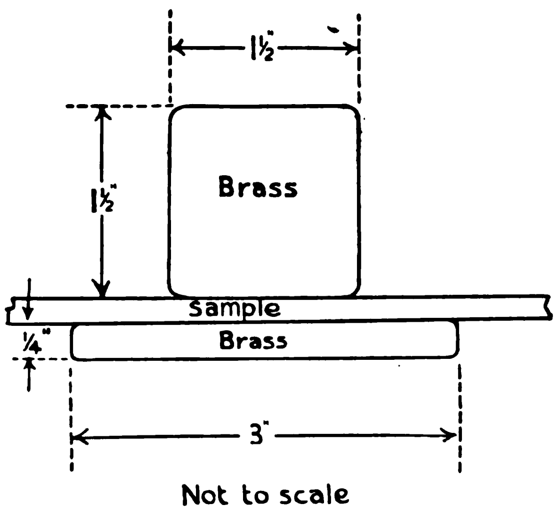

FIG. 4.—Electrodes for sheet material.

When a rapid application of a definite voltage is desired, a stop may be fixed at the required point on the regulator and the voltage applied by turning the handle rapidly from zero position to the stop.

(iii) *Tapped Transformer.*

This method does not permit the voltage to be increased smoothly and is not recommended when either method (i) or (ii) above is available. If used, the voltage between the stops should be as small as possible. This may be obtained by employing an auxiliary regulating transformer connected in series with the main regulating transformer, and having a voltage between taps of, say, 1/10 the voltage between the taps of the main regulating transformer.

When a rapid application of a definite voltage is desired, the regulator should be set to the required position and the voltage applied by closing the primary circuit through a suitable resistance, arrangements being made to short circuit the latter a fraction of a second later. The use of a three-pole switch in which one jaw is arranged to make contact slightly later than the others is a convenient way to obtain the above result.

(iv) *Series Resistance.*

An inductive or a non-inductive resistance could be inserted in series with the primary of the testing transformer. This method, although sometimes the most convenient, is not recommended, as it is liable to distort the wave shape.

If its use is unavoidable and a rapid application of the voltage is required, the same procedure as recommended in (iii) above could be used.

(*d*) *Wave Shape.*

The wave shape shall be as near sinusoidal as possible. If the wave shape is not known to be satisfactory, the peak value shall be ascertained, whilst a specimen is under test and near the point of breakdown, by means of a suitable spark-gap * or other method, and the equivalent R.M.S. value taken as 0·707 of the peak value.

(*e*) *Measurement of Voltage.*†

The voltage shall preferably be measured on the H.T. side of the testing transformer by means of a crest voltmeter, or an electro-static voltmeter. If it is desired to employ an electro-magnetic voltmeter, the instrument should derive its voltage from the H.T. circuit, either directly or through an auxiliary voltmeter transformer. If a special winding in the transformer is used to supply the voltmeter, it shall first be calibrated, when a specimen is under test and on the point of breakdown, by means of one of the other methods indicated.

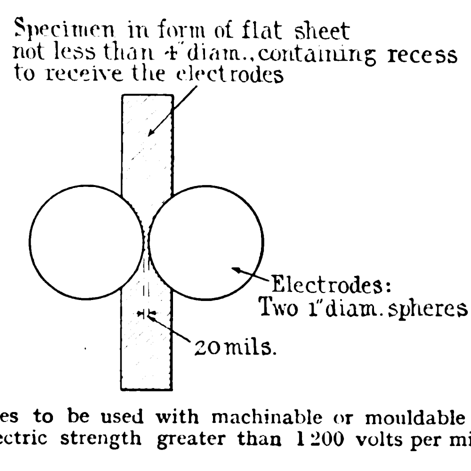

FIG. 5.—Electrodes to be used with machinable or mouldable materials having an electric strength greater than 1200 volts per mil.

* For information on suitable spark-gaps and method of use see Appendix V.

† It should be noted that the directions given in these clauses are not suitable for tests on finished machines. See fourth paragraph in Preface.

(*f*) *Prevention of H.F. Oscillation.**

The conditions of the test must be such as to prevent any H.F. oscillations. Precautions must be taken to prevent the occurrence of spark discharges in the circuit in which the specimen is being tested. When a spark-gap is used to measure the voltage a non-inductive resistance of about one ohm per volt of test pressure shall be inserted in series with the unearthed sphere. This resistance shall not be in series with the specimen under test.

A water tube is the most suitable form of resistance.

13. Electrodes.

(*a*) *For Samples in the Form of Flat Sheets or Boards.*

When the sample is in the form of a flat sheet or a board, the method of test to be employed is specified below :—

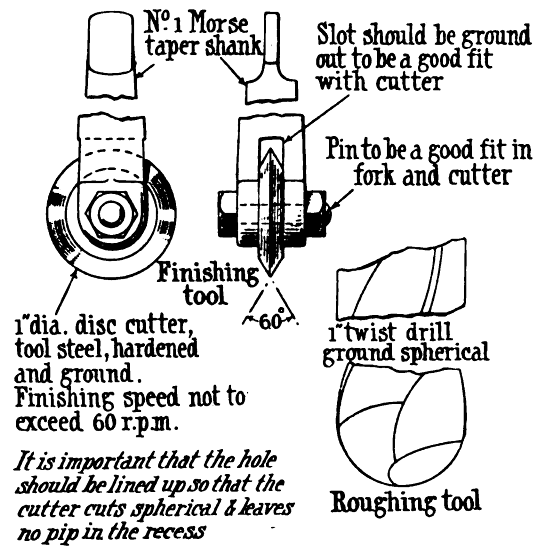

Fig. 6.—Cutter used to machine spherical recess in specimen in Fig. 5.

(i) *Machinable Materials having an Electric Strength greater than* 1 200 *volts per mil.*†

For the determination of the electric strength of high-grade ebonite and like materials, convenience and economy necessitate that the thickness of the specimen shall not be greater than 20 to 40 mils. The use of disc electrodes is therefore not practicable, and it is recommended that the electrodes employed shall consist of two spheres each 1 inch diameter,‡ arranged as shown in Fig. 5. A roughing tool and a finishing tool which have been found suitable for machining the recess for the 1 inch diameter sphere are shown in Fig. 6. When it is required to ascertain the electric strength of the interior of the sheet, the surface must be machined from the flat side of the test specimen.

* It should be noted that the directions given in these clauses are not suitable for tests on finished machines. See fourth paragraph in Preface.

† 50 kV per mm.

‡ In E.R.A. Report Ref. B/S1 the use of a recess with a diameter of 50 mm was recommended. This has now been modified to 1 inch diameter so that it may be machined in a drilling machine.

When it is desired to test a specimen with moulded surfaces proceed as in Section (*b*) below.

(ii) *Materials having an Electric Strength less than* 1 200 *volts per mil.*

The bottom electrode shall consist of a flat* disc of brass 3 inches diameter by ½ inch thick, and the top electrode of a solid cylinder of brass 1½ inches diameter by 1½ inches high.

The sharp edges shall be removed from the electrodes, but the radius at the edge must not exceed 1/32 inch (Fig. 4).

When it is desired to make electric strength tests in air at temperatures differing from room temperature, the bottom electrode shall consist of a brass block 3 inches diam. by 1 inch thick. (See Clause 5.)

(*b*) *For Compositions Moulded to Finished Shapes.*

When the sample is in the form of a moulded piece, the method of test to be employed is specified below :—

(i) *Materials having an Electric Strength greater than* 1 200 *volts per mil.*†

The specimen should be moulded to the shape shown in Fig. 5, and its electric strength determined with electrodes consisting of two spheres each 1 inch diameter. When it is required to ascertain the electric strength of the interior portions of the specimen, the surface portions must be removed by machining both the flat side and also the spherical recess. The finishing tool shown in Fig. 6 may be employed for the latter.

(ii) *Materials having an Electric Strength less than* 1 200 *volts per mil.*†

The use of specimens moulded to a special shape is not recommended for materials having an electric strength less than 1 200 volts per mil,† for the following reasons :—

Recent researches have definitely shown that in comparing one material with another the results obtained with different shapes of electrodes may vary over a very wide range: in the case of sphere versus disc electrodes, sometimes one and sometimes the other giving the higher result. The difference between the values obtained with different shapes of electrodes depends on the conditions of test, the moisture content, etc., and it has not been found possible to correlate the values obtained. It is therefore more important than has been realized in the past to employ whenever practicable the same shape of electrode for all classes of solid dielectrics.

It is recommended that in future the electric strength of mouldable materials should, whenever practicable, be determined with specimens in the form of flat sheets, thus permitting the use of the disc electrodes shown in Fig. 4.

The question of the shape of electrode which should be employed for the determination of the electric strength of porcelain is still under consideration. Recommendations will be made when the necessary experimental investigations have been completed.

* When the surface of the specimen is irregular or any difficulty is experienced in obtaining good contact, it is recommended that tinfoil should be interposed between the electrode specified and the dielectric.

† 50 kV per mm.

(*c*) *For Small Tubes* (*up to about* 3 *inches inside diameter*).

The outside electrode shall consist of a band of sheet metal 1 inch wide.

The inside electrode shall consist of a cylinder with the ends rounded to a radius of 1/8 inch, or when a cylinder with rounded ends cannot conveniently be obtained, a sheet metal * cylinder sprung into place may be employed. The length of the inside electrode shall not be less than 1 inch plus three times the thickness of the wall of the tube (see Fig. 7).

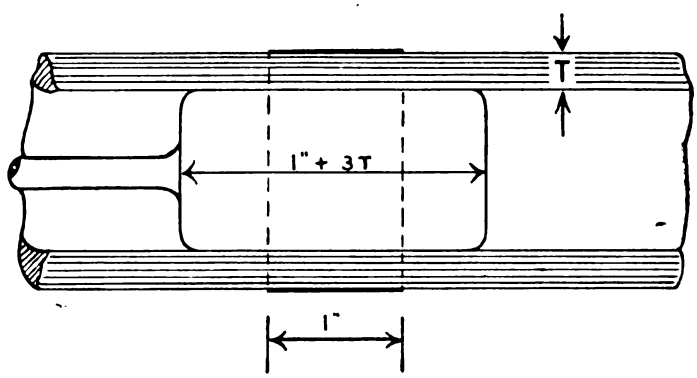

FIG. 7.—Electrodes for small tubes.

(*d*) *For Large Tubes* (*often called Cylinders*).

The outside electrode shall consist of a strip of sheet metal † 3 inches wide.

The inside electrode shall consist of a disc 1½ inches diameter of sheet metal sufficiently flexible to conform to the curvature of the cylinder: this disc of sheet metal to be pressed against the inside of the cylinder so as to make good contact over the whole of the area of the disc (Fig. 8).

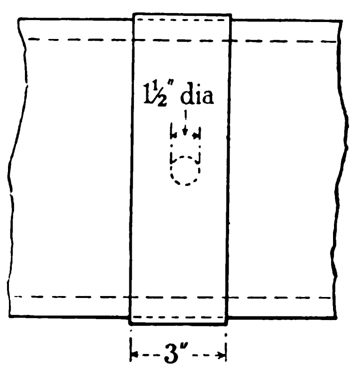

FIG. 8.—Electrodes for cylinders.

(*e*) *For Insulated Bars and Rods.*

The conductor on which the insulation is built up shall be employed as the inside electrode.

A strip of metal foil about 3 inches wide and sufficiently flexible to conform to the contour of the coil or bar shall be employed as the outer electrode, as shown in Fig. 9.

(*f*) *For Insulated Wires.*

When it is required to determine the electric strength of insulated wires the method of test to be employed is specified below:—

(i) *Wires of Overall Diameter of* 0·040 *inch and less.*

A single layer of the wire shall be evenly wound on to a smooth brass tube. The tension on the wire during winding shall be comparable with that usually employed in winding coils with wire of the size under investigation. The outside diameter of the brass tube shall be 1 inch for wires of 0·040 inch to 0·020 inch overall diameter, and ¼ inch diameter for wire of overall diameter less than 0·020 inch. The electric strength of the covering shall be determined by testing from the winding to the brass tube.

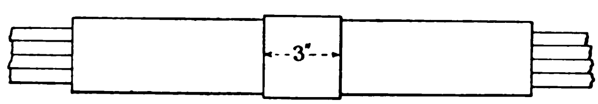

FIG. 9.—Electrode for insulation built up on conductors.

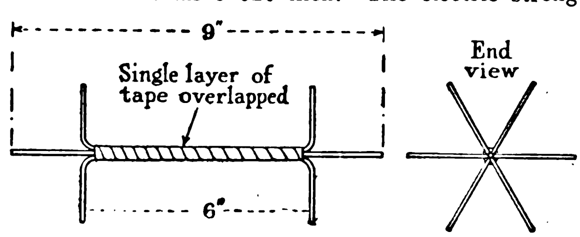

FIG. 10.—Method for large sizes of round insulated wire.

(ii) *Wires of Overall Diameter greater than* 0·040 *inch and all Sizes of Square or Rectangular Wires.*

When the conductor is circular in section, seven straight pieces shall be cut 9 inches long. Six of the lengths shall be arranged symmetrically round the seventh as core and shall be taped tightly together with one half-lapped layer of cotton tape 0·007 inch thick, for a distance of six inches, as shown in Fig. 10.

* Sheet zinc about 1/32 inch thick has been found convenient for springing into tubes for forming the inside electrode.

† Soft aluminium foil from 2 to 5 mils thick has been found convenient for use as the outside electrode on tubes.

When the conductor is square or rectangular in section seven straight wires each 9 inches long shall be laid together, as shown in Fig. 11, and taped together for a distance of 6 inches as directed above.

Previous to conditioning the ends of the wires shall be bent outwards, as shown in the end view in Figs. 10 and 11. The test shall be made between adjacent wires, and the electric strength of the insulation shall be taken as half the average value obtained by the above test, and expressed as the electric strength of one side of one wire.

(*g*) *Compounds Normally Solid at Room Temperature but Liquid when Hot.*

Methods of test for bitumens, waxes, filling compounds, etc., are under investigation, recommendations are not yet available.

General Note on the Mechanical Pressure to be exerted by the Electrodes on the Specimen.

When employed under service conditions the insulation may be required to withstand considerable mechanical pressure at the same time as it is subjected to electrical stress. Also it has been found that in the case of certain classes of dielectrics the internal heating caused by the leakage currents may volatilize

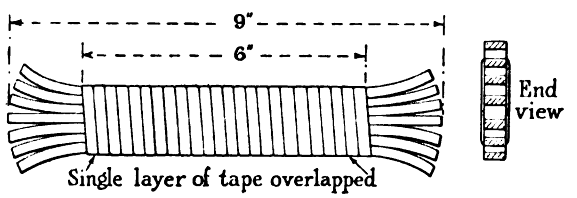

FIG. 11.—Method for square and rectangular insulated wire.

certain constituents of the dielectric and thereby cause the material to swell. As any swelling of the material between the electrodes is liable to result in an increase in the breakdown voltage, it is essential that the mechanical pressure on the electrodes should be sufficient to counteract any such tendency. When considered necessary, suitable * mechanical pressure shall be applied by means of deadweights, springs, screws, etc., to prevent any change in distance between the electrodes.

14. BREAKDOWN ALONG LAMINÆ.

Materials which are composed of a number of superimposed layers generally have a different electric strength in the direction parallel to the laminæ from that in the direction at right angles to the laminæ. All such material should, therefore, be subjected to a longitudinal breakdown test carried out as follows :—

(*a*) *Tubes.*

Cut a complete ring of axial length " *l* " and clamp " hand-tight " between flat electrodes as shown in Fig. 12. The width of material under the electrodes shall be such that the sectional area of the specimen under stress is approximately 1 square inch. In the case of large tubes three tests shall be made on each ring, the position of the areas tested being 120° apart. Various lengths of specimens shall be tested and a curve plotted showing the relationship between the average electric strength in volts per mil along the laminæ and the length of specimen. The range of lengths selected shall be such that the final result, in volts per mil, is approximately independent of the length.

All tests shall be made in oil at 90° C., and the following method employed :—

Make a trial breakdown by increasing the voltage from zero to breakdown, as rapidly as the reading on the meter will permit (approximately 5 kV per second has been used). This breakdown is not to be included in the average.

Apply to another specimen of the same length 40 per cent of the breakdown voltage found by the above method, and increase the voltage by 10 per cent

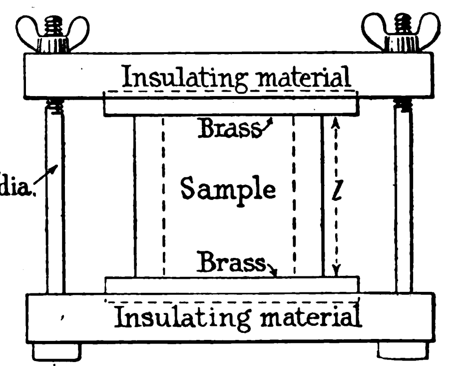

FIG. 12.—Arrangement of specimen for longitudinal breakdown test.

steps (i.e. to 50 per cent, 60 per cent, 70 per cent, etc., of the rapidly applied breakdown) at one-minute intervals till breakdown occurs. At least five determinations on each length shall be used to calculate the average, and the maximum, minimum and individual values shall also be recorded.

(*b*) *Sheet Material.*

Cut strips of various widths and of any convenient length. Test singly in a manner similar to Tubes (*a*) above.

15. ELECTRIC STRENGTH OF MATERIALS WHEN SUBJECTED TO LONG APPLICATION OF A.C. STRESS AT POWER FREQUENCIES AND UNDER SERVICE CONDITIONS.

Insulating material when in an electrical machine has not the same freedom to dissipate heat and moisture, and consequently will not withstand as high a stress as when subjected to an electric strength test as heretofore commonly applied. Such tests give a measure of the relative value of the different materials, but under the working conditions above described the material will not show the high strength so observed. It is, therefore, desirable to determine the maximum stress which the material will withstand when subjected

* In the case of tests on vulcanized fibre a pressure of 75 lb. weight on the 1¼ inch diameter electrode, Fig. 4, was employed. In general a weight of 50 lb. should be sufficient.

to long application of A.C. stress under such conditions as are comparable with these likely to be experienced in service.

The method for carrying out a sustained voltage test recommended by the Association in its previous Technical Publication Ref. A/S2 * is at present receiving further consideration with a view to rendering the test more suitable for standardization. The experimental investigations involved are not sufficiently advanced to enable recommendations to be included in the present tentative issue of the directions.

16. Tests at Radio Frequency.

Due to the high dielectric loss at high frequencies the breakdown voltage of insulating materials at radio frequencies is lower than at power frequencies. When a dielectric is overstressed at high frequencies the heating resulting from the dielectric loss is often of such magnitude as to render the material incapable of functioning as an insulator. Loss of insulating properties at radio frequencies may therefore occur without any evidence of a definite puncture, such as usually occurs when breakdown voltage tests are made at power frequencies. Due to the absence of any sharp point of failure, breakdown voltage tests at high frequencies are of but limited value.

Tests carried out by the American Bureau of Standards † have shown that due to the indefinite nature of radio frequency high voltage breakdowns the most satisfactory way at present known of comparing numerically the insulating properties of materials at radio frequencies is by a determination of their power factor and permittivity at radio frequencies. Based on the work of the Bureau of Standards, the American Society for Testing Materials has issued provisional specifications ‡ for high frequency tests. The E.R.A. in one of its researches is experimenting with the methods suggested by the A.S.T.M., and, whilst this research is not complete, certain changes in the methods have been found desirable and tentative recommendations are given in Appendix VII of the present publication.

Part II. ABRIDGED TESTS ON ELECTRIC STRENGTH.

The following methods for the determination of the electric strength of insulating materials are recommended when it is not required to ascertain the characteristics of the material in such detail as provided for in Part I.

17. Conditioning.

(*a*) Prior to test the materials shall be exposed to the "Normal" atmosphere as specified in Appendix I.

* *Journal I.E.E.*, 1922, vol. 60, p. 794.
† See Bureau of Standards Scientific Paper No. 471.
‡ See A.S.T.M. Publications D 150-23 T and D 175-23 T.

(*b*) If it is claimed that the material has special non-absorptive properties, it shall also be tested after exposure to either "Damp," "Tropical" or "Immersed" conditions, as specified in Appendix I.

(*c*) If it is claimed that the material has special heat-resisting properties, it shall also be tested after exposure to very dry conditions, as specified in Appendix I.

18. Method of Expressing Electric Strength.

The recognized method of expressing the electric strength of materials subjected to these abridged tests shall be the voltage required to produce breakdown in one minute when the material is tested at its appropriate temperature, as given in Appendix III. For ease of comparison the volts per mil, followed by a statement of the thickness to which it refers, shall also be given.

19. Methods for Obtaining the One-Minute Value.

To reduce to a minimum the work required to ascertain, with reasonable accuracy, the one-minute breakdown value, the following method of procedure is recommended:

(*a*) *Breakdown through the Thickness of the Material.*

Make a trial breakdown by increasing the voltage from zero to breakdown, as rapidly as is consistent with obtaining satisfactory readings of the measuring instrument (approximately 5 kV per second has been used).

Subject the material to two-thirds the breakdown voltage obtained by the above method and note the time required to produce breakdown.

From the results of this test an approximate idea can be obtained of the voltage which will produce breakdown in about one minute; this estimated voltage should then be applied and the time required to produce breakdown noted. From this latter result a still closer approximation can be made. In addition to the trial test, at least five breakdowns should be obtained on each sample, and the values plotted on a time-voltage curve, similar to Fig. 1, but for the time range round one minute only. From this curve the voltage required to produce breakdown in one minute can be determined.

(*b*) *Breakdown along Laminæ.*

Employ the one-minute 10 per cent step-by-step method as specified in Clause 14 of Part I of this document. Only one length of specimen shall be tested, the length to be employed for this test depends on the class of material and will be specified in the directions issued for the study of the particular class of material under test.

20. Other Factors.

In conducting the abridged tests for electric strength the conditions specified for the other factors entering into electric strength tests, such as electrodes, etc., are to be the same as for the research tests dealt with in Part I.

APPENDIX I.

DETAILS OF TEMPERATURE, TIME AND HUMIDITY TO BE USED FOR CONDITIONING THE CLASSES OF DIELECTRICS REFERRED TO, PREVIOUS TO THE DETERMINATION OF THEIR ELECTRIC STRENGTH.

Condition	Class of dielectric	Temp. ° C.	Time, hours	Humidity (relative) * per cent	Sp. Gr. of $CaCl_2$ † required to give the stated humidity at the stated temp.
Normal	B.E.S.A. Class O and A..	15–25	18–24	75 ‡	1·22 at 15° C.
	B.E.S.A. Class B ..	15–25	18–24	75 ‡	1·22 at 15° C.
	B.E.S.A. Class C	15–25	18–24	75 ‡	1·22 at 15° C.
	Unclassified	15–25	18–24	75 ‡	1·22 at 15° C.
Very dry	—	120–130	18–24	§	—
Dry	Treated papers and fabrics	75–80	2–3	§	—

	B.E.S.A. Class B.. ..	15–25	18–24	Approximately 95	Water only
	Unclassified	15–25	18–24	Approximately 95	Water only
Tropical	B.E.S.A. Class O and A .. B.E.S.A. Class B .. Unclassified	45–50 during the day (8 hours) and 15–25 during the night (16 hours)		Approximately 90 during the day. Saturated ‖ during night	Water only
Recovered	B.E.S.A. Class O and A..	75–80	8–15	§	—
		Followed by exposure to " normal " condition for one week			
¶Chemically Treated	B.E.S.A. Class C	15–25	168 (1 week)	—	—
	Unclassified	15–25	168 (1 week)	—	—

* For notes on the construction of conditioning chambers and the measurement of humidities therein, see Appendix VI.
† The use of H_2SO_4 is not recommended, as its vapour is liable to be absorbed by the specimen.
‡ This figure is adopted provisionally, awaiting recommendations from another Committee.
§ Air at ordinary room temperature and humidity is to be heated to the temperature specified, without any artificial drying or humidifying.
‖ The cubic capacity of the conditioning chamber compared with its internal area and the total area of the specimens must be such that a liberal condensation of moisture occurs on the latter during the lower temperature period.
¶ The treatment to be given will depend on the purpose for which the material is required, the following being employed :—

(i) If exposed to rain or water .. .. Distilled water.
(ii) If exposed to sea water .. .. 10 % solution of salt in distilled water.
(iii) If exposed to acid .. .. .. Sulphuric acid sp. gr. 1·25 at 15° C.
(iv) If exposed to alkalies .. .. 10 % solution of caustic soda.
(v) If exposed to ozone .. .. ..
(vi) If exposed to ultra-violet light .. Treatment to be given is under consideration.
(vii) If exposed outdoors .. .. ..

APPENDIX II.

Table I.

Periods to be allowed for bringing conditioned specimens to the temperature at which it is required to determine the electric strength when the material is to be tested in air.

Class of dielectric	Thickness	Periods for the temperature differences* indicated, during which the specimen is to be placed between 3 in. × 1 in. brass discs, previous to the electric strength test in accordance with Clause 13				
		40° C.	70° C.	100° C.	130° C.	160° C.
B.E.S.A. Class O, A and B	Not more than 1/8 in.	1 min.	1 min.	2 min.	2 min.	3 min.
B.E.S.A. Class O, A and B	>1/8 in. but not more than 1/4 in.	2 min.	3 min.	4 min.	4 min.	5 min.
B.E.S.A. Class O, A and B	>1/4 in. but not more than 1/2 in.	4 min.	6 min.	8 min.	8 min.	10 min.
B.E.S.A. Class C and unclassified	All thicknesses up to 1/2 in.	5 min.	5 min.	10 min.	10 min.	10 min.

* This refers to the difference in temperature between the conditioning and testing chambers.

Table II.

Period to be allowed for bringing conditioned specimens to the temperature at which it is required to determine the electric strength when the material is to be tested in oil.

Class of dielectric	Thickness	Periods for the temperature differences* indicated, during which the specimen is to be placed between the electrodes specified in Clause 13 previous to the electric strength test in accordance with Clause 13				
		40° C.	70° C.	100° C.	130° C.	160° C.
B.E.S.A. Class O, A and B	Not more than 1/8 in.	1 min.	2 min.	2 min.	3 min.	4 min.

* This value is being determined by means of experimental investigation; recommendations are not yet available.
† If the material is tested after exposure to "normal," "damp" or "tropical" conditions, the abridged electric strength tests are to be made only at 90° C. and where applicable all such 90° C. tests are to be made in oil.
‡ The maximum test temperature and maximum service temperature of moulded compositions will be governed by the grade temperature of the material determined from either mechanical or electrical considerations. Certain of these materials will be found to fall within the O, A, B, C classification, if their grade temperature is determined by an appropriate test.
§ The question of the temperatures and electrodes to be employed for the determination of the electric strength of porcelain is under investigation.

APPENDIX IV.

Method of Calculating the Electric Strength from the Maximum Voltage Gradient on the Dielectric.

(*a*) *When Concentric Cylindrical Electrodes are Employed.*

If a homogeneous dielectric is tested in the form of a tube between concentric cylindrical electrodes, the distribution of the electric stress throughout the thickness of the dielectric will be a logarithmic function of the thickness and will be greatest on the layer adjacent to the inner electrode.

Table A.

Variation of Maximum Stress to Mean Stress for Various Values of "a."

$a = \frac{\text{Outside diameter}}{\text{Inside diameter}}$	Maximum stress
3	1·82 × Mean stress
2	1·44 × Mean stress
1·5	1·23 × Mean stress
1·4	1·20 × Mean stress
1·3	1·15 × Mean stress
1·2	1·10 × Mean stress
1·1	1·045 × Mean stress
1·05	1·020 × Mean stress

Let V = the breakdown voltage
R = the radius of the outside of the tube
r = the radius of the inside of the tube

and $a = \frac{R}{r}$ or $\frac{\text{outside diameter of tube}}{\text{inside diameter of tube}}$

Then the maximum stress on the dielectric

$$= \frac{V}{r \log_e a}$$

and the mean stress $= \frac{V}{r(a-1)}$.

The relationship between the maximum stress and the mean stress for various values of "*a*" is given in Table A.

The above values for the maximum stress are only true when there is a logarithmic distribution of electric stress throughout the thickness of the tube. For various reasons it is frequently impracticable to predetermine the true electric strength by calculations on the basis of the maximum stress which would be given by the above formula.

(*b*) *When the Electrodes Consist of a 1-inch Diameter Embedded Sphere and a Flat Plate.*

In the case of a homogeneous dielectric, the relationship between the maximum stress and the mean stress is given in Table B for various thicknesses of dielectric.

Table B.

Variation of Maximum Stress to Mean Stress for Various Thicknesses of Dielectric.

Minimum thickness of specimen (Mils)	Maximum stress
20	1·03 × Mean stress
40	1·06 × Mean stress
80	1·11 × Mean stress
120	1·17 × Mean stress
160	1·22 × Mean stress
200	1·28 × Mean stress

As mentioned in the last paragraph of Section (*a*) above, the values given for the maximum stress do not always apply.

APPENDIX V.

Measurement of Voltage with Spark-Gaps.

(*a*) *General.*

If proper precautions are taken a spark-gap may be used for the determination of the peak value of the voltage wave and also for checking and calibrating voltmeters for H.V. tests.

Most of the recommendations contained in this Appendix are based on methods recommended in the Standards of the American Institute of Electrical Engineers.

(*b*) *Range of Voltage.*

For the above purposes a suitable sphere-gap shall be used for voltages above 50 kV and is preferable down to 30 kV. A needle spark-gap may be used for voltages from 10 kV to 50 kV.

(*c*) *Needle Spark-Gap.*

The needle spark-gap shall be between new sewing needles, supported axially at the ends of linear conductors, which are at least twice the length of the gap. There must be a clear space around the gap for a radius at least twice the gap length.

In the Standards of the American Institute of Electrical Engineers it is stated that the values given in Table A refer to No. 00 double long needles. As needles

are not standardized any specified size is liable to slight variation in gauge, taper, and diameter of point. The nearest English needle to the one specified by the A.I.E.E. is No. 17 double long, and this size may be satisfactorily used for the needle spark gap values given in Table A and Fig. 13.

TABLE A.

Needle-Gap Spark-over Voltages (at 25° C. and 760 mm barometer and 80 per cent relative humidity).

R.M.S. Kilovolts	Sparking distance, mm	R.M.S. Kilovolts	Sparking distance, mm
10	11·9	35	51
15	18·4	40	62
20	25·4	45	75
25	33	50	90
30	41	—	—

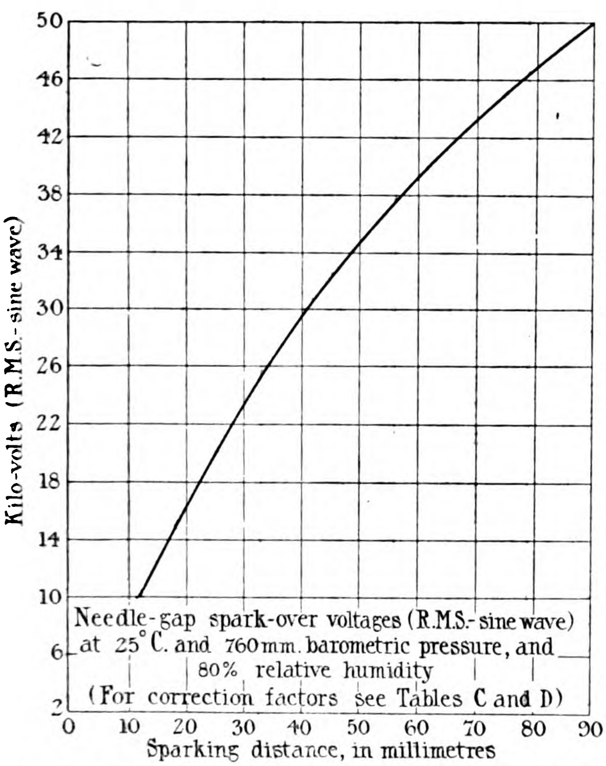

FIG. 13.—Spark-over voltages (R.M.S. sine wave) for needle-gap at 25° C., 760 mm barometric pressure, and 80 per cent relative humidity.

For accurate work it is recommended that a fresh needle be employed for each test, although there is evidence that slight burning of the points is negligible provided the distance be adjusted to compensate. This feature is the subject of further research.

The sparking distances in air between No. 17 double long sewing-needle points for various root-mean-square sinusoidal voltages shall be assumed to be as shown in Table A and Fig. 13.

(*d*) *Sphere Spark-Gap.*

The standard sphere spark-gap shall be between two suitably mounted spheres. No extraneous body, or external part of the circuit, shall be nearer the spheres than twice their diameter.

The shanks shall be not greater in diameter than 1/5th the sphere diameter. Metal collars, etc., through which the shanks extend, shall be as small as practicable and shall not, during any measurement, come closer to the sphere than the maximum gap length used in the measurement.

The apparatus shall be set up for use in a space comparatively free from external dielectric fields. Care should be taken that conducting bodies forming part of the circuit, or at circuit potential, are not so located with reference to the gap that their dielectric fields are superposed on the gap, e.g. the protecting resistance should not be arranged so as to present large masses or surfaces near the gap, even at a distance of two sphere diameters.

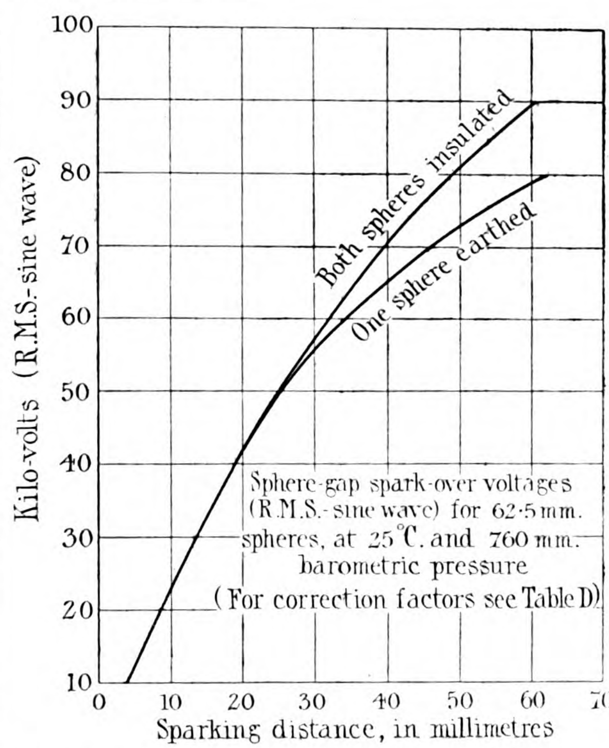

FIG. 14.—Spark-over voltages (R.M.S. sine wave) for 62·5-mm diameter spheres at 25° C. and 760 mm barometric pressure.

In case the sphere is earthed, the spark point of the earthed sphere should be approximately five diameters above the floor or ground.

The spheres shall be as truly spherical as possible.

The sparking distance between spheres for various R.M.S. sinusoidal voltages shall be assumed to be as shown in Table B and in Figs. 14 to 17 inclusive.

TABLE B.

Sphere-Gap Spark-over Voltages (at 25° C. and 760 mm barometric pressure).

Kilovolts	Sparking distance in millimetres							
	62·5-mm spheres		125-mm spheres		250-mm spheres		500-mm spheres

140	—	—	108·0	88·0	78	77	74	73
160	—	—	150·0	110·0	92	90	85	83
180	—	—	—	138·0	109	106	97	95
200	—	—	—	—	128	123	108	106
220	—	—	—	—	150	141	120	117
240	—	—	—	—	177	160	133	130
260	—	—	—	—	210	180	148	144
280	—	—	—	—	250	203	163	158
300	—	—	—	—	250	231	177	171
320	—	—	—	—	—	265	194	187
340	—	—	—	—	—	—	214	204
360	—	—	—	—	—	—	234	221
380	—	—	—	—	—	—	255	239
400	—	—	—	—	—	—	276	257

NOTE.—The sphere-gap is more sensitive than the needle-gap to momentary rises of voltage, and the voltage required to spark over the gap should be obtained by slowly closing the gap under constant voltage, or by slowly raising the voltage with a fixed setting of the gap. Open arcs should not be permitted in proximity to the gap. during its operation, as they may affect its calibration.

(e) *Factors Influencing Spark-over Voltage.*

The spark-over voltage of an air-gap is influenced by the following :—

(i) *Humidity.*

The voltage required to spark across a needle-gap is influenced by the relative humidity of the air.

The values in Table A refer to a relative humidity of 80 per cent. Provided a needle-gap is not used above 30 kV, variations in relative humidity will not affect the spark-over voltage. At higher voltages the spark-over voltage for a given gap setting decreases with decrease in relative humidity.

The magnitude of the effect of change in humidity is shown in Table C and Fig. 18. This curve gives the approximate correction factor and holds for the range from about 85 per cent to 55 per cent relative humidity.

TABLE C.

Variation of Spark-over Voltage of Needle-Gap with Relative Humidity.

Spark-over voltage for 82·5 per cent relative humidity as given by Peek *	Approximate reduction in spark-over voltage at 57 per cent relative humidity. Calculated from Peek's 82·5 per cent and 57 per cent relative humidity curves *		Approximate percentage increase or decrease in spark-over voltage for each 1 per cent increase or decrease in relative humidity calculated from the spark-over voltage at 80 per cent relative humidity
	kV	Per cent	
35	0	0	0
50	1·8	3·6	0·14
60	3	5·0	0·20
70	4	5·7	0·22
80	5	6·2	0·24
100	6·7	6·7	0·26
120	8·5	7·1	0·28
140	10·5	7·5	0·30
160	13	8·1	0·31
170	14	8·2	0·32
180	16	8·9	0·35
200	20	10·0	0·40

From Fig. 18 it will be seen that the effect of each 1 per cent change in relative humidity increases with the spark-over voltage, and for this reason needle-gaps are not as accurate as sphere-gaps for voltages above about 30 kV.

Provided a sphere gap is set so that corona does not form before spark-over occurs, the spark-over voltage of a sphere-gap is independent of humidity.

(ii) *Air Density.*

The distance through which a given voltage will cause a spark to pass through air depends on the density of the air.

The spark-over voltage for a given gap thus decreases with decreasing barometric pressure and increasing temperature. This variation may be considerable at high altitudes. When the variation from sea-level is not great, the relative air density may be used as the correction factor; when the variation is great, or greater accuracy is desired, the correction factor corresponding to the relative air density should be taken from Table D in which

$$\text{Relative air density} = \frac{0 \cdot 392\, b}{273 + t}$$

b = barometric pressure in mm.
t = temperature in deg. C.

Corrected curves may be plotted for any given altitude, if desired. It will be noted in Table D that for values of relative air density above 0·9 the correction factor does not differ greatly from the relative air density.

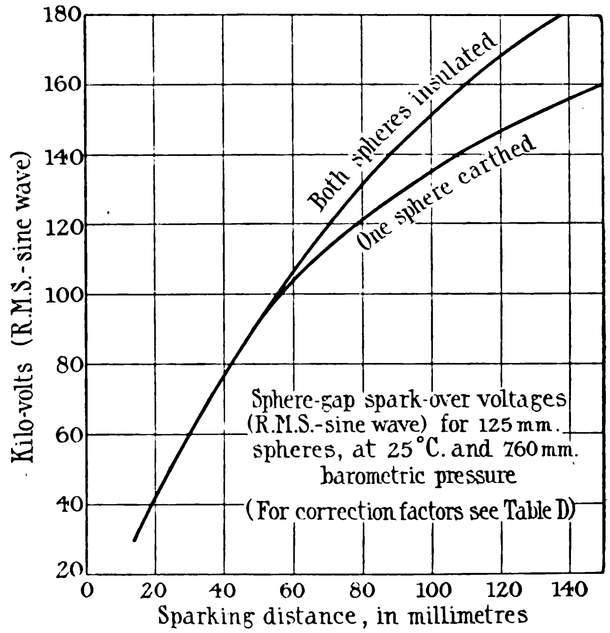

FIG. 15.—Spark-over voltages (R.M.S. sine wave) for 125-mm diameter spheres at 25° C. and 760 mm barometric pressure.

The spacing at which it is necessary to set a gap to spark over at some required voltage, is found as follows: Divide the required voltage by the correction factor given in Table D and use the new voltage thus obtained to find the corresponding spacing from Table B, using a graph of the latter if more convenient.

(iii) *Other Factors.*

As an indication of the effect of other factors the following results (see Table E) reported by F. W. Peek * are given for the guidance of those using spark-gaps for the measurement of high voltages.

Marvin † has shown that cotton lint from a dry cloth

1·10	1·090	1·092	1·094	1·096

may reduce the spark-over voltage of a 25 cm diameter sphere-gap set with gap of 123 mm to 78 per cent of normal value.

It is recommended that previous to use the spheres should be polished and wiped with a wash-leather which is slightly oily.

(*f*) *Use of Resistance in Series with Spark-Gap.*

To prevent high-frequency oscillations and to limit the current when spark-over occurs, a non-inductive resistance of about one ohm per volt of test pressure shall be inserted in series with the spark-gap. If the test is made with one electrode earthed the resistance shall be inserted directly in series with the non-earthed electrode, if neither terminal is earthed one-half shall be inserted directly in series with each electrode. In either case the resistance shall be as near the measuring gap as possible, but must be arranged so as to fulfil the condition set forth in (*d*) above.

TABLE E.

Spark-over Voltage of 12·5-cm Spheres under the Conditions Stated.

Condition of sphere	Per cent of normal spark-over voltage	
	5 cm gap	10 cm gap
Polished	100	100
Thin coating of dry dust ..	98	98
Excessive pitting (craters 0·4 mm deep and beads 0·25 mm in height)	90	75
Rain 0·2 in. ppt. per min. (polished spheres)	42	39

APPENDIX VI.

NOTES ON CONDITIONING CHAMBERS AND THEIR EQUIPMENT.

(*a*) *Construction.*

(i) *Cold Chambers.*

For conditioning or test chambers which are not required to be heated, a satisfactory and convenient method of construction is to make the chamber of 3/4-in. tongued and grooved boards and to line the inside with thin sheet metal. The latter should be soldered down all joints such as those occurring where the sides meet the top and bottom. The use of a sheet metal lining is essential when it is required to employ the chamber for very high or very low humidities.

(ii) *Hot Chambers.*

When a chamber is required for temperatures above those of the laboratory, an electrically heated oven having double walls of sheet metal with the interspace suitably packed is recommended.

(*b*) *Method for Obtaining the Specified Humidities in Cold Chambers.*

(i) *Relative Humidity of Approximately* 100 *per cent.*

Even when a large area of water is freely exposed in a chamber with walls of a non-absorptive material, it is impracticable to obtain a relative humidity exceeding 95 per cent. It has been found, however, that if a constant current of air be made to pass over the surface of the exposed water and the air in the chamber be kept continually stirred there is no difficulty in obtaining a relative humidity of 96 to 98 %. A simple method which has been used for obtaining this high humidity is shown in Fig. 19. Unless the conditioning chamber is really

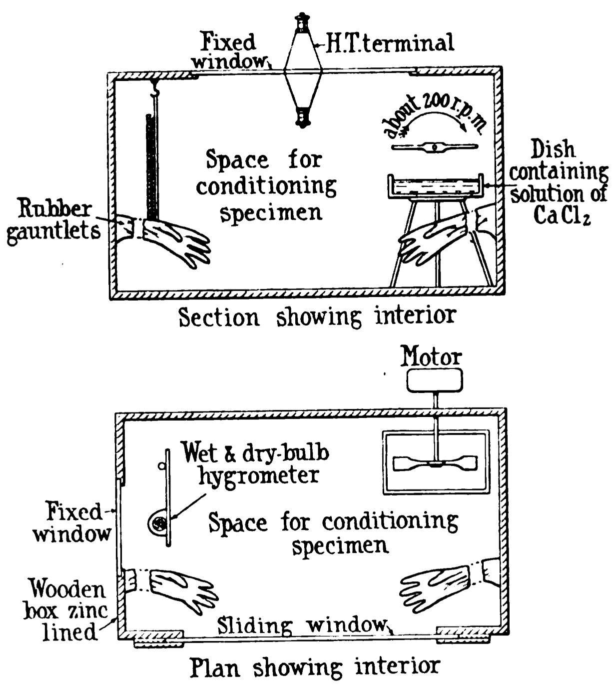

FIG. 19.—Cold conditioning chamber and equipment.

air-tight the fan must be designed as a stirrer only; any difference in pressure between the air in the chamber and the air in the laboratory results in leakage which renders the attainment of a high humidity very difficult.

(ii) *Normal Condition.*

For normal condition a humidity of 75 % obtained by the use of $CaCl_2$ of specific gravity 1·22 at 15° C. is specified. In order that the required humidity may be obtained in all parts of the chamber, especially when the chamber is loaded with specimens, it is essential that the air should be kept continuously circulating over the solution and between and around the specimens. The method shown in Fig. 19 has been found satisfactory.

(*c*) *Measurement of Humidity in Cold Chambers.*

The wet and dry bulb hygrometer is an unreliable instrument if used in still air, but by ensuring that the velocity of the air past the bulb is of the order of 3 metres per second it can be converted into an instrument of satisfactory precision. In the chamber shown in Fig. 19 a window is provided in one side through which the thermometers can be read. This arrangement has been found very convenient.

If for any reason an air velocity past the bulbs of at least 3 metres per second cannot be ensured a dew point hygrometer should be used. The surface on which the deposit occurs should be of well-burnished silver, and the usual aspiration method through ether, alcohol, or water can be used for producing the necessary lowering of temperature.

When temperature differences are small it is important that the fluid be in actual contact with the silver surface if accurate results are required. The temperature gradient through the glass, if a silver thimble is fitted on to a test tube in the usual manner, may be of importance, and the temperature of the fluid will be appreciably lower than that of the silver surface, giving too low a value of the estimated humidity.

(*d*) *Method for Obtaining the Specified Temperatures in Hot Chambers.*

Electrically heated ovens should always be employed. With a view to obtaining as uniform a temperature as possible, the heating elements should be distributed over the whole of the bottom of the oven and the temperature regulated by means of an external resistance. To obtain a wider variation of temperature series parallel connections can be employed, provided all the units are left in circuit. If the specimens and internal fittings are suitably arranged, the convection currents, set up by the heating elements, will be sufficient to keep the temperature and humidity in different parts of the chamber as uniform as is necessary.

(*e*) *Test Chambers.*

With many dielectrics considerable change of moisture content may take place in a very short space of time as the result of change of humidity or of temperature of the surrounding air. The effects produced by the conditioning may therefore be altered if change of moisture content is permitted during the time elapsing from the end of the conditioning period to the determination of the electric strength. When the latter is determined under oil there is less risk of change of moisture content than in the case of tests made in air. When tests are made in air and when it is likely that change of moisture content may occur, the electrical tests should always be made either in the conditioning chamber or, as is usually found more convenient, in an enclosed chamber specially designed for conducting the electrical tests. The use of rubber gauntlets fastened in the sides of the chamber, as indicated in Fig. 19, permits the investigator to change the connections and manipulate the samples without opening the chamber. The glass window at the top ensures good illumination of the interior, by either daylight or artificial light.

APPENDIX VII.

The Determination of the Electrical Characteristics of Insulating Materials at High Frequencies.

H.F. Test No. 1. *The Determination of the Power Factor and Permittivity of Electrical Insulating Materials at Radio Frequencies.*

(*a*) *General.*

The method of test described is put forward in tentative form in response to requests received for information on H.F. tests. The method described is based on the tentative method suggested by the American Society for Testing Materials in its Serial Designation D 150-23 T.

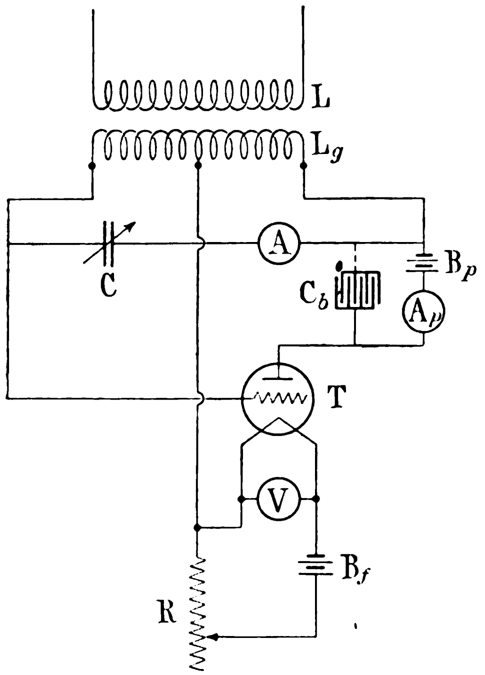

Fig. 20.—Generating circuit specified by the A.S.T.M.

This method of test as developed by the E.R.A. is intended to apply to all solid electrical insulating materials.

The behaviour of material under test at radio frequencies is fundamentally different from that at low frequencies.

In this test the power factor of the dielectric is determined at a measured frequency by determining the effective resistance (or equivalent series resistance) and capacity of a condenser made up with the material as the dielectric. The permittivity is calculated from the measured capacity of such a condenser, and the thickness and area of the dielectric.

The dielectric power loss is proportional to the product of the permittivity and the power factor.

(*b*) *Generating Circuit.*

The circuit in which the radio frequency waves are generated is called the generating circuit. The source of radio frequency voltage shall be an electron tube oscillator the frequency of which can be varied over the range desired and which can be coupled loosely to the measuring circuit. It shall furnish sufficient power so that the presence of the measuring circuit will not reduce its output. The output of the oscillator must be very constant, as any variation in voltage will cause a much larger variation in the final results, because of the differential method used. For this reason it is desirable to have the plate current supplied by a storage battery or other source of very constant power.

The generating circuit must be capable of supplying power at any wave length between 240 metres (1 250 kilocycles per second) and 3 500 metres (86 kilocycles per second).

An arrangement of the generating circuit suggested

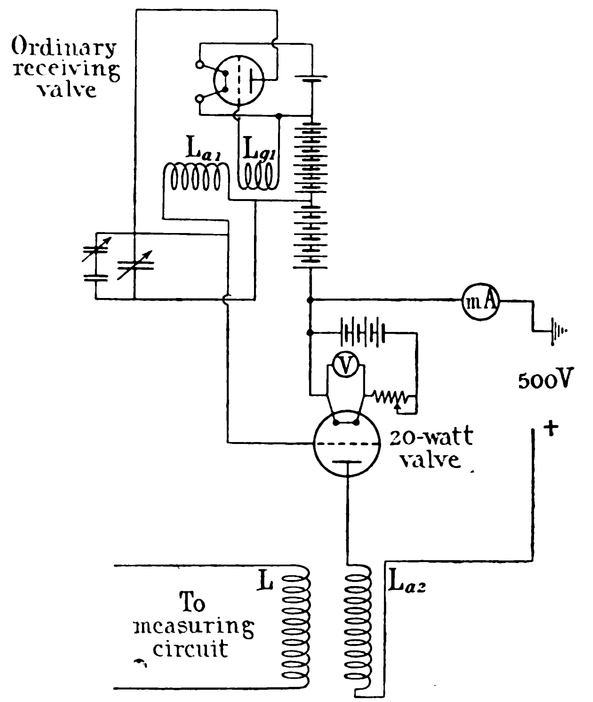

Fig. 21.—Generating circuit used by the E.R.A.

by the A.S.T.M. is shown in Fig. 20, to which the following particulars apply:—

The inductance coil L_g is any one of a series of detachable tubular single layer coils. For the tests outlined it is probable that not more than five will be required. The smaller coil may be made by winding 13 turns of wire on a $3\frac{1}{2}$-inch tube with 6 turns on either side of the middle clip. The larger coil may be made by winding 112 turns of wire on a $6\frac{3}{4}$-inch tube, 32 turns on either side of the middle clip and 24 turns outside of both outside clips. The other three coils may be made to cover the gap between these two extremes.

The variable air condenser C may be of any suitable commercial shielded type having a maximum capacity of about 0·003 microfarads (3 000 micro-microfarads). The ammeter A is of the hot-wire type having a range of 0 to 1 ampere. The by-pass condenser C_b may be

any type of fixed condenser capable of withstanding 500 volts (direct current).

The plate battery B_p may be a 100 to 300 volt accumulator having an ampere capacity of about 0·2 ampere at an 8 hour discharge rate. The ammeter A_p may be any type of direct-current instrument having a range of 0 to 50 milliamperes. The three-electrode electron

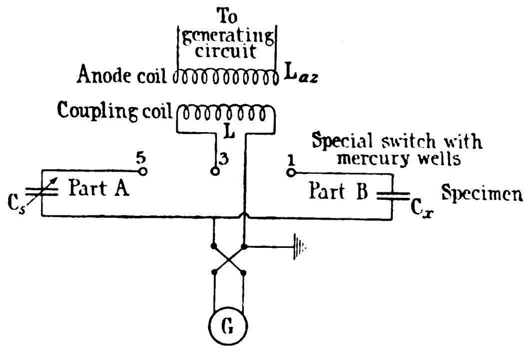

FIG. 22.—Measuring circuit used by the E.R.A.

tube T may be any of the so-called power tubes rated at 5 watts or over.

An alternative arrangement of the generating circuit is shown in Fig. 21. During tests made by the E.R.A. it was found that by using two valves as indicated in Fig. 21 the frequency was much less dependent upon the load taken than it was when a single valve was used.

To cover the required frequency range when employing the circuit shown in Fig. 21 three sets of coils made as indicated below have been found suitable.

For each of the sets coils L_{a1} and L_{g1} were wound

(c) *Measuring Circuit.*

The circuit in which the specimen is placed for test is called the measuring circuit (Fig. 22).

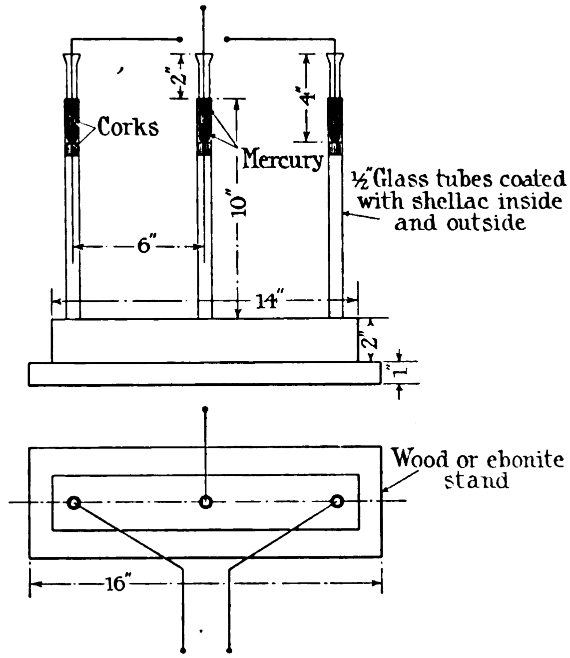

FIG. 23.—Special switch used by the E.R.A.

This circuit is composed of :—

A condenser employing the test specimen as the dielectric and two metallic surfaces as the conducting plates.

	Set No. 1 for wave lengths from 230 to 670 metres		Set No. 2 for wave lengths from 580 to 1 790 metres		Set No. 3 for wave lengths from 1 380 to 4 480 metres	
	Coil marked L_{a1} in Fig. 21	Coil marked L_{g1} in Fig. 21	Coil marked L_{a1} in Fig. 21	Coil marked L_{g1} in Fig. 21	Coil marked L_{a1} in Fig. 21	Coil marked L_{g1} in Fig. 21
Mean diameter (cm)	10·7	10·7	10·7	10·7	10·7	10·7
Length (cm)	2·54	1·15	4·65	1·85	8·6	3·7
Number of turns	26	32	82	52	242	104
Diameter of wire (inches)	0·020	0·0124	0·020	0·0124	0·0124	0·0124
Turns per cm	10·3	28	18	28·2	28·2	28·2
Approximate inductance (microhenrys) ..	100	200	800	460	5 000	1 420

on the same tube, each coil being wound in a single layer, leaving about ⅛ inch between the two coils.

The above mentioned coils are employed in the circuit of the first valve shown in Fig. 21. For the anode coil L_{a2} of the second valve a coil made as follows has been found suitable for the complete range of wave lengths covered by the above :—

Mean diameter = 15·7 cm
Length = 4 cm
Number of turns = 73
Diameter of wire = 0·020 inch
Turns per cm = 18·2
Approximate inductance = 1 100 microhenrys

A standard condenser of a suitable design having negligible power factor.

One or more suitable inductance coils with tappings.

A thermo-element of the vacuum type having a resistance of about 8 ohms when the material under test has only moderately good properties and a lower resistance (say less than 5 ohms) when the material under test has good properties at high frequencies.

A special double-throw switch equipped with mercury wells (Fig. 23).

A set of resistance links having direct-current

resistance values ranging from negligible to about 100 ohms (Fig. 24).

A sensitive low-resistance wall galvanometer of the deflecting mirror type or other suitable type of indicating instrument.

The arrangement of the measuring circuit used by the E.R.A. is shown in Fig. 22. This circuit has been found more convenient than the one suggested by the A.S.T.M.

The standard variable air condenser C_s should have a maximum capacity of about 0·001 microfarad (1 000 micro-microfarads). The special switch with mercury wells is shown in Fig. 23, and one of the non-inductive resistance in Fig. 24. The non-inductive resistance is made as shown in Fig. 24. Several of these resistances are required, but in all cases the distance between the spurs should be the same, because the resistances must fit into the mercury wells in the switch (Fig. 23). Each of these units has a different value of resistance made so by varying either the length or the diameter of the resistance wire or both.

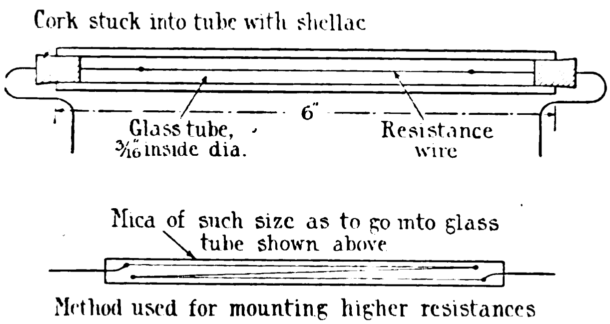

Fig. 24.—Special non-inductive resistance.

The condenser C_x is made either by floating the test specimen on mercury and pouring mercury on the upper surface until it is filled to a confining barrier or by the use of one of the other methods detailed in Clause (*f*). The mercury bath on which the specimen rests is contained in a glass dish which rests on a piece of insulating material which in turn is supported by a levelling device.

The coil L, Fig. 22, must be designed to have a comparatively low resistance so that the coil resistance will not be a large proportion of the combined equivalent resistance of the circuit made up of coil L and the specimen condenser C_x. To cover the frequencies (wave lengths) named, the following coils have been found suitable :—

For wave lengths from about 1 000 *to* 4 000 *metres.*

One single-layer coil wound as indicated below and having seven equidistant tappings has been found convenient.

Mean diameter = 15·7 cm
Length = 20·8 cm
Number of turns = 376
Diameter of wire = 0·020 inch
Turns per cm = 18·2

Approximate inductance of complete coil = 11 500 microhenrys.

For wave-lengths below 1 000 *metres.*

Two single-layer coils wound as indicated below and on the same tube arranged with a space of about 2 cms between them have been found suitable.

Mean diameter = 10·7 cm
Diameter of wire = 0·020 inch

Coil 1 consisted of 45 turns and had an inductance of approximately 300 microhenrys.

Coil 2 consisted of 15 turns and had an inductance of approximately 50 microhenrys.

For further regulation of the inductance a coil 4 cm in diameter and wound with 45 turns in 3 layers of 0·018 inch diameter wire giving an inductance of approximately 100 microhenrys was suspended inside the above coils. The small coil can be conveniently used with the other coils either as a variometer or as a loading coil.

The thermo-element T is of the crossed-wire vacuum type. The resistance of the thermo-element should be from 3 to 8 ohms.

The galvanometer G is a sensitive wall galvanometer of the deflecting mirror type. One having a resistance of about 30 ohms and a deflection at a distance of 1 metre of about 80 mm per microampere has been found suitable.

It has been found very important to arrange the circuits quite symmetrically with respect to the coupling coil and the anode coil. Unequal coupling between the coils and points A and B of the measuring circuit, Fig. 22, causes appreciable errors.

(*d*) *Conditioning of Specimens previous to Test.*

The power factor and permittivity of each sample shall be tested after being conditioned as follows :—

(i) Normal conditions as defined in Appendix I.
(ii) After immersion in distilled water for 48 hours at about 20° C., followed by exposure to normal conditions for 24 hours.
(iii) After being freely exposed for 24 hours to a dry atmosphere at 90° C.*

(*e*) *Condition of Specimen during Test.*

Tests shall be made as indicated below :—

(i) With specimens previously exposed to " normal " condition and whilst exposed to an atmosphere of normal condition.
(ii) With specimens previously immersed in water as (ii) in Clause (*d*) above and whilst exposed to an atmosphere of normal condition.
(iii) With specimens previously exposed to 90° C. and whilst at 90° C.*

(*f*) *Preparation of Test Condenser.*

The following methods are suggested for preparing the condenser required for measuring the power factor and the permittivity of the material :—

(i) *For Rigid Materials in the Form of a Sheet.*

Either circular or rectangular test specimens may be used, and the specimen shall be of such dimensions

* If the grade temperature of the material is less than 90° C., the conditioning and the tests shall be made at the grade temperature.

that the capacity of the condenser shall not be less than 200 micro-microfarads (200 $\mu\mu$F). For a thickness of specimen of $\frac{1}{8}$ to $\frac{1}{4}$ inch a specimen about 12 $\times$ 10 inches is usually satisfactory.

The test condenser is made by floating the specimen on mercury and by placing mercury in an enclosure on the top of the specimen. When tests are to be made at low temperatures the enclosure for the mercury may be made by casting a rim of wax on the top surface of the specimen and situated about 1 cm from its edges. For tests at high temperatures the mercury may be enclosed by means of an amalgamated metal rim placed on the top surface of the specimen and of such dimensions as to leave a clear space of 2 cm from the outer edge of the rim to the edge of the specimen.

(ii) *For Materials in the Form of Tubes.*

The dimensions of the tube shall be such as to enable a condenser of not less than 200 $\mu\mu$F being made. One end of the tube shall be plugged with a tight-fitting rubber cork and the condenser made by putting mercury into the tube and placing the tube in a tall glass vessel containing mercury to the required level.

(iii) *For Flexible Materials.*

The use of tinfoil as electrodes for flexible materials has been found unsatisfactory. Suitably constructed mercury electrodes have been found to give consistent results. Fig. 25 shows an apparatus which has been found satisfactory for flexible materials. The apparatus consists of two cast-iron blocks A in which are cut shallow circular recesses to hold the mercury. The rims of these recesses are made only 1 mm wide and accurately flat, so that when the arrangement is tightened up they form a good fit. Four bolts are fixed into lugs on one of the cast-iron clamps, and passing through holes in corresponding lugs on the other enable the clamp to be tightened by nuts. The insulation between the two points consists of amber washers, through which the bolts pass. The mercury is poured in from below through glass tubes which are cemented into holes bored in the casting, with a cement made from red lead and bakelite. For thin materials a cast-iron clamp having a mercury space about 3 inches diameter has been found satisfactory.

(*g*) *Method of Test.*

The test condenser prepared as stated in (*d*) above shall be arranged in the measuring circuit as stated in (*c*) and the radio-frequency generator arranged as in (*b*).

The measuring circuit is divided into two parts at the special switch; by connecting wells 1 and 3 the circuit is completed through the specimen, and by connecting wells 3 and 5 the standard air condenser is placed in circuit.

The three wells being unconnected the generating circuit is switched on, the galvanometer zero adjusted, a link of negligible resistance is inserted between wells 1 and 3, and the resonant frequency obtained by adjustment of the main condenser of the generating circuit Fig. 21, previously calibrated against a wave-meter. The magnitude of the galvanometer deflection is brought to nearly full scale by bringing the anode coil of the generating circuit nearer to the coupling coil of the measuring circuit. To make sure that an alteration in the position of the anode coil does not affect the zero reading of the galvanometer the link may be removed from 1 to 3 and the zero checked. The final adjustment of frequency for resonance is in the case of the circuit shown in Fig. 21 effected by means of the vernier condenser, and the galvanometer deflection then read. The link is next removed from wells 1 and 3, and replaced by a resistance of such a value that the galvanometer deflection is reduced to about half. A

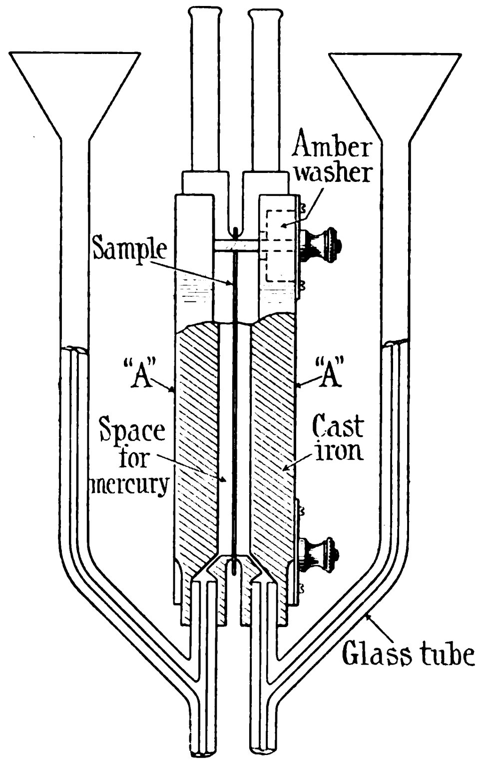

FIG. 25.—Apparatus used by the E.R.A. for the measurement of the power factor and permittivity of flexible materials.

slight adjustment of the vernier condenser may be necessary for exact resonance, and, this being done, the deflection is again read, the process is repeated in succession with three or more resistances, of values such that the deflections lie between a third and two-thirds of that which is produced without any added resistance. Then the link is again replaced and the maximum deflection read. This should be the same, to within 0·5 per cent, as that obtained at first.

The procedure detailed above is now repeated with the other part of the circuit, i.e. using wells 3 and 5, the only difference being that the main condenser of the generating circuit is left untouched, resonance being obtained by adjustment of the air condenser of the measuring circuit. The resistance of this part of

the circuit being smaller than that of part B, Fig. 22, looser coupling and smaller resistances are required.

(*h*) *Calculation of "Equivalent Resistance" of Specimen.*

In this calculation it is assumed that the condenser with the test specimen as dielectric is equivalent to an air condenser of the same capacity and zero power factor in series with a non-inductive resistance called the " equivalent " or " effective " resistance.

The equivalent resistance of the specimen is calculated as follows :—

Referring to Fig. 22,

Let R_x = the resistance of the specimen C_x.
R_s = the resistance of the standard air condenser C_s.
R_c = the resistance of the remainder of the measuring circuit including the coupling coil L.

Then the resistance of Part B = $R_x + R_c$, and that of Part A = $R_s + R_c$.

As the standard condenser may be considered to have negligible resistance, the resistance of the specimen is that of part B minus that of part A.

The resistance of parts A and B is calculated from the experimental values of galvanometer deflection and added resistance as follows :—

Let R_o = the resistance of the circuit with no other resistance inserted.
R_i = the resistance inserted.
D_o = the galvanometer deflection with no other resistance inserted.
D_i = the galvanometer deflection with resistance inserted.

Then

$$Ro = \frac{R_i}{\sqrt{\frac{D_o}{D_i}} - 1}$$

From the values obtained by inserting the three or four resistances, make three or four calculations of the resistance of parts A and B, take the average value for each part of the circuit, and the difference of these values gives the equivalent resistance of the specimen at the frequency used for the test.

(*j*) *Calculation of Power Factor.*

Let R_x = the equivalent resistance of the specimen in ohms.
C_x = the specimen capacity in micro-micro-farads.
λ = wave-length in metres.

Then power factor $= 0\cdot188 \dfrac{R_x \,.\, C_x}{\lambda}$ per cent (approx.).

The equivalent resistance of the specimen is calculated by the method detailed in (*h*) above, the specimen capacity is obtained from the reading of the standard air condenser, and the wave-length from a wave-meter.

(*k*) *Calculation of Permittivity of Specimen in the form of a Sheet.*

Let C_x = capacity of the specimen in micro-micro-farads.
T = average thickness in cm.
S = area of dielectric subjected to electric stress, and expressed in square centimetres.

Then permittivity $= \dfrac{C_x \,.\, T}{0\cdot0885 \,.\, S}$

(*l*) *Dielectric Loss.*

As the energy loss in a dielectric is dependent on both the power factor and also on the permittivity the best comparison of electrical insulating materials for use at high frequencies is obtained by considering the product of the power factor and permittivity.

(*m*) *Acknowledgments.*

As stated in Clause (*a*), the above method of test is based on the tentative method suggested by the A.S.T.M. in its publication Serial Designation D 150–23 T.

Certain features of the above method are based on uncompleted researches by Mr. D. W. Dye, B.Sc., and Mr. L. Hartshorn, B.Sc., both of the National Physical Laboratory. Certain other features are based on uncompleted researches at City and Guilds Engineering College by Prof. C. L. Fortescue, O.B.E., M.A., and Mr. J. E. P. L. Vigoureux, B.Sc.

H.F. Test No. 2. Comparison of the Effect on Electrical Insulating Materials of High Voltages at Radio Frequencies.

(*a*) *General.*

Methods of test for comparing the effect on electrical insulating materials of high voltages at radio frequencies are under investigation by the E.R.A. Pending the results of these experimental investigations attention is drawn to the tentative method suggested by the A.S.T.M. in its publication Serial Designation D 175–23 T. With but minor modifications, the above mentioned A.S.T.M. publication is reproduced below :—

(*b*) *Effects of Applying a High Voltage at Radio Frequencies to Insulating Materials.*

This method of test is intended to determine the electric failure and flash-over voltages of electrical insulating materials at radio frequencies.

The failure under radio frequency stress may take the form of charring, buckling, cracking, blistering, softening or chemical decomposition. Failure through the material is not abrupt, and it therefore requires a certain amount of judgment on the part of the operator to decide just what constitutes failure in any particular case.

When a sheet of insulating material is tested between two metal electrodes passing through it, the heat generated increases with the thickness of the material, while the radiating surface remains nearly constant. Consequently, as the thickness of the sample is increased, the voltage at which failure occurs will decrease. As

sufficient data are not available to allow results to be translated from one thickness to another, it is necessary that all comparative tests be made on samples of the same thickness. Hence, in the standard method given below, a definite thickness of sample is specified. This method, of course, is applicable to other thicknesses of material, but when so used the results should be compared only with similar tests made on like thicknesses of material.

In the flash-over test, heating of the material due to the high-frequency current is to be avoided, and it, therefore, is not so important that the samples being compared be of the same thickness. However, as a little heating is unavoidable, it is also desirable in this test to compare samples of the same thickness whenever possible.

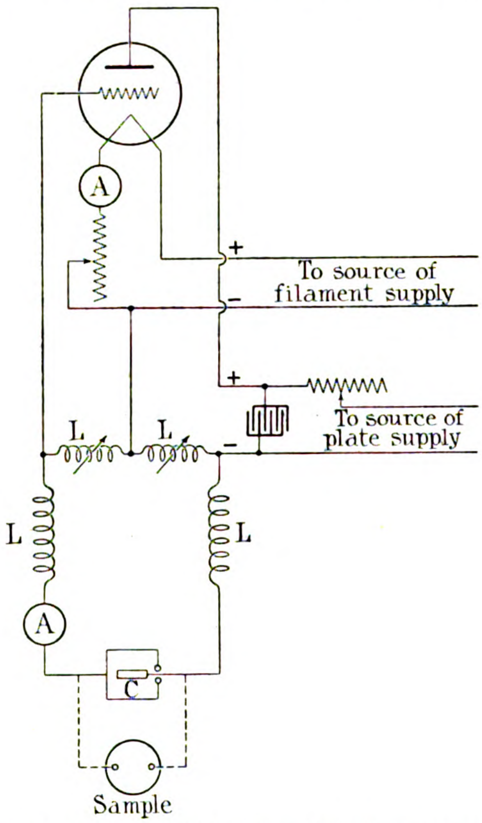

FIG. 26.—Circuit for high-voltage high-frequency tests.

(c) High-voltage High-Frequency Generator.

Any type of generator having an output of 500 watts or more and generating continuous waves of 100 and 1 000 kilocycles per second, respectively, and at voltages up to 5 000 or 10 000 volts, depending upon the class of materials tested, is satisfactory. If desired, a circuit similar to that shown in Fig. 26 may be used.

(d) Measurement of Voltage.

The voltage may be measured by means of the current through a shielded radio frequency ammeter in series with a small shielded air condenser of known capacity across the test terminals or by means of an electrostatic voltmeter designed to withstand radio frequency potentials. Suitable scales shall be provided so that reasonable accuracy will be obtained when measuring any testing voltages up to the maximum desired.

If the ammeter method is used :—

$$E \text{ (in volts)} = \frac{16I \times 10^7}{fC} *$$

where I = current in amperes,
f = frequency in kilocycles per second,
C = capacity of air condenser in micro-micro-farads.

(e) Electrodes.

The electrodes shall be of brass and shall be clean and polished.

For the dielectric failure test through the specimen the electrodes shall have the dimensions shown in Fig. 27.

For the flash-over voltage test across the surface of the material, the electrodes shall have the dimensions shown in Fig. 28.

(f) Test Specimens.

The specimens shall be representative of the material to be tested, care being taken to select material free from abnormal defects.

For the dielectric failure test, the specimens shall be 6·35 mm (0·25 in.) in thickness and may be of any convenient size or shape provided that the centre electrode (see Fig. 29) is at least 57·5 mm (2·264 in.) from the outside edge at all points. Other thicknesses may be used, but the results therefrom should be used strictly for comparative purposes as explained under Section (*b*). If any samples are milled to reduce the thickness, care should be taken not to tear, chip or otherwise change the character of the material. Four holes 12·7 mm (0·5 in.) in diameter, shall be provided in each specimen, one in the centre and three equally spaced in a circle of 25·4 mm (1·000 in.) radius as shown in Fig. 29.

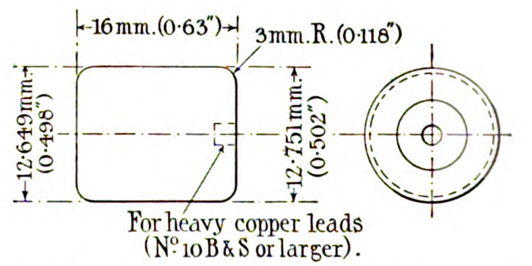

FIG. 27.—Electrodes for testing through the material.

For the flash-over test, the specimens may be any convenient size, the holes being drilled on 38·1 mm (1·5 in.) centres as shown in Fig. 28.

(g) Conditioning of Specimens previous to Test.

The effect of high voltage at high frequency shall be

* In the formula the value 16 is an approximation, 15·92 being the exact value.

determined after specimens prepared in accordance with Fig. 28 have been conditioned as follows :—

(i) Normal condition as defined in Appendix I.*
(ii) After immersion in distilled water for 48 hours at about 20° C., followed by exposure to normal condition for 24 hours.

instant when the prescribed voltage is reached, and the time required to reach this voltage not exceeding ½ minute. Whenever samples thicker than that specified are used, this testing period should be changed to three minutes.

Tests shall be made between the centre hole and each of the other three holes of each specimen, the specimens

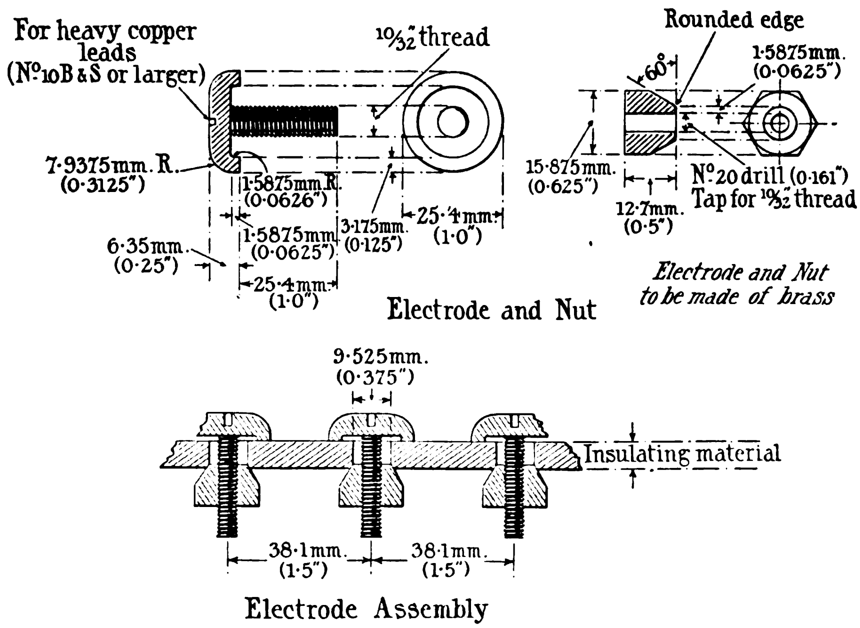

FIG. 28.—Electrodes for testing across the surface of material.

(h) Condition of Specimen during Test.

During test the specimens shall be exposed to an atmosphere of normal condition as defined in Appendix I.*

(j) Method of Test for Failure through the Material.

One electrode (Fig. 27) shall be inserted in the centre hole in a specimen and a similar electrode in one of the other three holes. The electrodes must be a tight fit, otherwise corona may form at comparatively low voltage and destroy the material.

The electrodes shall then be connected to the test terminals of the radio-frequency generator. One side of the generator shall be earthed, and this terminal shall be connected to the centre electrode of the specimen. The reason for this is that the failure generally occurs around the high potential terminal and this will allow the two subsequent tests to be made between the centre and the other two holes, the centre not being destroyed.

For materials which ordinarily fail below 3 000 volts the voltage shall be raised in steps of 500 volts. For materials which ordinarily fail above 3 000 volts, the voltage shall be raised in steps of 1 000 volts. Wherever possible, the initial voltage chosen shall be such that at least three voltage steps will be required to cause failure of the material.

The voltage at each step shall be impressed for two minutes, the testing period being counted from the

* Appendix I of Ref. L/S2.

being allowed to cool to room temperature after each test.

The average of these three voltages shall be considered as the electric strength of the specimen under the conditions of the tests.

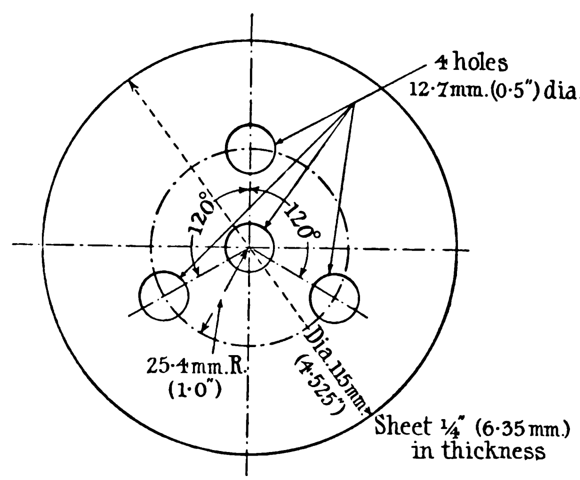

FIG. 29.—Specimen for high-voltage high-frequency.

Specimens shall be tested at 100 kilocycles per second (3 000 metres) and also at 1 000 kilocycles per second (300 metres).

(*k*) *Method of Test for Failure across the Surface of the Material.*

The flash-over tests shall be made under the same conditions and at the same frequencies as specified in (*j*) above.

The electrodes shall be clamped into position as shown in Fig. 28.

The voltage shall be raised at * the rate of about 1 000 volts per second until flash-over occurs. The power shall be removed immediately upon flash-over and the test shall be repeated (without moving the electrodes) until the insulation value has been practically destroyed.

* The voltage may be increased either by varying the grid and plate inductances or capacities or by varying the D.C. plate voltage.

The initial voltage chosen shall be as little below the flash-over voltage as practicable so that the flash-over will occur as soon as possible without appreciable heating of the material.

The voltage which exists across the specimen when flash-over takes place cannot be determined with the specimen in place since the voltage would not remain constant until a steady deflection of the measuring instrument was reached and the sample would heat up. Therefore, as soon as discharge occurs the plate voltage shall be thrown off, all other controls remaining constant, and the test leads removed. The plate voltage then shall be reapplied and the voltage measuring instrument reading taken when a steady deflection is reached.

Tests shall be made in at least three places on each side of each specimen.

INSTITUTION NOTES.

Associate Membership Examination.

The next Examination will be held on the 15th, 16th and 17th April, 1926. Candidates must be either Students or Graduates of the Institution or have lodged with the Secretary a duly completed form "E" for election as Associate Member. Entry forms for the Examination, which must be completed and returned by the 1st February, may be had on application to the Secretary.

Associate Membership Examination Results.

OCTOBER 1925, SUPPLEMENTARY LIST.*

Passed.

Anderson, J. P. (South Africa).
Burke, R. T. (India).
de Beer, C. L. (South Africa).
Eales, A. B. (South Africa).
Freeman, C. E. (South Africa).
Gillespie, A. (South Africa).
Lester, A. E. (South Africa).
Loveday, G. K. (South Africa).
Nash, W. A. (South Africa).
Stanton, W. A. (South Africa).
Wood, C. F. (South Africa).
Wright, A. M. (U.S.A.).

Passed Part I only.

Collins, H. (South Africa).

* See page 92.

Passed Part II only.

Ambalavanar, P. (Ceylon).
Chapman, R. F. (South Africa).
Dawes, E. A. (South Africa).
Gray, T. A. (South Africa).
Rhenius, S. T. (India).

Further results relating to other candidates who sat for the Examination will be published later.

THE ENGINEER: HIS DUE AND HIS DUTY IN LIFE.

By THOMAS CARTER, Member.

(*Paper first received* 13*th May, and in final form* 9*th June,* 1925; *read before* THE INSTITUTION 19*th November, before the* MERSEY AND NORTH WALES (LIVERPOOL) CENTRE 16*th November, before the* NORTH-EASTERN CENTRE 23*rd November, before the* NORTH MIDLAND CENTRE 24*th November, and before the* NORTH-WESTERN CENTRE 1*st December,* 1925.)

SUMMARY.

(1) THE RIGHTS AND THE DUTIES OF LIFE.

In these days, when many standards of the past are disappearing, when new thoughts are being conceived and new views are struggling for recognition, and when more than ever the safety of the future depends on the well-directed efforts of men of wide vision and clear understanding, it is not too much to say that unless each of us is contriving somehow to increase the common good, he were much better dead. It was a very profound thinker who said: " When ye shall have done all the things that are commanded you, say, We are unprofitable servants; we have done that which it was our duty to do." Has it not been the exceeding of mere duty that has hoisted the lamp of knowledge a little higher and has furnished it with a brighter light, so that the confines of our ignorance are not so narrow as they were, and the darkness still to be searched is less terrifying than once it seemed?

We are born into a family, into a nation, into the world; we inherit from all the past; we are played upon by things around us, and we react on them in our turn; each one of us has his own qualities, his own defects, his own potential contribution to the service of his fellows. In theory, at least, the nation desires each of its members to have the fullest opportunity for self-expression, so that the aggregate excellence may be increased. But unless the members work in harmony, there will be mere confusion; unless the many feet of a centipede all decide to carry the body in the same direction, the poor animal may find it difficult to avoid an early death. There are, then, two sides to a man's life, together making it complete: the one, his right to live; the other, his duty to the community. As to the first, the lethal chamber at birth would be a kinder fate than the life that some people unfortunately grow up to. If we let a child live, we must in decency see that no great unclimbable rocks are left lying in his path. His right is to expect to be prepared in his youth for a job that he can do in his working days with enough comfort to leave his spirit unquenched if he grows to be old. Political thought seems to be groping after some means of achieving this, but the free meals, the free education, the doles, and all the other things that are handed out, are not even the beginning of the kind of care that should be lavished on us. In these there is death to the nation in the end rather than the intense common life that we ought to grow into, and until we learn how to use our human resources adequately we shall lose much that may be had for the taking. On the other hand, the more we give every man a chance to reach his best, the more must he recognize that this good comes to him from the community, and the more must he strive, while following his own bent, to avoid every activity that will put a brake on the wheels of progress. This, then, is a proper life: a constant giving and receiving, a perpetual interchange of services, ideas, and commodities, with an unfailing consideration of our neighbour's good as well as of our own, and a constant recollection that those who forget their common obligations, and merely demand their own due without caring what happens to others, are the slayers of the nation's soul. There is no right without its corresponding duty.

(2) THE RISE OF MODERN ENGINEERING.

The world has never been wanting in engineers. Almost before the dawn of history, Zillah, the wife of Lamech, " bare Tubal-Cain, the forger of every cutting instrument of brass and iron"; and his kind have always played a leading part in human development. The famous buildings of the past witness to the greatness of the engineers who created them; and the works of early races and of the Middle Ages sometimes put our own to shame.

The Oxford English Dictionary tells an interesting story in its articles on words referring to our profession. " Engine" is related to the Latin " ingenium," and to our " ingenious." It first meant " native talent" or " mother wit." It was also used in the senses of " natural disposition," " skill in contriving," and " ingenuity," and, later, in the transferred sense of " a product of ingenuity" or " a device," and sometimes " a snare" or " a wile," like the kindred word " gin." Then it came to mean, more narrowly, " a mechanical contrivance," especially in the restricted sense of " a large mechanical instrument of warfare"; and finally, after denoting generally " a machine, with parts working together to produce a given physical effect," such as, for instance, a watch, it acquired its modern significance in words like " steam-engine" and " heat-engine." The word " engineer," that is " one who is concerned with engines," has varied similarly in meaning. It first denoted " a contriver or designer or inventor," sometimes in the special sense of " a layer of snares," as in the phrase " That great engineer, Satan." Later it was applied to constructors of military works, and

then to designers and constructors of works of public utility, named civil engineers for distinction from military engineers, who had previously carried out public works also.

The modern engineering profession has grown up within the last two or three hundred years as a consequence of the new interest in science and scientific investigation that arose in the sixteenth century. Sir Hugh Myddleton, who died in 1631 and who conceived the New River water scheme for London, has been called "the first English engineer"; and names of great men, like Newcomen, Brindley, Smeaton, Watt, Telford, Rennie, the Brunels, and the Stephensons, meet us in the succeeding period. Associations of engineers began to arise. "Before or about 1760," (I quote from the preface to Smeaton's Reports) "a new era in all the arts and sciences . . . commenced in this country. . . . Manufactures were extended on a new plan . . . by men of deep knowledge and persevering industry engaged in them. It was perceived that it would be better for establishments to be set down in new situations . . . than to be plagued with the miserable little politics of corporate towns, and the wages of their extravagant workmen." A demand arose for internal navigation as a means of communication, and "this general situation . . . gave rise to a new profession and order of men, called Civil Engineers." Some of these engineers used to meet in the Houses of Parliament and in the Courts of Justice, without knowing much of each other, and someone proposed to Smeaton that "it would be well if some sort of occasional meeting, in a friendly way, was to be held, where they might shake hands together, and be personally known to one another; that thus the sharp edges of their minds might be rubbed off, as it were, by a closer communication of ideas, no ways naturally hostile; might promote the true end of the public business upon which they should happen to meet in the course of their employment; without jostling each other with rudeness, too common in the unworthy part of the advocates of the law, whose interest it might be to push them on perhaps too far in discussing points in contest. . . . In March, 1771, a small meeting was first established, on Friday evenings, after the labours of the day were over, at the Queen's Head Tavern, Holborn. . . . Conversation, argument, and a social communication of ideas and knowledge, in the particular walks of each member, were at the same time the amusement and the business of the meetings." In May, 1792, a disagreement caused the dissolution of the Society, but it was afterwards revived "in a better and more respectable form." The members dined together and passed the evening "in that species of conversation which provokes the communication of knowledge more readily and rapidly than it can be obtained from private study or books alone. The first meeting of this new institution, The Society of Civil Engineers, was held on the 15th of April, 1793." There were three classes of membership: Ordinary Members were real engineers, employed as such; men of science and gentlemen of rank, who might, for talents and knowledge, have been engineers, together with persons employed in kindred public service, formed one group of Honorary Members, and a second consisted of various artists, whose professions and employments were useful to civil engineering. The meetings were held at the Crown and Anchor, in the Strand, every other Friday during the session of Parliament, and an early list of members shows 12 real engineers, 10 of the first kind of Honorary Members, and 7 of the second, namely, a geographer, two instrument makers, a millwright, an engine maker, a printer, and a land surveyor. So much for this predecessor of all our present-day Institutions.

The Institution of Civil Engineers, established in 1818, and chartered in 1828, nobly defined the profession of a civil engineer, that is, of any engineer not a military engineer, as "the art of directing the great sources of power in nature for the use and convenience of man"; The Institution of Mechanical Engineers began in 1847, and The Institution of Naval Architects in 1860; and the Society that grew into The Institution of Electrical Engineers was founded in 1871, as a mark of the progress of the new science that began to find its modern application when Faraday discovered the existence of electromagnetic induction in 1831. The engineer of to-day has the whole range of natural forces to deal with; and in no department of his profession is the variety so great as amongst electrical engineers. Our Institution has for its members some who roam at will in the tiny empty space between the nucleus and the electrons of an atom, not only seeing with some special vision the wonderful processes of that region, but actually taking matter to pieces and remaking it differently; some who, at the opposite end of the scale, construct machines so large that one of them will keep the wheels turning for thousands of workers; some who take these machines and build them into power stations; some who run these power stations, and test them complete as a single machine used to be tested, always endeavouring to make more and more use of the energy of their fuel; consultants who work out schemes for the application of electric power; public advisers who regulate and co-ordinate the electrical resources of the country; those who install plant and wire buildings; those who teach others; those who control communication with and without wires; those who made that kind of communication possible; and many others. All these are engineers, every one in his own sphere trying to direct some great source of power in nature for the use and convenience of man.

(3) The Finding of Engineers.

Having obtained a conception of what constitutes a proper life, and having reminded ourselves of what an engineer is, let us think how the life of an engineer may have its fullest usefulness. We have not long begun to realize how much a problem like this concerns us as a nation. Some children are born to be engineers, and some to be anything but engineers: our part is to separate the engineers from the others. We make far too little attempt to ascertain whether those who decide to be engineers have done so merely because their parents think it right, or because they have somehow drifted aimlessly into it; or whether, on

the other hand, they are real engineers. We also let many escape into other occupations who should be compelled to come into engineering. The finding of engineers to train is far more important than the finding of methods of training them. First catch your hare, then cook him, says the old saw; but be sure he is a hare, and do not merely label your snare "For Hares," and then take whatever you find in it, if you are really fond of hare soup. Strictness at the beginning may reduce the number of those who become engineers; but that is what is needed. The proper selection of potential engineers and the rejection of all others would so increase the efficiency of the profession that there would be no lack of directing ability. To keep its place in the world, a nation must more and more cherish and utilize every one of its members to the fullest of his possibilities; somehow (it is a matter for the patient thought of the very best men amongst us to discover exactly how) we must cease to be haphazard. Faith, and the vision of the unseen goal, will be needed; but they are not wanting, and they will suffice.

In pursuit of our aim, we must discover the inmost nature of children at an early age; and it may be hoped that teachers will more and more try to do this as part of their work. Tests of intelligence and vocational tests are being made tentatively in many places, both of children still at school and of those passing out into employment; and although much time will be required before their data can be properly interpreted, some very suggestive information has already been collected. By checking attainment against prediction, thus keeping abreast of each child's development, it will eventually be possible for the head of a school to give definite advice regarding the career of at least some of his scholars. There will always be many who are without marked bias, who will go through life doing mostly as they are told, and who will perhaps do as well in one thing as in another. It is the head-and-shoulders-higher-than-their-fellows people whom we want specially to discover; but only by watching all will these be found. So we shall avoid, on the one hand, the keeping down of a leader amongst the led, and, on the other, the letting through to the leader's place of one who is bound to fail.

Dr. Johnston, of Highgate School, has very kindly sent me some notes of what is being done there in this connection. The records of all boys, even those of average capacity, are systematically studied as they go through the school, so that they may be guided into appropriate callings. Dr. Johnston writes: "I cannot pretend that we have achieved very much, because the problem bristles with difficulties. As a nation, we are quite unorganized; there are no records kept in public offices of the state of supply and demand in the various professions, and all boys have to face the welter of extreme competition without any knowledge of the facts. The question of a career is therefore in most cases determined almost entirely by accident rather than by a careful survey of the fitness of persons for particular walks in life. There are two ways in which help can be given: first, and in practice more important and helpful, though it is on the negative side, we are able to inform parents with great confidence what form of activity the boy should not attempt, and in this way we can correct the prejudices that may have been formed about the boy's future work." After instancing one who rightly became a journalist instead of the engineer his parents wanted him to be, and another who is now a brilliant scientist and a possible future Fellow of the Royal Society, having been rescued from the prospect of a quite different kind of career, Dr. Johnston says: "With respect to your own profession, I have always advised parents to let no boy become an engineer unless he combines in his capacity two particular forms of talent: (*a*) real aptitude in dealing with scientific apparatus and adapting means to ends, and a real feeling for the purpose of machinery in general; and (*b*) distinct capacity in the practical applications of mathematics and the use of mathematical formulae for utilitarian purposes. If he has higher mathematical knowledge and could deal with the abstractions of theory, so much the better, and he might become a better and greater designing engineer. . . .

"Secondly, on the positive side I have found it possible to do a certain amount, but not very much. It is easier to make positive recommendations in the case of boys with scientific bent than those with a bent for language and literature. . . . I have dealt with boys who showed no liking whatever for language work, but were incomparably handy and fertile when they came to deal with instruments in a physical laboratory." Dr. Johnston mentions two such people, who might have been regarded as hopeless according to the older-fashioned view, but are now on the high road to become experts in wireless engineering and broadcasting; he then states that of the many positive suggestions that are given, all valuable in some way, 20 or 30 per cent yield important results; and he concludes by saying: "The engineering boy is one of the most difficult to determine, because nowadays a very large proportion of boys can mend a bicycle pump or find out very rapidly why a motor car will not start or run properly; but I want the boy who can inspect a structure and tell instinctively what parts are in a state of tension or pressure, and what must be done to ensure stability; I want the type of boy who, pouring a fluid into a vertical vessel, will almost visualize the descent of the centre of gravity at first and its subsequent rise as he goes on, who could plot and graph the process and get results even if he could not complete the question mathematically. If this kind of boy takes to mathematics and can learn to use the principles of the differential and integral calculus, he is, from my point of view, the right kind to make an engineer. But he must have both forms of talent: one without the other makes an intelligent foreman or an unpractical theorist."

The value of this comparatively new work of investigating intelligence and capacity is clearly enormous, and as it extends, and more experience is gained, its increasingly definite results will allow more and more accurate estimates to be made. Further, a boy's personality will develop finely under treatment like this; he will discover that he is an individual, not merely a drop in an ocean, but a separate being, capable of impressing himself upon others; he will climb so high in thought that great things and small things will

appear to him truly related in his ever-widening view; if he is more than usually favoured, he may even, looking higher, see the "dawn of more than mortal day strike on the Mount of Vision."

The careful guiding of boys to the discovery of the dominant tendencies in them, and of the things to be rooted out before their best powers can have full scope, is exactly what is wanted to prepare them for the still more specialized training of the next stage of their development.

(4) The Training of Engineers.

I will not do more than mention the several varieties of engineering education; their details have frequently been described far better than I could do it. Some take a college course, followed by a short apprenticeship in workshops; some go straight from college to administrative work; some serve a long works' apprenticeship and get what theoretical training they can in their spare time; some, following sandwich systems, alternate in longer or shorter periods between study and practice. Each method has its advocates and its advantages, and suits the circumstances of some students more completely than others; but in all of them, let it be repeated, the one great essential is to see that the people put through the process are real engineers. If this were secured, more value would come to be placed on a record of achievement than on the result of an examination; there would be far less weeding out to do than there is now. There would be small chance that a purely academic man would be put to research work in matters where intimate practical knowledge is required; or that a merely practical man could cause calculations and minutely thought-out instructions and even carefully prepared drawings to be regarded as very nearly superfluous; and possibly the perennial question of the engineer-salesman would be found to have solved itself. Perhaps, too, although we seem to have reached the end of discovery and initiation in some directions, and to have settled down largely to a working out of details, we should find amongst the new engineers some who would hit upon really new principles, or ways of combining things so novel that, as in the transverter, for example, they practically embody a new principle. To one who said that a man could achieve anything if he were made of the right stuff, Steinmetz is reported to have replied: "The scientific fact is that people are made out of the right stuff, but our problem is to find a way to release their creative energies."

A very useful summary of the obviously necessary scope of an academic engineering training was given a few years ago in the *Journal* of The American Institute of Electrical Engineers; I cannot do better than use its words:

A. It should offer directly:

- (1) Instruction in engineering knowledge, both
  - (*a*) fundamentals, and
  - (*b*) specific applications.
- (2) Instruction in non-engineering subjects, such as English, Economics, Law.
- (3) Instruction and training in hygienics.

B. It should also make adequate provision for:

- (4) Inculcation of habits of clear thinking, concentration, persistence, observation, decision, imagination.
- (5) Infusion of principles of fairness, unselfishness, tolerance, refinement, courtesy.
- (6) Formation of friendships.

To live the life we have been thinking of, with its reciprocal aspects of individual growth and service to the nation, such men are required as were turned out by Job Huss, the schoolmaster in H. G. Wells's "Undying Fire": "I have had dull boys and intractable boys, but nearly all have gone into the world gentlemen, broad-minded, good-mannered, understanding and unselfish, masters of self, servants of man, because the whole scheme of their education has been to release them from base and narrow things."

There may be many opinions about what and how an apprentice must learn as he goes through the works; but one thing is sure: he will be dependent for his instruction almost entirely on others employed there, and he must commend himself to them in his personal bearing and his general friendliness if he is to get all that he can out of his intercourse with them. Besides being an open book for the student of human nature, a factory brings the learner into contact with people who in ways not described in manuals or in college courses have inherited the skill and the traditions of the past, and hold in themselves the power to teach him the knack of doing things. One of the awful losses occasioned by the war was the destruction of the personal knowledge and aptitude of so many tens of thousands who lie quietly at rest in ground that they have made their own for ever, and by reason of whose departure to the place from which no word of these things comes back we are immeasurably poorer. All the more, then, must a young man be thankful now if he can find an older man with knowledge, willing to take his hand and lead him on. It is so difficult for anyone to see ahead the exact niche into which he will eventually fit that the only safe rule is to acquire and store up either in his memory or in some other accessible place all the information presented to him, however varied it may be, and however apparently out of the line of his immediate work. Then, if in the days to come he has to direct the work of other men, he will know by unfailing instinct in what terms he should issue his orders, because he knows so well the way in which they will be carried out. A wise old book, now out of print, said: "Politeness is as indispensable to a learner in the works as to a gentleman in society. The character of the courtesy may be modified to suit the circumstances and the person, but still it is courtesy. . . . Without the art of questioning, but slow progress will be made in learning. . . . There is not a more generous or kindly feeling in the world than that with which a skilled mechanic will share his knowledge with those who have gained his esteem."

Thus are worthy leaders made; and here, as always, the development of personality, the acquirement of the art of standing firmly alone and yet all the time making contact with those around, is still the thing that counts

almost more than anything else. For a man possessing it will be in living touch with life, and will add knowledge to knowledge, and strength to strength, until his last day; he will more and more easily distinguish the temporal from the eternal; he will move confidently amongst great thoughts and great affairs. "The aim of education," says the COPEC report on that subject, "is the full and harmonious development of the resources of the human spirit, the making of the perfect man or woman. Such a one will possess a single wide interest; a consistency of feeling, thought, and conduct; a perfectly integrated personality rightly related to the society from which it is inseparable."

(5) Principles and Problems.

There are fundamental things that all of us must bear in mind at every stage of our career, if we are to avoid pitfalls. We are bound in our work by conditions that require first of all our promises and afterwards our adequate performance of them; how needful it is, then, that those who direct the work shall have clear thoughts, flexible ideas, and so wide an understanding of the possibilities of any undertaking that out of the varied views that may be held they will select the one best calculated to ensure success. The very facility with which we may pick up a smattering of a subject nowadays, and the ease with which a thin veneer of showy knowledge is spread over great slabs of essential ignorance, may lead us back to the conditions of the dark ages, if we are not careful. When men had to puzzle things out for themselves, many of them could survey and carry out a whole job, but this is rather the day of the specialist, who is limited to his own sphere; and although the change was perhaps inevitable, because of the expansion of the range of our subjects, in many respects the old way was, for once, better than the new. If we are to apply our knowledge to the best advantage in our practice, we must keep it as varied as we can, consistently with thoroughness; and, in addition to knowledge, we must try to acquire and preserve the wisdom that will show us how to use it. The man who with wide-open eyes sees most will constantly find opportunities thrust on him for seeing more. What we call luck is often nothing else than a readiness for the coming chance, and an immediate grasping of it when it arrives. Alas for us if we let it go by! The moment's hesitation that loses it might as well be an eternity. I recall how once at a travelling menagerie, when I was a very small boy, I was offered a ride on an elephant's back, and for some reason of childish fear refused it. But at night I wept bitterly, repenting in vain of my negligence, for even an elephant will not wait for ever, and the unreturning caravan had passed on. So a proverb has arisen in my family: "Remember, you may wish you had ridden on the elephant."

The reports we must make and the records we must keep will be of more value as we ourselves acquire a greater facility in the accurate use of words. Our power to communicate with each other at all is a perpetual wonder. We write marks on paper; and when we pass them from one to another, they somehow convey ideas and summon thoughts. We open our mouths and make sounds; and they, like the writing, mean something to those who happen to be near. It is as great an insult to a hearer or to a correspondent to be slovenly about our words as it would be if we gave him a picture that we had first slashed into ribbons. So we must assure ourselves that we know what we want to say—no easy matter in itself—and then we may attempt its expression in words. It is terribly difficult to write sentences and paragraphs with only a single meaning, even if we try; how impossible it is if we have never troubled to realize the difficulty! Our aim should be to keep clear of extremes on either hand. The wife of one of the dictionary makers, a convivial fellow, returned home one night unexpectedly to find him carousing with his companions. "Well, sir, I am surprised," said she. "No, madam," was the reply. "You are astonished: I am surprised." We need not cultivate so pedantic an exactitude as this; but we must equally avoid falling into such mental confusion as caused the schoolboy to declare that, according to Euclid, things that are trebles of the same thing are trebles of one another. A study of the great writers and poets will lead us to some sense of the fitness of words, and will keep us clear of the dreary baldness of expression to which we are so prone. We get habits in writing our letters that tie us down to a painfully small vocabulary; and a written application for a position is often the one thing that prevents a man from being interviewed. I do not suggest that we should draft our bye-laws so that they can be made into an anthem, or that we should write our specifications so that they would more naturally be sung than read; but if we realize the essential music of things like the praise of love by Paul the Apostle to his friends at Corinth, the everlasting beauty of Keats's "Ode to a Nightingale," or the perfect fitting of expression to meaning in Hamlet's last words: "The rest is silence," we shall make bye-laws and draw up specifications and write letters far better than if we had never thought of these lovely things. Ben Jonson says: "The best writers in their beginnings imposed upon themselves care and industry; they did nothing rashly; they obtained first to write well, and then custom made it easy and a habit. By little and little their matter showed itself to them more plentifully; their words answered, their compositions followed; and all, as in a well-ordered family, presented itself in the place. So that the sum of all is, ready writing makes not good writing, but good writing brings on ready writing."

Our incomplete understanding of the mechanism of the universe, our inevitable lack of knowledge of all the conditions and circumstances that will affect a piece of work, and often the mere shortness of time itself, compel us to realize that, in so great a complexity as we have to deal with, our judgments must sometimes be partial, and only our experience can guide us into the probably right path. We help ourselves by using formulæ; but unless these are truly based on first principles, or unless we understand their limitations and keep in mind the physical facts behind them, they are the most dangerous of our tools. Formulæ are of two distinct kinds. The first are a mere shorthand notation, like multiplication tables, or like an algebraical

expression that states some invariable relation in a convenient form. These are safe so long as we use them appropriately and make no mistake in our calculations based on them. Even if an error does arise, it can usually be discovered by the simple means of checking the end against the beginning. Formulæ of the second kind are expressions of generalized conclusions drawn from experiments. Their value depends both on the competence of the investigator and on the completeness of his investigation, and the limits within which they may be safely used must be very carefully stated and observed. Interpolation is then reasonably safe; extrapolation is occasionally fatal, and always dangerous. Natural laws, the great generalizations of master minds, are formulæ of this order, and all through the ages they have had to be revised and restated and often rejected in the light of new knowledge. The old statement serves for a time, and then some quick eye sees a discrepancy between it and something that looks like a fact. Either the seeming fact is no fact, or the law is untrue; and it is from a refusal to smooth out a kink in a curve merely because it has been said that there should be no kink, or from a confident scepticism that will not force a new idea to square itself with an accepted view merely because it is accepted, that many a great advance has come.

A resolute determination to avoid preconceived conclusions, to allow just enough play to the imagination, to face facts at every stage, and not, as it were, to refuse to look in the last corner of a room for a lost coin, in case it should not be there either, will bring us to the point at which we can say: "Thus and thus ought we to do"; we shall be wise if we do it then once and for all, and pass on to the next task with the satisfaction that comes of achievement. To engineers, above all other men, faith is essential; the faith that removes mountains, not by sitting still and wishing them gone, which will never accomplish anything, but by setting out with picks and shovels, and hacking and digging and carting away, in the sure belief that at length, however long it lasts, the end of the job will come.

Difficult and complicated as are our technical problems, those of us who deal directly with men, either in controlling their work, or in negotiating affairs with them, are faced with still harder human problems. Many subjects in this region are so controversial that they cannot be touched on here; but we may consider a few things that will fit us to think clearly about them. It is not easy to secure a correct statement of some of the problems, especially if they are debated by partisans; and the inmost facts themselves are often not accessible. In discussions, words are used vaguely, or even with no recognizable meaning at all; they may become mere catchwords, thrown about as missiles rather than exchanged as currency of thought; and here, if anywhere, we must think for ourselves. Our equipment must therefore be adequate, and we shall do well to dig down into all sources of reliable information on such questions as unemployment; industrial relations between owners of concerns and those who manage them or earn wages in them; the effect on men of the gradual change from much manual labour to much minding of machines; the consequences from the national point of view of the conditions involved in mass-production; the problem of leisure, and whether in efforts to secure more of it those who are striving are forgetting that leisure implies occupation either in amusement or in recreation, and that the demand thus created for things that amuse and recreate will not go unsatisfied. Dr. Jacks says, in a recent article in *The Hibbert Journal*, "Of course we may imagine our community spending its long leisure in a state of mental or bodily torpor. . . . But as education increases the activity of men's minds and the vigour of their bodies, it is hardly to be expected that they will adopt this way out of the difficulty. Nor would it prove altogether effective if they did, as we were forcibly reminded by the wife of a Yorkshire miner with whom we were discussing these things. After remarking that 'short hours for the men mean long hours for the women' (a fact which not many sociologists have noted), she described at some length the leisure occupations of her husband, who at the moment was asleep upstairs, and then wound up as follows: 'When he's nowt else to do he lies abed; and that wears out the sheets, which I has to mend'—the economics of leisure in a nutshell."

To think out the details of the processes by which the ordinary things of life are made possible—for example, how it is that I can buy a pair of boots—is undoubtedly one of the best methods of realizing the dependence of every one thing upon every other thing; and a recognition of the kindred fact, that none of us liveth unto himself, will allow a man to meet his fellows with the success that comes from feeling his way tactfully amongst them, instead of ramming his views down their throats. "Although there exist," someone has written, "many thousand subjects for elegant conversation, there are persons who cannot meet a cripple without talking about feet." That is the way to kindle resentment against us in the hearts of others, some day to burst out and bring much pain that could have been avoided had sufficient care been taken. We simply must recognize that there are many points of view, and that it is at least worth while to see whether some of the others are not as tenable and as satisfying as our own. Robert Louis Stevenson has a fable about intolerance. "Be ashamed of yourself," said the frog. "When I was a tadpole I had no tail." "Just what I thought," said the tadpole. "You never were a tadpole." This is particularly apt as a parable of the feeling that often exists between the old and the young.

We must acquaint ourselves with the principles of economics sufficiently to avoid confusion when we think or read or talk of them. Some of the subjects we should try to be clear about are:—The fixing of prices for profitable output, and the relation between prices and turnover; ways of increasing production, without which not much advance can be looked for; the basis of national finance, with a recollection that taxes are not imposed for fun, and that national activities have to be paid for all the time; whether it would have been better to scrap all our war surplus as part of the wreckage of the war, and thus to keep some men, now unemployed, working at their own jobs instead of being dependent on national charity and in danger of becoming unem-

ployable; the meaning of a gold standard, and why it does not necessarily imply an internal gold currency; the usefulness of paying a man a large salary to do nothing but go round looking at things in his works, in the country, and abroad, and drawing conclusions from what he sees; the meaning of fluctuations in foreign exchanges as they concern the economic position of countries internationally; whether there are ascertainable reasons for the apparently more or less regular periods of good and bad trade, and whether any means can be discovered for smoothing out the variations so as to make prosperity more continuous; the essential importance of never doing a thing ourselves if we can find someone else to do it well for us; the whole problem of trade union conditions, how far they have been useful and how far not; the study of industrial fatigue, and how to use the results of the study; the impossibility of both eating our cake and having it; the sound sense, as the Chinese proverb says, of selling one loaf, when we have two, and buying a lily instead.

A few simple rules will keep us right in our meetings with others. Remember that although conventions may seem very stupid, they are usually based on common sense, and should not be too rashly broken through. Remember that while a continuance of endeavour in the face of difficulties is sometimes hard, its continuance when success comes is often harder and more noble. Remember that, as Walter de la Mare reminds us somewhere, the bears under the bed are all the more terrifying because they are not real bears at all. Remember the inestimable worth of humour, and cultivate every real spark of it. Remember that there is a time to keep silence, and a time to speak. "Refrain not speech, when it tendeth to safety; and hide not thy wisdom for the sake of fair-seeming. . . . If thou hast understanding, answer thy neighbour; and if not, let thy hand be upon thy mouth." Remember the value of friendship: a friend, they say, is one who knows all about us, and likes us in spite of it. Remember that small achievements often have frightful striving behind them. The farmer asked the boy: "What are you hanging round there for? Trying to pinch them apples?" "No!" said the boy. "I'm trying 'ard not to." Remember the pitifulness of much in human life; how fleeting it all is; how little we can foresee. Remember that each present moment is but a thin partition between the irrevocable past and the future that is always inevitably emerging from it, as a flower, fair or loathsome, springs from a planted seed.

(6) Engineers and Public Life.

One of the most remarkable things about engineering is that there is scarcely a region of the world's activity into which the engineer's direct influence does not extend. If we think through the whole of history, we shall find that his work has somehow entered into everything; but its effect on society has been most marked since the comparatively recent time when men began to devise aids to their own strength and capacity so powerful that they ushered in a new era. The whole fabric of commerce is kept in being to-day by the efforts of engineers; if they were to cease, it would perish as completely as if the world itself had stopped. Engineers have gone on inventing, often enough not realizing that the results of their work might be used for merely commercial ends, and in such ways that they could not conduce to the convenience of man. It is largely because of what engineers have done that towns have grown up, with their grey skies and crowded dwellings, and that our mode of existence, from being quite simple, has become oppressively complex and hurried. The world has been rendered almost immeasurably small by modern methods of transport and communication, and we have become so used to its smallness that we scarcely ever pause to consider whether it is good for us. The contrivances of engineers having made so much of this possible and even inevitable, although perhaps no moral responsibility attaches to their part in it, must not they now, when they see the monster that has been created, design some new contrivance that will so mollify and tame it that the world may once again be safe? To change the metaphor: The mechanism rattles and rumbles as it works; cannot those who made it discover a lubricant for it?

On the whole, engineers have not taken much part hitherto in public life. It is true that many of them are by nature not fitted for it, though that is not to say that all who are in it now are pre-eminently suitable. Some engineers, however, in addition to their technical accomplishments and their ingrained habits of reflection and investigation and logical deduction, have so clear a view of what is wrong in affairs generally, and of what may have to be done to put it right, that they ought certainly to be in positions of wide authority, dealing with public problems not merely as engineers, but as men of the world with special qualifications because they are engineers. To take only one example: Some of them, by their contact with all sides and all parties, may actually have had even more opportunities of arriving at an understanding of industrial problems than some of the people officially concerned with them; and their help would be invaluable in the discussion of such questions.

Efforts after improvement are being made in many directions: a League of Nations Committee on Intellectual Co-operation is trying to bring together for common aims teachers and students all over the world; the whole industrial situation is being analysed by competent people in discussions and writings; a Government Commission of inquiry into the conditions and prospects of British industry and commerce was set up in 1924; the co-ordination of technical education and its relation to other branches of education and to industry are being considered; those who lead in industry are feeling more and more their responsibility as the channels through which the opportunity must come for those under them to live adequately in return for services rendered through them to the community; and the attitude of all recent Governments towards these matters has revealed their view that they are the concern of the nation and not of individuals alone. But the way out of the turmoil will only be found by patient thought and long consideration and conference; and the public-minded engineer is peculiarly well suited for this. Parliament cannot do much to devise remedies; its main province is to register in its Acts the state of public

opinion at a given moment, and thus to create conditions favourable to progress along desired lines; and it is for those who are faced by any problem to work out a solution for it, and then, convinced that they have found it, to ask Parliament to sanction it. If some engineers were also members of Parliament and of other great deliberative bodies, many problems would be passed into practice with increased effectiveness, and the whole outlook of public life might be redirected for the better. Thus would full usefulness be reached in service to the nation; engineering would become a still finer thing than it is; and the life of an engineer would be more desirable because his work would be more highly appreciated.

(7) Conclusion.

I have tried to take, and put into words, a few of the thoughts that have come to me about the common things of our common life. The mind of each of us colours every view differently as it looks at it from its own standpoint; but there may be agreement on fundamental things, and our examination of some of them now may bring us a more vivid realization of them. I would plead specially for consideration of the problem of the finding of real engineers to be trained, and of the suggestion that engineers have it in them to smooth out much that is now tangled and to throw light on many obscure things. I think that we must try to consider more than we have done, in the literal sense of being alone with the stars; in the great open spaces we shall find enlightenment and rest and peace. We shall discover there that the man who wrote the 23rd Psalm is worth more to us than all the noisy and futile people who built the city and the tower of Babel. We shall realize that although we tear aside the veil that hides the last secret of the material universe, we can never take away the enduring reality that makes things pure and noble and beautiful. We shall find that however hard it is to see even the closest things clearly, there are some glad certainties that can never grow dim. We shall learn in quietness to refresh our soul.

I heard a broadcast voice utter three great words: "Justice, Freedom, Fellowship"; and perhaps these sum up the worthiest aims of all existence, and so of every single life. The individual dies and disappears, but our great profession continues, perfecting itself through change succeeding change. I see the mighty loom of the universe at work, and the strands of its warp are old things, long known, like birth and death and love and hate; others as old, but discovered only yesterday, like protons and electrons and the transmutation of elements; and still others whose nature cannot as yet be clearly discerned. I myself and all my fellows are the weft, passing to and fro among the alternating threads to make the pattern of the piece that stretches between the two infinities, putting into it every bit of us, our faults, our excellence, our frequent negligence, our strong endeavour. And I perceive that without each one of us, however little or however much we contribute to the finished web, the unending variety of the design cannot be fully worked out.

Discussion before The Institution, 19 November, 1925.

Mr. J. Swinburne: The author has rightly treated his subject very widely; and I will follow his example, and begin with the general or school education of a boy. Education should, I suggest, (*a*) enable a man to earn his living, (*b*) make him a good citizen, (*c*) teach him how to be healthy, and (*d*) enable him to enjoy his leisure. The early education of a boy cannot well be vocational; but at present it is nothing more than iniquitous waste of the best years of a man's life. Beyond reading and writing, and sometimes elementary arithmetic, the young man from the public schools and universities really does not know anything that counts, and cannot earn his living. There was an early civilization in Egypt, and the Egyptian astronomers and engineers did work which was very wonderful for the time. I may mention incidentally that the engineers were priests. When the more barbarous Greeks overcame Egypt they absorbed their knowledge. Later the still more barbarous Romans overcame the Greeks, and absorbed their knowledge. It was then the fashion for Roman highbrows to admire the culture of Greece, probably unaware that it was largely of Egyptian origin. Then when the Roman Empire fell, mediæval Europe was completely controlled by the priests. In order to keep the public ignorant the priests kept Latin to themselves. The Bible, for example, was in Latin, so that laymen should not learn its contents. The clergy were the only people supposed to know anything, and what they knew, especially Latin, was considered to be learning. Even scientific men wrote in Latin. The clergy had complete control of education; and their whole object was to bring people up so as to support the Church. In addition to that, a priest has a type of mind which has immense reverence for the authority of earlier ecclesiastics, and a hatred of any reasoning, or knowledge of facts. The result is that education has developed along narrow clerical lines. The priests kept Europe in the dark or retarded civilization about 1 000 to 1 500 years. They do not now prevent knowledge directly, as their teeth have been drawn; but they have left us a legacy of bonds, if one can use such a mixed metaphor, and we are only just beginning to throw them off during the last two or three centuries. Education, as it is now, consists mainly in training the memory; or exercising it, and letting its exercise train it. There is not even any systematic training of memory. The stuff that the memory is exercised in acquiring is not knowledge. A language is not knowledge—at most it is a means of acquiring knowledge; but had either the Greeks or the Romans any knowledge worth our acquisition? The author mentions Keats. When some highbrows were appreciating Keats, a mere person asked "What is a keat?" The highbrows may really have liked it, or have thought it was correct to admire all the conventional classical allusions with which Keats is

saturated; but it is quite likely that the person knew more than the highbrows. The knowledge of the "educated" man counts only because others have it, and not to have it is a drawback. Its value is not real; it is purely conventional. Ability to epitomize the "Catalogue of the Ships" is of no value whatever, and does not raise an Englishman above a Hottentot. The person who asks what a thebe is but knows that he does not drink down his throat, is to that extent superior to the university man and the Hottentot. There is no hope for boys' education until it is got out of the hands and influence of the clergy. The clergy cannot now control education so as to preserve their pre-eminence by keeping laymen ignorant, but they run it along obsolete and wrong lines. It is difficult now to realize the power of the clergy in the past, as school history books do not mention it. For instance, up to the sixteenth century parsons held many of the most important and lucrative public positions. It is said that in the early part of the fourteenth century very nearly half the soil of the kingdom was in the hands of the clergy. Even now the architecture of the Law Courts is ecclesiastical, the law terms are those of the Church year, and some of the judges change their robes according to the church seasons. But the greatest evil at present is that people admire, and therefore try to cultivate, a type of mind which depends on memory, does not reason or think for itself, is subservient to authority and precedent, and is really stagnant. Engineering is the essence of common sense and the perfection of applied logic. When an engineer is tackling a technical problem he uses his logical brain. When he discusses anything outside his special subject, such as any of the public questions of the day, he does not apply his logical mind at all. He is just as stupid as anyone else, because he uses only his fallow mind, and is just as full of the ignorant prejudices we call opinions as is anyone else. Some years ago there was a public discussion among engineers on "Free Trade and Tariffs." It was clear that the disputants thought the question could be settled without any knowledge or study of economics, by the application of vulgar sense. In designing a new kind of polyphase machine an electrician does not depend on vulgar sense, nor does he make it according to the opinions of some class, or in accordance with the leading articles in his favourite daily paper: he studies electrotechnics and uses his brains. If he has to design a boiler house, he does not say "I advocate phlogiston; down with those who believe in the caloric theory." As engineers use their logical minds in connection with boiler houses, both the phlogiston and caloric notions are dead long ago. Now the dynamic theory of heat is not a century old, but no one questions it. The theory of international trade is a century and a half old, but it is not generally understood, because, being a matter of general and not individual concern, even those who have trained minds do not apply them, but approach the subject with their fallow minds only. A democracy is by its very nature a community of fools governed by the greatest of the fools. But it does not follow that all the fools are fools in every way. Every individual may be sensible enough in his own work, where he uses his trained mind, and quite foolish about all public matters. It may be asked how an engineer who wants to apply his trained mind to matters of general interest such as poverty, war, or narrower questions such as wages, housing, international trade, is to do any good. Is he to go into Parliament? If he talked sense at the election no one would vote for him: and if he could get into Parliament and talked sense he would be of as little use as J. S. Mill was. Is he to improve the world by voting wisely? There is no opportunity. Two candidates are up. Neither has any knowledge of sociology, economics, finance, hygiene or anything else of any value. Both are ambitious for self-advertisement only. To anyone who has thought, both their policies or collections of policies are idiotic, and are merely sops to the prejudices of the ignorant; and the engineer feels that it is a national calamity whichever gets in. Suppose he votes; his vote is negatived by that of some hooligan who believed something one of the candidates said, and accidentally voted for the other because he was too far intoxicated to know which was which; or by the hooligan's wife, who had been got at by the local Womens' Federation For Putting Themselves In Evidence. Now in engineers' society the layman will not air engineering opinions, because he realizes he is in the presence of people who know, and he does not like to make a fool of himself. If the same layman meets a sociologist he will air his opinions on social questions without realizing what an ass he is, because he does not understand that there is anything to know. If the majority of engineers, or even a small percentage, were to apply their active minds to public questions, the average man would eventually realize that he was always making an ass of himself, and in time people would grow to be afraid of expressing ridiculous opinions, and would study public questions out of mere self-respect. If a proportion of the numerous engineers of this country used their trained brains on public questions, it is quite possible they would start a leaven which would, in time, leaven the whole lump. I do not believe they will.

Dr. S. Z. de Ferranti: One conclusion that may be readily drawn from the paper is that however great knowledge is, character is greater still. The author has dealt principally with the professional engineer. The term "engineer" is very broad and, in a sense, somewhat indeterminate. I do not think we can be all quite agreed upon the definition of an engineer. I should like to remind members that outside the engineering profession (and in that term I include the makers of machinery just as much as the writers of specifications) there is an enormous class of engineers, and one which in these present days is growing extremely rapidly. To-day there is a great deal which is mechanical; we all desire to enlist mechanism to lighten our tasks. We use a steam engine or an electric motor, or a combination of them, to do the mechanical work which once was done very largely by manual power. A business man instead of writing innumerable letters employs a shorthand writer and a typewriter to lighten his labour, and so gets through a great deal more work than it was possible for him to do before. Perhaps some day when engineering has developed it may be possible to

dictate into a machine which will simultaneously type a letter, or there may be some better instrument invented for conveying a message and recording it. From time to time various devices are invented and put into practice which lessen labour, but none of them can be fully useful unless they can be dealt with by engineers. Hence it is fortunate that the number of engineers in the world is growing so rapidly. The motor-car, which has been with us many years, has done a good deal to make mechanical engineers of the bulk of the population. When I say " make mechanical engineers " I mean to say giving people mechanical knowledge which enables them to handle machinery carefully and to exercise some care in order to keep it going properly. Wireless telephony, which is a much more recent thing, has made us all into electricians. To-day an amateur handles not only a wireless set, but all the various contrivances he uses, with an extraordinary amount of technical knowledge. In fact, the great advancement which has been made in wireless telegraphy and telephony—the development, really, of the whole thing after the original idea was given to the public—has been brought about by the amateur electrician, another form of engineer. And it is more than ever certain that the great bulk of the population of a country will in the future have to be fairly good engineers; that is, if we wish to live (I speak in the physical sense) with the greatest comfort in respect to the amount of effort we put forward. I should like to touch on another side of the question. The professional engineer has very often to do much more than develop and perfect, and make useful mechanical things. If he has ideas which he thinks he can work out to the point when they will be useful to the community, thus fulfilling one of the author's ideals, he has first to obtain the means of bringing about this result. That entails the use of his persuasive powers upon people to come to his help to enable him to carry out the work of investigation and construction and the putting into practice of his ideas. For this purpose a general knowledge of character becomes of very great importance. Just think of the position of some of the great engineers of the past. Think what George Stephenson had to do to persuade people to build railways. Surely the engineering of men is a more difficult task than the physical engineering of things. When George Stephenson was building the Liverpool and Manchester railway he had to cross Chat Moss—a terrible place to deal with. Many people thought that the railway would never be taken across it, but he was determined to do it, and he did it, but he had to go week after week to his Board and tell them that the embankment, or the way through the Moss, was no nearer completion than it had been a few weeks before. The material that he used kept sinking. It seemed as though the ballast for the line to make up the permanent way was being poured into a bottomless pit; and I am sure that the greatest mental effort and the most wonderful personality must have been brought to bear in so keeping up the courage of those men that they went on and enabled him to bring that engineering work to a success. Take another great man, the French engineer, de Lesseps, who made the Suez Canal. Everybody seemed to combine to discourage him, to tell him of the impossibility of the work, the uselessness of it when it was done and the undesirability of having such a thing at all, but he had that high courage which enabled him to go ahead in the face of difficulty and he persuaded people to give him that support which was necessary to carry out that great work. I have had some little experience in my own way in trying to develop things electrically in the City of London. A great many people said that it was ridiculous to try to bring current from a power station down the river to supply London. They said it would be fatal, and our opponents—I think quite rightly from a business point of view—even went so far as to get an ordinance passed that this high-pressure current was of such a dangerous nature that it ought not to be used in the Royal Palaces and public buildings. They succeeded, and we were handicapped in consequence. That is just an example of the difficulties that we continually experienced. In those days there was no machinery with which we could carry out our ideas. We had to scheme out everything for ourselves, and everything that we did failed, and yet we had to go on devising other means. Then there were the risks which had to be taken. It certainly was, in the then state of electrical engineering, a very dangerous thing to handle 10 000 volts. It was expressly stated in the Board of Trade Regulations that no part of the circuit should be connected to earth. It was essential, with a system which should give the necessary safety for such a supply, that the conductors should be earthed at the generating station and at the substation, and for earth provision to be made in other places; and one had deliberately to break the law and do what one was prohibited from doing, and take the personal risk of that in case anything went wrong and people were killed or any great injury resulted. The engineer experiences all these difficulties. He not only has the mechanical and electrical problems to deal with, but he also has to engineer people if he wishes the country to have the benefit of what he thinks right. I do not complain; I think it is a good thing. I think that opposition does a great deal of good, just as a critical discussion is very valuable before any new idea is adopted.

Mr. C. E. G. Hinshelwood: As Dr. Ferranti has just said, the ideals set forth by the author are indeed very high, and it seems to me that, although it is easy for the higher class of engineer to follow those ideals and to absorb them, it would be a great asset if some of these ideals could be absorbed by the working class. If that were so I am sure that a great proportion of the present industrial troubles could be solved. In all trades union disputes the worker thinks mostly of himself and pays but little consideration to the community, whereas if he followed the author's suggestions he would be able to help not only the nation but industry as well. From the point of view of the education of the engineer, the author has detailed various schemes which can be followed, and has said that it is desirable for engineers to be more carefully selected. At present many hundreds of engineers are produced every year, and out of these only a very small proportion can ever hope to gain success in engineering. If the selection were more carefully made, the right men would get to

the top, and the rest would not have ambitions instilled in them which they can never hope to attain. The average engineer would then have a better chance of getting a good appointment, whilst those who are not really engineers at heart could turn their attention to other professions.

Mr. W. Day: The ideas embodied in this paper are characterized by exalted aspirations and generous enthusiasm. Nevertheless, in my judgment the author's treatment of his great theme is somewhat disappointing and inadequate. It is disappointing for this reason: A great deal, if not most, of what is contained in the paper is equally applicable to all professions and to all honourable callings and has no special significance for the engineer as an engineer. Practically the whole of Section (1), and the greater part of Sections (4), (5) and (7), with the alteration of a few words or the elimination or addition of a sentence, might be taken to apply to all callings. I consider the treatment to be somewhat inadequate because the author does not sufficiently emphasize and stress the unique and permanent contribution of engineers to the common weal, to which I hope to refer later. In Section (3) the author suggests that he believes in the possibility of a social organism arranged with geometrical precision and it appears that he favours some form of academic selectivity for the engineering profession, ultimately involving a limit to the number of engineers. If that were theoretically desirable—although of course in practice it is absolutely impossible—for the engineering profession, then it is equally desirable for all professions and indeed all callings. Assuming, however, that such limiting conditions are possible, I should like to ask the author what he would do with the residue of the population. Carried to its logical conclusion, his proposal amounts to State regulation of birth control, which may be scientific but is certainly not humane. Then again, with regard to the academic selection for the entrance to any profession, we know that insight into the potentialities of personality is extremely rare. Distinguished men have spoken here to-night of men who have overcome great obstacles, but will anybody have the temerity to suggest that those great qualities were discovered by their teachers? They were developed in after life by dint of overcoming obstacles. The proper solution to this question seems to be the open door to all duly accredited persons. This method gives the nation the greatest possible area from which to select. Again, many of the statements contained in the paper are, I submit, too nebulous to be of value. Take the reference to the lethal chamber. What does it amount to? It is of no practical value whatever, even if we could determine, in any section of the community, the potentially unfit. The author refers to unclimbable rocks, and he suggests that free meals, free education and doles are death-dealing proposals. But he does not suggest what should be put in their place at the present time. No statesman has ever considered the free gift of these things as desirable in itself. This has been done to meet special emergencies. Statesmen cannot amuse themselves by constructing hypothetical Utopias. I think that the contributions which engineers have made to the common weal consists in this—that they have continually extended the powers and elevated the happiness of mankind, and that more than any other single profession, not excluding the medical, and certainly not excluding the theological. The progressive application of increasing physical knowledge has constituted, and does constitute, an exceedingly fruitful contribution to the construction, maintenance and improvement of the fabric under which men dwell. That, in my opinion, constitutes the peculiar, the unique, and the permanent contribution of engineers to the common welfare.

Mrs. M. L. Matthews: The author says that the safety of the future depends on the well-directed effort of men of wide and clear vision contriving to increase the common good. I have seen this gift of vision described as the "spirit of progress"—defined as "the desire to know what constitutes true success and the willingness to take the patient steps which lead to it; the desire to correct errors, traits and tendencies which retard progress and the willingness to receive new ideas and to act upon them; the desire to act from sound motives and the willingness to give up false and temporary success for vital growth; the eagerness to utilize every wholesome opportunity; the enthusiasm to strive for excellence for its own sake and the energy to push on, pausing only when the victory is won." The author says: "The nation desires each of its members to have the fullest opportunity of self-expression." If we have wisdom and knowledge enough to express our best selves, how good it is. Nowadays, however, the term "self-expression" takes the place of that good old-fashioned term "self-sacrifice." One wonders how much of the industrial unrest of our time is the result of a mistaken clamour for self-expression when life and the world and service never called more insistently for self-sacrifice. How frequently one hears the obvious shirking of a duty for more congenial effort expressed as a fulfilling of the need for self-expression. And yet the whole due and duty of man, whether engineer or artisan, poet, priest or peasant, cannot be expressed in terms of self-expression or self-sacrifice; in fact until we proceed a step further than self, i.e. to future generations, whether as workers or as a people, we shall not grasp the meaning of life, nor its message, nor its fullness. It is well-expressed in this thought from Ruskin: "God has lent us the earth for our life; it is a great entail. It belongs as much to those who are to come after us and whose names are already written in the book of creation as to us; and we have no right, by anything we do or neglect, to involve them in unnecessary penalties, or deprive them of benefits which it is in our power to bequeath. And this the more, because it is one of the appointed conditions of the labour of men that, in proportion to the time between the seed-sowing and the harvest is the fulness of the fruit; and that generally, therefore, the farther off we place our aim, and the less we desire to be ourselves the witness of what we have laboured for, the more wide and rich will be the measure of our success." Whilst then, it is the *due* of the engineer to reap his full of the harvest his work and talent have brought him in the present age, let him keep well in mind that the *duty* and privilege of caring truly for the future of engineering

and the engineer is his: and this he may secure most adequately in "finding the engineer." I suppose that the ideal is still that a profession or business should pass from father to son, and where it is practicable to give a schoolboy with a turn for engineering a certain judicious freedom of the works the results can be most beneficial in after-life. Youngsters, before that age of self-consciousness creeps on, get an insight into the hearts and lives of the workers that is never granted them in later years and may stand them in good stead in after days. Impressions of work, processes and methods are subconsciously absorbed in interested watchings of some one of youth's ideal heroes of toil while much of interest is shown them that would be kept from more experienced eyes. Then it should be the pleasant duty of the older man to choose out the promising youngster and give a wise and helping hand in his career. As in stock rearing, it is not the man who can choose the champion when it is priced at 1 000 guineas who has the insight of genius but the man who can pick it out in the rough and turn it out, through training and competent handling, the unbeaten pride of the show ring. And so the man who is a judge of men and character should be able to mark and select the coming man and handle and train him for his future good and the good of engineering. If such a man have faith in his own destiny, he will find no fear in this. The author recommends the study of the great writers and poets in order to obtain a sense of the fitness of words, and then gives some valuable advice in this respect. I would firmly endorse this and recommend their study as an aid to right thinking, wisdom and general guidance. It is a strange and regrettable fact that at the time when it would be most helpful in a young man's career there is, if not a positive distaste, a decided disinclination on the part of youth for the literature which contains the helpful and thoughtful advice from the rich experience of the master minds, who have found the real road to success in the true things of life, spiritually and materially. For though youth would chiefly benefit by its perusal, it is often the older man who best appreciates such literature; because if he has himself, however haltingly, endeavoured to walk in the straight paths of wisdom, experience enables him to enter into its truths; though he is always conscious of an underlying regret that this taste for good literature did not come to him in the morning rather than in the evening of life. If youth would but realize it, success is for him if he will not fear to dig deep down into the true and lasting things of life. Thirty minutes or an hour a day spent with the master thinkers will provide him with a treasure house upon which to draw as the years pass. A man may be called upon to speak at a moment's notice. If he speaks well it is because he draws from a storehouse of well-nourished thoughts and impressions garnered throughout the years. Men's careers have been marred by basing their action on unsound theories of life and business, and a change from a wrong thought to a right thought may open his eyes to a broader field of opportunity and activity. Thoreau says, "I know of no more encouraging fact than the unquestioning ability of a man to elevate his life by conscious endeavour." More sure than anything else is the value of a right thought. If a man will be positive, a personality and not merely a person, let his thoughts be straight and true. Thought is a creative force. And even as an engineer designs his masterpiece first in thought, so a man may design his life that it may be built four-square, by taking heed to his thoughts. Let him hold firmly in mind his ideal of what he would be, water it continually with confident assurance of achievement, do faithfully and well his present duty, however far it may seem from his ultimate hope, and he shall achieve miracles; and the greatest miracle will be that the good has come by such natural means that when it comes it seems no miracle, but something that was bound to happen. There is not a successful man to-day who cannot look at some achievement in his life that is not more than he at one part of his career could ever have dreamed. Whether he realizes it or not, a man's whole career depends on his attitude of mind, whether it is straight and clear and sound. Give the young engineer a sound, true mind in that sound young body of his, and his due, his duty and his future are well assured. And if there be one who has not yet learned how good it is to lean in faith on our All-Wise Father, this for his consideration and the good of engineering: "In the darkest hour through which a human soul can pass, whatever else is doubtful, this at least is certain. If there be no God and no future state, yet, even then, it is better to be generous than selfish, better to be chaste than licentious, better to be true than false, better to be brave than to be a coward. Blessed beyond all earthly blessedness is the man who in the tempestuous darkness of the soul, has dared to hold fast to these venerable landmarks. Thrice blessed is he who, when all is drear and cheerless within and without, when his teachers terrify him and his friends shrink from him, has obstinately clung to moral good. Thrice blessed, because his night shall pass into clear, bright day." (FREDERICK WILLIAM ROBERTSON.)

Mr. B. O. Anson: There are many of us who think that there is something wrong with engineering, and particularly electrical engineering. It is difficult to diagnose the complaint and to ascertain exactly what is the remedy. A few years ago I attended a dinner at which Mr. Atkinson, who was then President of the Institution, made a speech in which he recounted certain failings in the development of electric lighting, referred to delays on the telegraph and mentioned the costliness of the telephone in this country. The burden of his speech, however, was that although it is necessary for engineers to push forward with vigour, it was not to be assumed that the fault of the present state of affairs is always with the engineer and he used the expression: ". . . we engineers are in some way or another being cheated of our victory over time and space." In my opinion that summarizes the situation exactly and it is for us as engineers to discover the reason. Amongst other things I think we may say that there is a feeling amongst business men and administrators generally that engineers are not competent to occupy big posts. Lord Balfour on one occasion said that one of the most difficult tasks he had at the Admiralty was to reconcile the conflicting opinions of

experts. Other eminent people have made similar statements, and we as engineers have to challenge the general impression that is evidently abroad that people who are experts are, of necessity, unsuitable to be general managers or managing directors. Perhaps I might be permitted to read an extract from an article that appeared in the Commercial Supplement to *The Manchester Guardian* of the 5th November. This article was written by a cost accountant on the subject of cost accounting, and the importance of this subject was enlarged upon. I suppose that, as engineers, we all appreciate the importance of cost accounting, but it is hardly likely that we shall appreciate the following: "The training received by a cost accountant, and his necessary habit of bringing every business problem down to bedrock fact, has made some of the most progressive firms in the country take the logical step of making the cost accountant a director. And when one thinks of it there can scarcely be any better school for directors than that of really thorough cost accountancy. It enables a man to see a business steadily and to see it whole, which is just what the ordinary technical man, by virtue of his technical training, cannot do. And also, unlike the technical man, the cost accountant has no axe to grind; he is not personally implicated in conclusions, and is not tempted to avoid them because they are unpleasant." The announcement of this article was placarded all over London three weeks ago, and it was evidently regarded by *The Manchester Guardian* as one of considerable importance. The point I want to make is that engineers are not regarded as suitable individuals to occupy high business positions. It is no doubt well known that the Civil Service is controlled by a body of men known as administrative officers. These officials occupy practically all the highest posts in the Civil Service, and in many Government Departments a large amount of work is of an engineering or highly technical character. It is a very rare occurrence for engineering officers to occupy these high administrative posts. I think that the time has come when engineers generally should make a special point of developing themselves by special business training and engaging in public propaganda so that they will more naturally fall into higher positions than they do to-day. Considering the great effect of engineering on modern civilization, it is inevitable that in course of time more and more of an engineering atmosphere will drift into the general business world, and it seems that engineers will have to meet the position and even to follow the example of lawyers and take their place in the House of Commons. It is perhaps not too much to say that eventually the engineer must fight the lawyer for the control of the country.

Mr. P. Dunsheath: I imagine that the Papers Committee may have had some misgivings about accepting a paper so unorthodox as this. Though not a long paper, it is packed with valuable, inspiring and original suggestions for all engineers, and I think that I shall not be alone in reading it again and again. To take one small point in the paper, the author advocates flexibility of ideas. How important this is, but how very rarely is it appreciated. In my own particular branch of engineering—research—I find it very necessary to impress on my colleagues the fact that because they believed a certain thing 12 months ago there is no reason for their still continuing to believe it. It is surprising how people object to changing their views. The author's comment on the choice of words should be read by all engineers who have to write specifications or reports or letters. It seems to me that what we really lack is simplicity of language. We should not say "The answer is in the negative" but simply "No." The author says "If we let a child live, we must in decency see that no great unclimbable rocks are left lying in his path." I agree with the author's treatment of that point, but I think that the metaphor is dangerous as he uses it. It suggests that we must remove difficulties, but I think the whole spirit of this paper is that character is formed by difficulties. There is far too great a tendency to-day to smooth the path for everybody, with the result that initiative is destroyed and the prosperity of the community suffers. I do not think we should preach comfort too much. That which appears unclimbable to-day will not be so to-morrow, and in this connection I should just like to quote some words of J. J. Stephens: "He finds out what he cannot do and then he goes and does it." With regard to the Section dealing with the finding of engineers, I think that the author's remarks are very well illustrated by what happened in the recent war. Technical units frequently had to draft into themselves men who were not engineers and it was very surprising and interesting to notice the natural way in which a man, who had never done engineering in his ordinary commercial life, took to it. I knew a case of a lawyer who was so drafted and who was put on engineering jobs; he did them in a far better way than many trained engineers. Of course, on the other hand, many of those temporary engineers were utter failures. I am rather dubious about leaving the question of selection to schoolmasters. I do not think there are many schoolmasters who really understand what makes a successful engineer. There is some truth in Bernard Shaw's gibe: "He who can, does. He who cannot, teaches." I think the best way of dealing with the matter would be for certain men with insight, such as the author, to set up as consultants. Parents would surely willingly pay adequate fees for a consultation on what to do with their boys.

Mr. W. J. John: As a teacher of engineering I am chiefly interested in Sections (3) and (4) of the paper, namely the finding and training of engineers. To the teacher at the engineering college come young men who have recently decided that they are to take up engineering as a profession, and it is the teacher perhaps, more than anyone else, who realizes how tremendously important it is that they should be fitted by natural aptitude for the profession they have chosen. In my opinion one important matter has not received in this paper the consideration which is its due. Suppose a class at an engineering college is carefully and successfully selected by vocational tests. Suppose further that the curriculum to which they are trained is that given on page 196. On whom does the success of the training depend in its entirety? It depends on the professors and lecturers —the teaching staff at the college. When the training

of engineers is being discussed, I think this side of it should receive consideration, and there are one or two points I should like to put forward. In my opinion the engineers who comprise the teaching staff at an engineering college are separated by too wide a gulf from their brother engineers in works. As a consequence I am afraid that to many students there must be a rather artificial air about college engineering. It is hard for them to believe that when they enter the college they are being trained to become engineers and that it is not all a continuation of school. Things are so similar—lecture rooms and teachers—blackboards and chalk. There is not sufficient smell of oil, not sufficient rumbling of machines. The gulf, in my opinion, can only be successfully bridged by the lecturer. He must make the students realize the actuality of the work they are doing, which one day will be made concrete in terms of steel and copper. Knowing something of the psychology of the ordinary student, I say that the influence of the lecturer will be much more potent, his power to bridge the gulf greatly enhanced, if the word goes round "He has just come back from the engineering works of Messrs. So and So." He will seem a real engineer to them then. Would the young doctor being trained at a hospital have so much confidence in his lecturers if he knew they were only telling him how to carry out a dangerous operation and could not actually do the thing themselves? Should not then the lecturer on, say, electrical power be able to carry through the technical calculations involved in supplying a community with power and light as well as a brother engineer who earns his daily bread by so doing? Should not the lecturer in electrical machine design be able to design a generator or transformer or rotary converter which would be approved of by the specialist designer in the works? Surely lecturers ought to be able to do what they talk about doing. There must be a limit, of course, to what is expected of a lecturer, but much more could reasonably be expected of him if more were done to help in fitting him for his great task. I believe that a scheme such as I outline now is quite feasible and would produce good results. It is not new, but the importance of it renders an apology unnecessary for introducing it here. The college authorities should give engineering lecturers one year's leave in four; three years at college, one year on leave. The engineering manufacturers of the country should be prepared to give the lecturer an executive post in a works during his leave and allow him special facilities to make himself fully conversant with the latest practice. I know of no single thing which would more positively improve engineering training as given at the colleges than this scheme where special provision is made for keeping engineering lecturers fully abreast of the latest practice in their subject. The cost of this suggested innovation would be trifling. Its results would be considerable. With lecturers such as these would be, the specially selected students would reap fuller benefit from their training. The lecturer would be the link between college and works; keeping in touch with both and removing a little of the troublesome make-believe from the engineering lectures, making his subject at college a living one illustrated by examples from current engineering practice and not from that of a decade ago. All the splendid work which may be done as regards selecting the right men to be engineers, and the correct curriculum to which they are to be trained, will not have its full value unless attention is given to the problem of selecting the right men to teach them at the training colleges, and then giving these men an opportunity to keep abreast of current engineering practice as a complement to their acquirement of ripe teaching experience as the years roll on. The paper contains one sentence which appeals to me very particularly; it is this: "All the more then must a young man be thankful now if he can find an older man with knowledge willing to take his hand and lead him on." It was my good fortune when I left college to become the author's assistant. In him I found the older man with knowledge and I have never forgotten how well and how patiently he led me on. I do my best to repay that great debt now—not to him, that debt in the nature of things I can never repay. But I am now myself an older man with some knowledge, and to the younger man I try to hold out a helping hand. It is the one way I can repay the great debt I, personally, owe to the author.

Mr. D. G. Hurlbatt: I still think that overseas work in particular is not yet so highly civilized and therefore specializable as to render incorrect the old saying "an ounce of practice is worth a ton of theory." There are many people who can rise to important, well paid and highly useful positions mainly through practical and not academic experience. In view of the present hopeless state of affairs in England, I think that this paper should be sent to all the well-known teachers in this country, and also to all professions, Members of Parliament, and industrialists. I feel that the paper should not have been first read from the rostrum of an engineers' organization. The engineering profession is associated, in the public fancy, with hard ways, hard blows, hard deals and hard words. The engineer gets his due vastly more in the United States than elsewhere, especially the United Kingdom, hence the greater prosperity of the States. I do not think that the English engineer pays less attention to duty than does the American engineer, but he gets less chance and encouragement, owing to the lower ideals of the politicians in this country. I hope that most of the author's ideas will prevail in the future. This is not a "quick" country, but it is not so "dead" as many seem to think, and this little pill with its various coatings (as we may term the criticisms) in repeated doses will not do Englishmen any harm. It seems a pity that big annual events like the I.M.E.A. Convention cannot be made even bigger—more collective—and include, for two or three days at least, fair-sized deputations from each and every profession, etc., and also a large deputation of Members of Parliament, when such pills could be swallowed in pleasant, useful, collaborative unison, with more effective results. It seems cruel to criticize such a poetic simile as that on page 200, but a loom has to be driven and its output distributed. From the tone of the whole paper I should guess, perhaps wrongly, that the author favours the group drive, with mass consumption for use, and not the individual, personal-gain, motor, so to speak. As for aiming too high, it is certainly better to give than

to receive, but the margin of ideal here seems rather on the high side in this respect, and also in everyday life now for engineers.

Mr. E. Kilburn Scott: Some time ago Mr. Hilaire Belloc said that the way to carry out reforms was for a determined group deliberately to set to work to "capture the executive," by which he meant the controlling positions in public and private affairs. As a result of long and rather varied experience, I have come to the conclusion that engineers will be forced to act on this principle. A step in that direction would be the formation of an Engineering Foundation on similar lines to that in America, because by co-ordinating the various engineering and scientific societies of the country, the status of engineers would be raised socially and politically. Records of those now in control show that some are related to the aristocracy, some are financiers, many are members of the legal profession, especially barristers, whilst newspaper proprietors have become menacingly powerful since the war. Almost all these men have been trained on the old classical lines of public schools and older universities, which cultivate the habit of looking back to precedents for guidance. It is peculiarly the habit of mind of members of the legal profession. Scientists, engineers, chemists, and especially electrical engineers, have completely changed the art of living, even as compared with the last century, and therefore the men who are required for executive control should have the scientific, forward-looking minds which arrive at decisions by reasoning and research. For a long time the classically trained have been out of their depth, and as scientific and engineering progress speeds up, they get further behind every day. They must inevitably drop out of the running, in which case the scientifically trained will have an opportunity of taking their places. For some years it has been my duty to teach young engineers who were just about to leave college, and I always found some in every class who had social and other qualifications that fitted them for leadership and for public life. Such men should be encouraged to take part in civic affairs in addition to their engineering work, because by doing so there will in time grow up a body of scientifically trained men who have also the experience to take any position in national affairs. Unfortunately, some teachers of science and even of engineering are more academic than practical, and by lectures and freak examination questions divert the attention of some students to mathematical gymnastics. It interferes with their gaining the intimate knowledge of human nature that follows from learning the handicrafts of engineering work. Engineering experience in workshops and on outside constructional work is of tremendous advantage from the point of view of training leaders, and it is beyond compare better than the knowledge gained from books in professions such as law and accountancy. By working as bench mates with workmen, engineers get the first-hand information of human nature which enables them successfully to handle people in any situation. I am firmly of opinion that a great deal of unrest in industrial affairs is due to individuals being placed in executive and political positions for which they have no training or real sympathy. It is nothing short of disgraceful that there are concerns in this country, wholly or partly engineering in character, which have on their directorates lawyers, accountants, retired soldiers, promoted book-keepers, and company promoters. One often hears the parrot-cry that business men are necessary in engineering, but my experience of the business men so-called who batten on the engineering profession and especially on inventive engineers is that their main characteristic is a species of "low cunning." Why is it that several English firms are making hundreds of electric locomotives for use on railways in Argentine, France, India, Japan, etc., and that so few are being made for railways of this country? It is because the men in control of our railways have no first-hand knowledge of electric traction. Consider how the situation would be changed if on the directorate of each railway company there were men with working knowledge of electric traction. Why should there not be at least one electrical engineer on the directorate of every engineering concern in the country? Wherever electrical power has made headway in a particular industry it will be found that it was because some younger man with electrical engineering knowledge has got into a controlling position as manager or director. That is what I mean by saying that it is high time that engineers should set out deliberately to "capture the executive" whenever and wherever they can. An example of retarding engineering progress is to be seen at Lots Road power house, where 64 old boilers are used for raising steam, when about a dozen boilers of modern design could do the work much more efficiently. From the point of view of boiler makers who supply spare parts, it has been good business, but it is poor engineering to have such an ancient boiler plant in existence at the present time. In the Dominions and the United States, where engineering concerns are controlled by engineers, such inefficient boilers would have been scrapped long ago. My experience as a resident in Australia and the United States leads me to say that if we are to maintain this country as an engineering centre we shall have to go in for the scrapping habit a good deal more. There are men in this and other engineering Institutions who are excellently equipped, not only to direct engineering concerns, but also to lead in affairs which are not of that nature. Some have managed to capture positions already. I have in mind a consulting electrical engineer who, after electrifying a cement works, was asked to join the board, and as a result of his executive ability in that position is now managing director of the concern and some others. It is quite possible that such members of the Institution as are fitted for public life will have to be "boosted" into it because they are modest, or they wish to live the "quiet life," but the other members must encourage them to take such positions and if necessary work for them to get in.

(*Communicated*): At the meeting when the paper was discussed, I referred to one who would make an ideal Member of Parliament if he could only be persuaded to try. I say that, because he started his engineering career in a steam locomotive works, then designed mining machinery which brought him into close touch with miners, and subsequently, as head of a large electric manufacturing Association, had to attend to

negotiations of high finance and the personnel of many works. Even his recreation is farming. There are many men of wide experience of everyday affairs in the Institutions. Engineers who are fitted for public life should enter it as a duty to the profession and to themselves. All who have had to attend the hearing of Bills more or less connected with engineering in committee rooms of the Houses of Parliament know of the great waste of public money in paying parliamentary agents, barristers, town clerks, etc., and great waste of time in trying to teach members of such committees who have no technical knowledge. Engineering progress in this country has for years been retarded by inquiries, and talk before committees and commissions, largely made up of men without technical knowledge. It is necessary for the engineering profession to be largely represented in Parliament, because there are many matters connected with the development of national resources, the patent laws, etc., which cry aloud for attention by scientifically-minded men, and especially engineers.

[The author's reply to this discussion will be found on page 229.]

Mersey and North Wales (Liverpool) Centre, at Liverpool, 16 November, 1925.

Prof. E. W. Marchant: I am particularly interested in what the author says about the efforts that have been made by schoolmasters, in particular Dr. Johnston of Highgate, in attempting to select suitable vocations for boys, and training them more or less vocationally. I think that the results to be obtained by this method are rather limited in the case of a large number of boys. The plan undoubtedly works well in the case of boys with very strong natural inclinations, but I have come to the conclusion that a large proportion of boys at the school age have no very definite inclinations—they will go one way or another according to the direction in which they are encouraged to go. The most famous of the "vocational" schoolmasters was Sanderson of Oundle, with whom I had the good fortune to discuss this matter on several occasions. He had very strong views indeed. He started with the assumption that every boy has a very definite vocation in life, and that it was the duty of the schoolmaster to find it out. (I think he was the schoolmaster in Wells's "Undying Fire.") After some experience of the practical working of this system I have come to the conclusion that it is impossible to say definitely in the case of a very large majority of boys when they are of school age, which is the best vocation for them to fill. There is another factor which should be taken into account when vocations are to be chosen. Although it is referred to in the paper, that is a point on which I do not think sufficient stress has been laid. A schoolmaster cannot say, "I have here a certain number of boys; these are to be engineers, and those are to be something else," and so on. I think that it is necessary to study the possibilities of employment. It is no good dividing the boys of a school altogether in accordance with their inclinations. There may be a preponderance of boys in one direction or the other, and I think a great deal is to be done, and should be done by schools and universities, in trying to exercise this kind of selection. It is necessary so to train boys that they will fulfil the needs of the community. That is a point which we have had very much before us in the Liverpool University, i.e. to try to turn out boys who will find occupation when their training is completed. There is another point. A great deal of any man's life is occupied in uncongenial employment. I think we all have to spend a lot of time in doing things that we do not care about, and I think, therefore, that a great deal is to be said in favour of the exact opposite of the plan which Dr. Sanderson advocated, that is, to train boys to do things they do not like and to make them work hard at them. If a boy is trained to work hard and do his duty whether it is congenial or uncongenial, then I think that he will be useful wherever he goes. The boy should be given the idea that he is in the world to serve his fellows and not merely to make his own living. It may be said that that is rather an unpractical point of view, but I think it is very important. If an engineer sets out in life with the idea of making his fortune I do not think he will give his best service to the world, but if he recognizes that all he does is of service to the community, and that his work is of the greatest value when it does the greatest service, he will become a much more useful member of society. I am encouraged to quote the last four lines of one of Kipling's poems:—

> "If you can fill the unforgiving minute
> With sixty seconds' worth of distance run,
> Yours is the world and everything that's in it
> And, which is more, you'll be a man, my son."

Mr. J. A. Moreton: I do not share the author's fear that so-called free education, etc., is demoralizing. As a matter of fact these things are not really free at all; we pay for them as citizens in our rates and taxes, and we have the right, without feeling demoralized, to draw on all these fundamental things that are provided by ourselves as a community. If we had each to provide them individually we should never have time to practise our own profession. The author says that some are born engineers, and that others have engineering thrust upon them. I feel doubtful about the born-genius attitude to a particular profession. My experience is that a man who has a fairly good class of mind and has had a good general education will make a useful engineer or useful anything else. The author suggests that we should compel certain people to enter the engineering profession. It is not, I think, very easy or desirable to do this, and who is to be the judge? I should say to a young man: "If you want interesting and hard work and anxiety, be an engineer, but if you want to make money you had better be a shopkeeper." I quite agree with the author that it is useful to have a good knowledge of literature. Coming to the last part of the paper, it is quite true that we engineers have much to teach others and it is good, of course, to be able to teach,

but it is better to be able to learn, and we need not become too proud because we can teach. I often wonder whether an engineer or a dustman is of the more real value to society. The author says that engineers have made life complex, and it is true that machinery has become in some ways a Frankenstein monster. It gets out of control and, instead of us running it, it runs us. We have invented all sorts of machines which kill people indiscriminately without being meant to do so. The engineer has a further duty as a member of society and his responsibility cannot cease when he has made the machine; he must take his part in controlling its proper use in society's service. The dustman at any rate does not invent things which will kill people: he saves us from death in the form of fever and pestilence. So that although we are undoubtedly clever we may as well be humble about it. As Michael Faraday said, "The education of the judgment has for its first and last step—humility."

Prof. C. O. Bannister: Every instructor of engineering subjects should study the paper, and also every student and every schoolmaster who has boys under him who will eventually become engineers. I am not quite in agreement with the author's view in regard to compelling boys to enter the engineering profession and I think that the first sentence on page 195 should read: "We also let some escape into other professions who should be encouraged to come into engineering." The most difficult children to deal with from a career point of view are undoubtedly those who show no indication of interest in some special calling, and it is the parents' and teachers' duty to study these cases and if possible to develop some definite interest. Dr. Johnston has certainly gone further than most schoolmasters in this direction and it is to be hoped that his methods will be more largely used and developed. It is a comparatively simple matter to distinguish a boy with a decidedly engineering or scientific bent from a boy with a decidedly literary or artistic bent, but unfortunately there are many cases in which no definite aptitude can be discovered, and these require special study and guidance. With regard to the training of engineers, there is much to be said in favour of students obtaining an insight into works methods in the early days of their study, in order to enable them to learn something of the application of the principles involved at the time they are learning those principles. In this connection the arrangements made at the Liverpool University for vacation voyages and works experience are most valuable. The scope of the training, as given on page 196, etc., considered necessary for engineers at first somewhat alarmed me, in view of our own fairly full time tables; on second thought, however, I realized that if the types of instruction mentioned in Section A were correctly given, they would inevitably be associated with the development of the virtues and graces mentioned in Section B. This is undoubtedly the case with students who take an active part in sports, student societies, etc. I recently learnt from an American who had visited England to study our methods of training engineers, that engineering courses are being largely followed in America by students who do not intend to become engineers but who are going into banks, insurance companies, large business houses, etc. On page 197 the author pleads for a varied experience; I always make a point of advising undergraduates and young engineers to take advantage of every opportunity of widening their experience and in many cases to make a change in their occupation, even if this does not carry an increase of pay. From a recent experience I can substantiate what the author says in regard to writing. In connection with a recent vacancy I received applications from several graduates I had previously met as their external examiner, and the written applications of several men with good knowledge and good degrees were most disappointing and were sufficiently bad to render even an interview unnecessary. My own experience is that men who are educated in boarding schools or who have had to leave home for their college courses are the best letter writers, possibly because they have had more practice at this important art.

Mr. C. Rettie: On page 196, items (5) and (6) deal with "Infusion of fairness, unselfishness, tolerance, etc.," and "Formation of friendships." In my present occupation I am working side by side with university men who are well educated and have won degrees, and whilst some of them are always willing and very patient to help me in the problems in which I am interested, there are others who are not so willing. I am interested in the abstract theory of the steam turbine and in connection with this theory there is a very interesting problem on the weight of the steam when it leaves the nozzle, described in H. M. Martin's pamphlet on "The New Theory of the Steam Turbine," published by *Engineering*. I tried to get one of our university men into a discussion on this problem, but because I did not understand a mathematical problem in the middle of the paper I was not successful. I think that that is a wrong attitude to take and I make this appeal to the younger generation to have more patience with their elders who have not had the chances of a better education such as is available to-day.

Mr. E. W. Ashby: The author, in his remarks on accuracy of expression, utters a warning to would-be critics. In finding engineers (see Section 3) considerable caution is desirable. A scholar may excel for the time being in a particular subject solely because of the way in which it is presented to him; or conversely he may *appear* unfitted for a certain occupation—although actually his natural tendencies lie in that direction—because he is repelled by the teacher's handling of the subject. My personal experience is that wherever advice or information is sought—in the drawing office or in the works, from designer or mechanic—it is given freely. Obviously tact is essential in the search for information. I cannot agree with the suggestion that boys living at home during their later education are likely to be less proficient correspondents. Taking part in the general topical conversation at home, the student is far more likely to develop powers of expression than he would be when exploring the rather limited range of subjects available for discussion and correspondence as a boarder.

Mr. A. Wynne-Jones: This paper bears on every page evidence of wide reading and deep culture, and contains references to authors of widely different char-

acter. This appears to me to be the side of an engineer's education which is often neglected. Among my colleagues I cannot recall one with whom, so far as I know, I could discuss the beauty and profundity of Shakespeare, or with whom I could discuss astronomy, or languages; and I feel it has been a great loss to me. Prof. Marchant in the course of his remarks quoted, half-apologetically, a verse of poetry from Kipling, but I do not think that any man need be ashamed of having a taste for poetry. The study of literature has an effect on the mind which enables us to deal more easily with the problems of life. The author shows that he has also the faculty of humour —the most precious gift of the gods. It is for that reason that I think he has not done himself justice in the first paragraph, in which he hints at the lethal chamber for the innumerable company who are not doing their best. I think this is rather drastic, and I would anxiously inquire, if every man who is not pulling his weight is to be dealt with in this drastic fashion, what is to become of us?

Mr. W. G. Taylor: It is not often that an engineer comes forward and speaks about these matters in such an able manner as the author has done. This is probably because the art of easy speech in public is given to but few of us. Engineers are apt to become so absorbed in their own business that they do not enter public life to the extent which is desirable. If it were possible to achieve adequate representation of the engineering profession in municipal and national political circles there is no doubt but that the community in general would benefit and the technical man would acquire greater facility in the public presentation of his views. In a paper of this character there is much matter for discussion, and I should like to put forward a few points for consideration. The author has stated that "the confines of our ignorance are not so narrow as they were and the darkness still to be searched is less terrifying than once it seemed." I am not at all sure that "terrifying" is the right word to use in this connection and would rather say "awful," but it seems to me that the wider our knowledge the greater our awe at the spreading field to be explored. I do not understand why the author should recommend the removal of great unclimbable rocks from the path of a child. If a rock is unclimbable it could hardly be removed. However, is it not a good thing for a child to encounter rocks to prove its mettle and assist in the formation of character? It seems to me that the path of the modern child is made too smooth and that the child's future is jeopardized thereby. Certainly the route should be blazed and the helping hand ready, but initial effort by the child should be stimulated. The author, in referring to the loss sustained by the world through the war in which so many able men were killed, mentions "their departure to the place from which no word of these things comes back." Does he not believe that that place is the source of all inspiration? In advocating entrance into public life of specially suitable men one wishes that mention had been made of the body which at the present time is urging the claims of the engineer to be heard as an authority on industrial problems of the day—I refer to the Society of Technical Engineers. It is the duty of every engineer to realize his responsibilities to his profession and country, then to put his shoulder to the wheel—that way lies happiness.

Prof. C. E. Scholes: To those engaged in training engineers on the academical side the paper is full of interesting and provocative points. The definition of a civil engineer drawn up by the Institution of Civil Engineers in 1828 and given on page 194 has been the standard definition in this country for nearly a century. The definition of "engineering" drawn up by the American Society of Mechanical Engineers some 10 years ago is as follows: "Engineering is the science of controlling the forces and utilizing the materials of nature for the benefit of man, and is the art of directing and organizing human activities in connection therewith." To my mind this later definition has much to commend it since it suggests that the engineer has not only to control the sources of power but to utilize the materials in nature and, furthermore, to be responsible for the successful direction and organization of the human element involved. The author has raised an interesting point in the suggestion that a much wider attempt should be made to find engineers by observation of the characteristics of boys at school. I think that the problem is one of considerable difficulty and that the suggested method is open to question. Presumably the decision as to whether or not a boy should be trained as an engineer is to be made at a comparatively early age, but this appears to me to be a great weakness in the scheme. The average boy is a mass of independent variables and it is, I feel, an impossibility to predict the line of his future development. Another factor which must be taken into account is the rate of development of the boy. Some boys mature slowly and their early training gives little or no indication of their future ability. Other boys are precocious and in some cases their early brilliance dies away, leaving them as a spent force with a capacity and intelligence which compares unfavourably with those who have developed more slowly but with greater sureness. In academic life the case of the student who matures slowly is not infrequent, and teachers are familiar with many such students who have developed into first-rate engineers. The scheme suggested would probably prevent the entry of such students into the engineering profession, which would be the loser thereby. The syllabus of a suitable academic engineering training given on page 196 agrees very closely with the training given in the Liverpool University, the only omission here being the instruction and training in hygienics. This may be a desirable feature, but, as Prof. Bannister has already said, the difficulty in arranging a suitable course is the wealth of material and the limited amount of time available. It is not so much a matter of deciding what to put in as to being reconciled to the amount which has to be left out. I think that the academic training of engineers of all branches should consist mainly of the teaching of fundamental principles and that the specialization allowed should be a minimum consistent with the preparation needed for the branch of engineering chosen. As one engaged in this training of engineers I should like to say that the academic training is only one factor, and to stress the importance of the other factors which are essential. No amount of genius or technical ability will

compensate for the lack of character, personality and loyalty. What the world requires and what is best for the engineering profession is the steady supply of trained men of character and courage who, whatever their talents may be, use them to the best advantage and who, because of their character, are trustworthy and loyal. Academic or technical training is a valuable asset, since it enables a man to use his brains and to think clearly, but for the best results this training must be associated with a stable character, honesty of purpose and the desire to do the right thing. Mention has been made by a previous speaker in this discussion, as well as by the author, of the inability of students to write clearly. In spite of repeated efforts made to get students to see the value of this accomplishment, many fail to appreciate the necessity for cultivating the art. In courses where a large amount of laboratory work is done the writing up of the laboratory record book, if done intelligently and consistently, very much improves the style and ability of the student to write reports and this is probably one of the most useful ways of acquiring the art of expressing oneself in writing.

[The author's reply to this discussion will be found on page 229.]

North-Eastern Centre, at Newcastle, 23 November, 1925.

Mr. C. Turnbull: The paper gives us a timely reminder that we are citizens first and that it is our privilege and duty to use our energies for the good of the State. Engineers often keep out of politics because they feel that politicians give too much thought to getting the better of the other party, but there is great need that they should interest themselves in all that pertains to the State to bring about good results there without troubling as to which party is to receive the reward. When we study history we find that historians have a peculiar method of giving to rulers the praise which really belongs to the men who carried out engineering work. The Roman Empire became possible by reason of its roads, bridges, aqueducts and engineering work generally, whilst the British Empire has also come into being largely through the work of its engineers. Much work yet lies at our hands which engineers can carry through if they set themselves to the task. We still waste a year on our childrens' lives in fogging their brains with our jumble of weights and measures. Lord Kelvin said that these were brain-destroying, but I used to think that this was an exaggeration until I recently read some school arithmetics, when I was astonished to find what a muddle the whole thing is. Not only is the jumble useless, but it hinders us from trading with other nations. The time has come when the engineering world should make up its mind to give up this relic of barbarism, and to adopt the simple metric system, so putting us on an equal footing with other nations. I should also like to recall the late Mr. Wordingham's proposals for the improvement of the Institution by the creation of additional departments of activity. The educational department is greatly needed; it would help our textbook writers by guiding them in the teaching of pupils. Our textbooks could well afford to omit many of the absurd problems which now cumber them, whilst they could very well develop many useful ideas which now are neglected. For example, one engineering textbook asks its readers to calculate the time taken for a large tank of water to empty itself through a hole, and gives the result to a hundredth part of a second, although in actual practice the tank would drip for half an hour or so. An educational committee would save students from that kind of thing, and also help textbook writers to deal with points which are necessary to the engineer in his future career.

Mr. W. T. Maccall: There is one phrase in the paper that appears to require further explanation to avoid misunderstanding, viz. "the importance of not doing things ourselves if we can find someone to do them well for us." As it stands, it is rather reminiscent of the perverted proverb: "Never do to-day what you may get someone else to do to-morrow." I am in agreement, however, with the author's real meaning, which I take to be that as soon as a man reaches a position of the least responsibility it is important to realize the necessity of leaving some things to other people, even if he can do them better himself. Otherwise the time comes when they have to be so left, and the result may be disastrous if the deputies have not had any previous experience of such work. With regard to the "finding of engineers," any satisfactory test would be most valuable. The present difficulty is that when a boy has once started on a course of training for engineering or any other profession it is often impossible to change over to a different one. Once I came across a youth who, after a three-year full-time day course in a university, gave up engineering because it was too dirty. He might have found this out sooner, but on the other hand the majority who had reached that stage would carry on even if they had an equally strong dislike of dirt. Another reason that enhances the value of the early testing of aptitudes is the greater length of present-day training. And though the training will in no case be thrown away entirely, as engineering knowledge is always useful, it is still of great importance throughout the course of training, whether in works or in college, to test the suitability of the youth for higher work. Examinations may not be ideal for this purpose, but when conducted by the teachers (works or college) they are a very useful test. With the author's remarks on the actual training I am in general agreement, but I should like to emphasize certain points. One is that the memorizing of results alone is very poor training—what is wanted more is the knowledge of where to find certain things when they are needed, and of the methods to use in tackling new problems when they arise. Another is the importance of being able to use words well, and hence the value of literary training, even when it has no direct bearing on engineering. A third is the advantage of mixing with all classes, so as to be able to deal with the human problems that arise. And a

fourth, which I wish to stress particularly, is the benefit to be derived from travelling in other countries, especially in youth, as was realized in other connections when "the grand tour" was an essential part of every gentleman's training. Finally, I should like to suggest that an important aid to "the finding of engineers" would be to remove the financial barrier by the provision of further suitable scholarships. But, to quote from my address last year as chairman of this Section, this should be accompanied by tests to prevent costly education from being wasted on unsuitable students.

Mr. A. W. Crompton: It will be agreed that, apart from an occasional Presidential or Chairman's Address, the many very important matters with which the average member of the Institution is vitally concerned have not had that prominence and consideration given to them which they deserve. Even when such addresses have been delivered their full benefit has not in general been received, since no opportunity has arisen for discussion and as a rule they have only to be read at one meeting. It may, however, be within the memory of some members present that the Institution has, as a body, appreciated the necessity for engineers to take steps to secure due monetary recognition of their services. It may be of interest, therefore, to quote in this connection the following resolution passed at a Council Meeting held on the 17th October, 1918: "That the Council of the Institution of Electrical Engineers officially recognize the Electrical Power Engineers' Association as the protective Association for engineers qualified to hold a responsible position directly concerned with the transmission, distribution or utilization of electrical energy." Since that time the above Association has fully justified its existence and at the present time the final preparations are being made to put into operation a scheme of training which has been formulated after some 3 years in co-operation with the representatives of the various undertakings acting through the National and District Joint Boards (Electricity Supply Industry). It is hoped, as a result of the operation of this scheme, to secure the right type of trainee and to ensure that a sufficient number of qualified men are available to fill in due course the positions of responsibility in the industry which is growing so rapidly. It is proposed to invite the assistance of the Institution particularly in regard to the necessary proficiency tests. I fully agree with the author, however, that technical qualifications are by no means the only requisite of an engineer. His potentialities for evil as well as for good must be realized. The use made of engineers during the recent war is an indication of what might happen in the future, to the loss of the world in general, unless the morality of all engaged in the profession is of the highest. There is, I think, at least one important omission from the author's summary (page 194) of those constituting the Institution, that is the large number concerned with the transmission and distribution of electricity, e.g. mains engineers, etc., and I suggest that the important function of such entitles them to "honourable mention" rather than inclusion in the phrase "many others."

Mr. C. Vernier: Section (1) of the paper contains, perhaps, a greater number of arresting sentences than is usually compressed within any similar number of words. Its general application would, I firmly believe, provide the remedy for our present ills, most of which are derived from ignorance and selfishness. Let us note clearly that the author's remarks in this Section do not apply only to engineers, but to everyone, high and low, rich and poor, in all walks of life. There is no right in this world which, as he remarks, if properly understood does not carry a corresponding duty to others, and the most despicable of all is the man who demands and contrives to filch what he deems to be his rights without thought or consideration of the rights and of the suffering he may cause to others. Yet we see examples of this every day and especially in the mass where, for some strange and inexplicable reason, men in concert with others will act in a way which they would not do or sanction as individuals. For this the responsibility rests chiefly on those who are called upon to be leaders of men, and in such measure as they have received authority it is their duty to exercise it prudently, wisely and to the common good. There is so much contained in this Section that "an unwise man doth not consider and that a fool does not understand" that it would be possible to discuss it further with great advantage. I must only confine myself to endorse and commend the author's statement with but one comment as to the free meals, free education, doles, etc. These, in the present imperfect state of our social and political organization, are essential, and are only harmful in so much that the recipients have never been taught, or have forgotten, or even deny that in such measure as they are accorded them they are in debt to the community. As to doles, much can be forgiven, for the community itself in these post-war years has signally failed in giving to so many who endured untold sacrifices for it during the war the only thing which can bring them contentment and self-respect; that is, honest work. If the hundreds of millions of pounds which have been spent, having as their only result the deterioration, if not demoralization, of some 10 per cent (more or less) of our working population by idleness, had been spent on useful improvements of the country's industrial facilities, such as docks, railways, canals, harbours, electrification, housing and the like, and even if some of these schemes had proved ill-conceived and wasteful, the country would have been immeasurably the richer in the broad sense, and more contented to-day. The community also has its duty towards its members, that is its due to the engineer (and others), but it commonly falls far short of its duty and seldom recognizes its best servants and greatest benefactors, and too often only when they are dead. I do not attach anything like the same importance as the author does to the finding of engineers, and most strongly do I deprecate enlisting the heads of secondary and public schools for their selection. Most of these heads have so little conception of the qualities necessary to make a successful engineer that the suggestion is positively dangerous. "The engineering boy is one of the most difficult to determine." I agree with Dr. Johnston, and only a process of elimination can sort him out

from the rest. Besides, not only do many boys of school age totally fail to reveal much of the engineering aptitude which they do in later years—some develop later than others—but the work of the engineer is so vast in its ramifications as to make it impossible to determine what niche any particular boy may eventually fit into and fill successfully. We have only to look at the few descriptions of electrical engineers given on page 194 as being comprised in our Institution, to see how varied are the qualifications necessary to fill the numerous grades of each of these classes. For the same reason I am of the opinion that our recognized academic training and examinations for engineers leave much to be desired, and are largely wasted except for special positions, of which there are but a very limited number to be filled. Is it really necessary that most of our young men wishing to be engineers should, merely to secure a hall-mark in their profession, strive to spend so many of the most receptive years of their life in the attainment of theoretical knowledge which they will, in many cases, never use in after-life? We have become so unreasonable in educational matters during the last 20 or 30 years that there is now a tendency to shut the door on, or at least make things extremely difficult for, the young engineer who is not in possession of a degree. Let us look at the successful electrical engineers of our day, and we shall find that the men holding the big positions are not often men of great academic attainments. I believe there are at least two reasons for this: first, because, with the exception of particular branches of work such as teaching, designing electrical machinery or in the applications of physical science and chemistry to industrial processes, no very great theoretical equipment is required, as, for instance, for constructing or running electrical plant or installing plant and wiring, etc.; and second, that for most of the latter positions the years between the ages of 18 and 22, if not spent in the works acquiring the extraordinarily valuable experience which only those years can give them by association with workmen and plant, are irretrievably lost. For this reason so many engineers with degrees fail to attain (or if they attain them at all have to wait many years before doing so) the positions to which their training would seem to entitle them. We should attach more importance to a record of achievement, with or without examination, than to examination qualifications alone; the qualities necessary for the passing of examinations are, by themselves, frequently of little use in business life, and by no means the most important. Let us not forget that a real engineer does not finish his education at an age when he leaves, or would usually leave, college. It will be within the knowledge of most engineers who are in middle life that at that age their real education had scarcely begun. Among the best qualities of a real engineer I should count enthusiasm in his work and profession. With enthusiasm, whatever the deficiencies of his training, he will go far; without it he cannot progress much. It should be our duty to create such enthusiasm; to destroy it should be unpardonable, and I was interested to find on my visit to America last year how much thought and prominence is given to this question, one of the reasons, I am certain, of the unexampled prosperity of their electrical and other industries at the present time. Another important quality of the engineer is imagination, the ability to visualize a design, a piece of work, a new device, the probable result of a certain line of action, etc., before it is entered upon. This quality is in a large degree an inborn gift, but it can be cultivated and should receive more attention in our educational system as it is not merely of value to the engineer alone. Its wider diffusion among the masses would make impossible such things, for example, as strikes of munition workers during the recent war, whilst to the engineer it is the basis of all sound initiative. As to engineers engaging in public life, where time and inclination permit of this we should not shirk this duty any more than any others where we can be of use to the community. Probably one of the reasons why more has not been done is that our comparatively young profession, with its tremendous rate of progress, can, and does, absorb all and even more (were it possible) of the energies of its members, leaving little time for work, which to busy men must often seem deplorably unfruitful. I am not sure either that the qualities of the engineer as an individual are so much superior to those of other professions in dealing with public affairs. Many of them are so much more capable in their understanding of the laws of Nature than of the laws of men and of the mind that, unless specially fitted for this work, they can only excel in questions for which their special training entitles them to speak with authority. That is not to say that they would not serve quite as well as, if not better than, many who now unfortunately deal with our public affairs.

Mr. P. F. Allan: For breadth and scope, insight and lucid analysis, the paper must be difficult to parallel, but for study I should especially commend the second part of Section (5), dealing with human problems and economics, and the first part of Section (6), dealing with the engineer in public life. Those parts in Section (3) dealing with the boy—and should we not now include "girl"?—who is to become an engineer, and that part of Section (4) which discusses the necessity for early contact with skilled craftsmen, are of great importance and merit our earnest consideration, even if we do not agree with all the author's conclusions. Difficult as it is to criticize, there is one point on which I should like a more definite pronouncement from the author, because I infer that on this point he has failed to take his own advice to consider every problem on its merits without being influenced by the preconceived notions of others. In Section (4) there is a cryptic reference to the solving of the "perennial question of the engineer-salesman." It is therefore evident that the modern tendency to question the usefulness of this type of engineer has been working on the author's mind. Further, in his description of the various types of engineers who form the body of members of our Institution, I note with regret that he has omitted to mention the much-maligned individual to whom I have just referred. I trust that this is inadvertent but, as indicated before, I have an uneasy suspicion that the author has fallen into what threatens to be a common error. I wish to take this opportunity

of ensuring that the proper place of the engineer-salesman in the economic structure of our industry shall not be overlooked in a paper of such importance. Perhaps it is not correct to say that the importance of the engineer-salesman—or, as I prefer to call him, the sales engineer—is too often forgotten, but it is certainly too often misunderstood. There appears to be an idea that he is merely the medium through which orders, which must, in any case, be placed with some one or other manufacturer, are diverted to one channel or another, according to his personality or persuasiveness. Actually, however, he is the link between the manufacturer or supplier and the user. Through him, many technical problems of great importance are discussed in a way that cannot be equalled by correspondence, and to his wide technical knowledge, insight and energy, must be placed the credit of very many of the improvements in the design and application of the plant in which we are all interested. It is within my personal knowledge that some of the most marked improvements in the design and construction of modern plant which have been made during the last two decades have owed their origin to the knowledge of working conditions and practical technical abilities of the sales engineer. The mathematical equipment of some of these men may not always be of the same high order, and so well kept up, as that of their brother engineers in works, designing offices, etc., although this is by no means an invariable rule, but it is always severely practical and is often of immense value to those whom they serve, who are not only their employers but also their fellow employees and the community at large.

Mr. W. G. Guns: It has been said that the greatest study for man is man, and the author has brought this subject before us in an interesting way in speaking of engineers. It has been said that a minister sees a man at his best, a solicitor sees him at his worst, and a doctor as he really is. How does an engineer see a man? Surely in the light of what he can get him to do, what use he can make of him, not for selfish ends, but for useful ends. An engineer's whole training is for construction, and not destruction—destruction of any sort goes against the grain. It is by exercising their constructive policy that engineers can be of service to the community.

Mr. A. H. Marshall: I should like to lay more stress than the author has done upon what is due to the engineer, as from my experience the engineer compares very favourably with people in other walks of life, both in his ability and in the discharge of his duty. What is wrong is that his activities are too much limited by financial and economic considerations and his status is not sufficiently well defined; whilst he does not get the public appreciation that more assurance of his own importance would command. One always feels that the engineering profession suffers by comparison with the medical and legal professions in that it has not the traditions and privileges of these older bodies. In this respect probably nothing has done more than the registration of the individual member and I could have wished that the author had said something more on this aspect of the matter. It is to such papers as his that one looks for the development of ways and means to give the engineer a better position in society, and I hope that the outcome of this discussion will be the setting up of a defined course of training with engineering degrees and the creation of a statutory body to register ability and character. These would do much to stimulate the moral qualities which, as the author so ably points out, are the basis of a successful life.

Mr. J. Gibbins: We get many scientific papers during the course of a session, some very highly technical, and we are not all so clever as to follow them and discuss them, but I venture to suggest that such papers as the present one would prove very popular. The educational value of the paper is tremendous, and those of us who are fathers will do well to digest it thoroughly.

Mr. H. Bridges (*communicated*): This paper should be read in conjunction with Mr. Maccall's Address to this Centre, and the Training of Engineers Scheme now being introduced by the National Joint Board of the electrical power supply industry. It is good sometimes to get away from the mathematical problems and technicalities of everyday experience and consider for a time the human side of life. To have our attention drawn to the fact that we are something more than mechanical instruments, that we are human and divine, that there is that part of our being which requires nourishment as well as the physical, is certainly most stimulating. The author has reminded us that we are soul as well as body and, after all, it is the soul which makes the man. There is very little, if any, room to-day for the soulless man. It is good to get beneath the thin veneer and get to the heart of things, and the author is to be congratulated on bringing this important factor to our notice. Throughout the paper, importance is laid upon seeing that the right man gets into the right place, and this would appear to be the aim of the author. Whether he will succeed in establishing the right formula remains to be seen, but I certainly think and believe that he has taken the right course. The author also emphasizes the fact that many become engineers who would have succeeded better in another sphere, and vice versa. In consequence, the whole world suffers and progress is somewhat retarded. After all, considering the rate of progress in engineering as outlined in the paper, there must have been a great many round pegs in round holes and square pegs in square holes, or otherwise such progress would not have been accomplished. The author has also laid stress upon the importance of the method of training and seeing that those who get through are "real engineers." To secure this end, the author states that "more value would come to be placed upon achievement than on examination results." The tendency to-day is inclined towards the latter rather than the former. It would be interesting if the author would enlarge upon this aspect of the position, seeing that achievement has in the past had more or less equal consideration with examination; the future, however, will make equal demands upon both, and the engineer who shows equal ability will no doubt be in first demand. The author states that "the finding

of engineers" (and I take it he means "real" engineers) "is more important than the method of training." That may be so, but he does not state how one is to be sure "he is a hare"—he may be a rabbit, but may make just as good soup after he is "cooked." Surely some method of training is essential before the "real" engineer can be found, and therefore the method of training appears to be the most important, so that one can at an early stage find one's "hare." The author appears to favour restricted supply, but this restriction should at least be limited, as the requirements of the future are unknown. Also, by being too strict at the beginning, many who would otherwise have made "real" engineers may be excluded; unless, as the author hopes, the teaching profession may, by careful study to this end, be able to establish some formula which would give some indication of a positive nature to guide pupils as to what profession they are most fitted for. The author quotes Dr. Johnston as saying, apparently with regret, that "there are no records kept in public offices of the state of supply and demand in the various professions." It may be of interest to state that the Training of Engineers Scheme previously mentioned provides for a register of qualified engineers for the electric supply industry, so that it may be possible for youths to find out if it is worth their while entering this section of engineering. This register should prove of great value to all concerned. Some are born engineers and are quickly discovered, some are not, but the fulfilment of that purpose is destroyed in a multitude of instances by the adverse influences which attack the life in its early stages; the life is weakened at its start and, unfortunately, the new life never finds its real purpose except by determined effort on the part of the individual in after-life—hence the world is all the poorer. It is gratifying to know that gradually, but surely, an improvement is being established and many causes of stumbling are being removed so that the mind of the future generation will become clearer and more powerful and the whole universe will benefit extensively. We hear a good deal to-day about industrial problems, and the question is often asked: "What is wrong with industry?" There is nothing wrong with industry—it is the soul of man that is wrong and requires righting. Most people look at things from a selfish standpoint and wonder how they will profit, but, after all, the man who wraps himself up in himself makes a very small parcel. Industrial trouble is caused by the employer and employed failing to realize their duty in life. One asks for a reduction of wages and the other a reduction of profits, whereas both are wrong. We should centre our thought on increase, not reduction. It is a change of outlook that is required, the employer interesting himself in his employee and the employee interesting himself in his employer. Everyone, from the office boy to the manager, has his duty to perform and, if either neglects it, the whole concern suffers. He that hath much, much is expected of him. The author states that "the mechanism of the world rattles and rumbles as it works" and asks the question, "cannot those who make it discover a lubricant for it?" The lubricant is mentioned in the first paragraph, namely, "the exceeding of mere duty." In other words, quoting from the Scriptures, "if a man compel thee to go one mile, go with him twain"—obey the law and give something over. Duty only takes us one mile, love and sacrifice take us to the second. It is the overflow of our service that counts and acts as the lubricant. Most of us can manage the one-mile limit; it is not really difficult, but it is a poor type of life. To go the second mile costs us something; therein lies its value, it means a struggle to do the extra, but that is the test, there lies the opportunity. The man who takes a long view of life to-day is often depressed, there is something in the future which gives a feeling of fear, strange stirrings of the coming storm. The time has surely come whan all men, in spite of party, creed or class, should begin to practise a little generosity in their dealings with one another. So soon as we all begin to tread the second mile, so soon will things change. This may be described as sentimentality, but surely there is room for the exercise of love and sacrifice, even in the commercial relationship of men. Has not the application of the principle of "exceeding mere duty" been the spirit of all pioneers to whose efforts we owe so much to-day? I venture to say that the application of this principle is the only safe and permanent solution to the industrial problems of the present day. It may be said that this is idealism. It may be asked: "Where, or when, has this sort of thing been tried, when was it accepted as a principle between individuals or classes or nations"? When? Where? The answer may be, "Never." Then why not try it now? The world is stuck at the first mile at mere duty, which is irksome. I venture to predict that if this principle was adopted by all there would be no question as to the engineer's due—he would get it. May this paper be the means of awaking in the minds of all engineers a new zeal, calling to them all over the world to realize their duty in life (and duty includes seeing that the engineer receives his due) and to show the way to the second mile and, quoting the author, "putting into the making of the web every bit of us." When we have done that, and not until then, shall we be sure of finding the right man for the right job and so providing the lubricant which will make all industrial machinery run smoothly.

Mr. J. Dickinson (*communicated*): With regard to the subject of examinations, I should like to point out that at Armstrong College, in the electrical engineering department, the students' performance and aptitudes are observed continually by their teachers, who are also examiners, and notes are made on each individual. These observations all play a very important part in the examinations which the students take. So it is clear that an arbitrary set of questions, answered during a fixed time, does not by any means provide the only criterion of the students' fitness for receiving a degree in electrical engineering. They are carefully studied during the whole time appointed for the degree course, which may be either 3 or 4 years. There is no doubt that examination tests are themselves unsatisfactory, but I wish to show that judg-

ment is formed on sustained performance. However, the most important period for sifting students into their proper vocations is during school training before they are admitted to the university. Another point to which I should like briefly to refer is the subjects of economics and finance. Engineers generally do not give these subjects the attention which they require. They feel, perhaps, that such things are highly specialist in nature, and fear to express opinion or even to study the facts, doubting their own competence to deal with them. Yet these facts must be faced, especially when there is even the possibility of the author suggesting "whether it would have been better to scrap all our war surplus . . . and thus to keep some men . . . working." This is a dangerous and sorry plight. I should like to suggest a line upon which, in my opinion, careful thought might be directed with advantage. What is the primary function of industry at the present time? Is it the provision of goods and services essential to the well-being of the State, or is this merely subordinate to the more immediate purpose of operating upon money in order to increase that money? In other words, are goods and services just a means to profit? It seems that this is so, and, consequently, any new scientific device which produces the same goods and services at a cheaper rate than those devices already in use, is beneficial to this end. However, directly opposed to this is the necessity of providing adequate work for the majority of individuals in the State in order that they may earn sufficient money to meet their immediate needs. Can these two sets of apparently conflicting conditions be reconciled ultimately without modifying the principles governing industry to-day? Wealth does not consist in a static quantity of things possessed, but in the potential capacity of producing goods and services. In other words, if Q be quantity, then current-flow is dQ/dt, or the rate of change of Q, and this latter condition is, strictly speaking, analogous to wealth. Under such conditions money would be the means, goods and services would be the real aim or end of industry, and unemployment a much less difficult problem.

Mr. G. N. Peel (*communicated*): After speaking of the value of intelligence tests, the author proceeds to say: "Further, a boy's personality will develop finely under treatment like this . . . he will climb . . . high in thought. . . ." I take it that the actual results of the intelligence tests are to be made known to the students; but this hardly seems to be a desirable course, because, under the influence of his "intelligence quotient," the clever boy might tend to become an intellectual prig, whilst the less-gifted boy might receive a mental snub which would spoil his future outlook and ambition in life.

[The author's reply to this discussion will be found on page 229.]

NORTH MIDLAND CENTRE, AT LEEDS, 24 NOVEMBER, 1925.

Mr. S. D. Jones: The majority of boys want to be electrical engineers. Parents have come to me and told me that their boys are sure to make good engineers, as they have put up, say, electric bells. I have asked the parents if they have observed their boys as regards their bent, and I find that they are amazingly ignorant of the characteristics of their own boys. They really seem to be the very last people to decide what their boys should become. This also applies, I think, to schoolmasters. I recall the case of a schoolmaster, a very able man, who sent to me a lad who wanted to be an engineer. He was a very clever lad, but I had not been speaking to him many minutes before I came to the conclusion that there was nothing in his disposition to warrant his entry into the engineering profession. I am very glad that in his case his parents thought the matter over, and the lad is now going in for another occupation. At the same time the author is evidently thinking of the boys who are pre-eminently fitted to become engineers. In the main I agree with Dr. Steinmetz that "The scientific fact is that people are made out of the right stuff, but our problem is to find a way to release their creative energies." After all, most men, women, boys and girls going through life have to fight; they have to overcome their difficulties. I believe that the average lad, in whatever walk of life he goes, must experience a great deal of drudgery and difficulty, and, after all, the first thing is to cultivate personality by the boy's strength of character and his readiness to face life. I have had some boys working under me since I have been an engineer, quite ordinary boys, who have gone out into the world and made good. Some of those boys have gone to America and other places; they have fought their way through. At the same time there is not the slightest doubt that a great deal can be done in finding out what boys should become. It is no use putting a boy entirely musical, or with an artistic disposition, into the engineering profession. I think that all engineers should study economics. A year or two ago I saw about a hundred new locomotives lying useless on the banks of the river Dee. They were locomotives that were built during the war. For some strange reason—uneconomic, I think—those engines are still lying there, because it is felt that if they were put on the market they would enter into competition with engineering firms who build locomotives. That seems to me an utterly foolish way of looking at the matter so far as economics are concerned. Surely the locomotive works, which would have been deprived of work if those engines were put into commission, ought to have diverted their energies to some other work. It is not so long ago that first-class newspapers would have considered it a matter good for trade if a fire took place, or if windows were broken. It is not good for trade. Waste of any kind is a terrible loss, but the same economic fallacies still largely obtain. How is it that engineers with their great brain power—for, after all, engineers have done a great work in the world—do not take a greater part in public life? The only reason that I can think of is that engineers are more in contact with material things, whereas men of affairs come into contact with persons, and in doing so see many points of view. If engineers

were to become members of borough councils and of Parliament their minds would be broadened; and they would have a tremendous influence on public things and public life.

Mr. W. E. French: Before we start to discuss how to find the engineer, which appears to be the kernel of this paper, it is necessary to be quite clear what an engineer is and what constitutes his qualifications and his duties. The old adage, that an engineer is a man who produces for a penny what most people can produce for a shilling, provides a crude, but singularly apt, definition. It implies a fine scientific training which gives him a clear conception of the forces of Nature, and a sound knowledge of the materials she places at his disposal. It implies the ability to use them to the greatest possible advantage, and to apply them usefully. Ultimately, it implies that he must possess keen financial instincts and great business acumen; to this add faith and courage, indomitable perseverance, imagination tempered by clear thinking—in short personality—and we have the perfect engineer, the "head and shoulders" above the average kind, and the leader in his profession. This type of engineer who combines the scientific mind with talent for application and financial ability is indeed rare; so we are immediately driven to compromise and to discover who is likely to excel in any one of the branches to be enumerated. This already leads to partial specialization, because we have to find and train men whose bias may be either scientific, or may lie in application, or may be towards finance and engineering economics. At this point I should like to state in a general way what appear to me to be the duties of an engineer, and how they may be classified:—

The Research Engineer.—His inclination and abilities belong to the provinces of pure and applied science, and his realm is, to use the author's metaphor, the tiny empty space between the nucleus and the electron. The sphere of his activity is the research departments of the great engineering and manufacturing concerns. His training will be entirely the charge of the science and technological departments of the universities.

The Design Engineer.—His abilities are still highly scientific, and his mathematical equipment must be good; but above this he must also possess a high capacity for application. His field is the design of machinery, bridges, ships; the design of switchgear and protective devices used in electric power systems, and the apparatus for radio telegraphy and telephony. His education and training is the conjoint responsibility of the universities and the engineering works. The next class is not so easy of definition, and I shall designate the engineer who belongs to this class as the *organizing and projecting engineer.* My meaning will become clearer if I enumerate what I believe to be his activities. He is the man who plans and directs our electric power supply, irrigation, water supply and the sanitation of large cities; the man who is responsible for our communications, whether they be the railway, the telegraph or telephone services. His education should have a definite practical tendency, and the major part of his training should be received in manufacturing works, electricity supply work and other civil undertakings. His technology may be received at a university, but I think he will be equally well served by our senior technical colleges and senior technical schools.

The Works Engineer.—He is familiar to us as the works manager. He may have been classified under the title of organizing engineer, but his work is so intensely specialized towards shop and works practice that he becomes in this respect a type of his own. He must have served a full apprenticeship, preferably in large and modern works, and he need only gather such knowledge at senior technical schools as will enable him to appreciate the scientific facts placed before him in designs and drawings, his business being to put them into material form with sound workmanship, at the lowest cost and with the greatest speed. He is essentially an individual with an accurate knowledge of men, materials and methods.

Finally, there is the *sales engineer,* or the "*engineer salesman,*" possibly better described as the "commercial engineer"; although none of these appellations correctly describes the case. The highest type of commercial engineer must be a man of great and universal ability. He must be a diplomatist, a first-class debater and psychologist: Having to meet the leaders of industry and of the engineering profession, his technical qualifications must be of a high order; the designs and technical policy of his firm must be at his finger-tips. In addition, he must be well up in political economy and international politics. From the rank of the commercial engineer will be drawn the general manager and the managing engineer, and what the author describes as the public organizer of our engineering resources. The sales engineer of the past just happened; the commercial engineer of the future will have to be carefully educated and trained. He is undoubtedly a university man; not only for the sake of his technology but because the universities will also equip him through their social and corporate activities with the qualifications so needful to his career. The stepping-stones in the practical career of both the commercial and the designing engineer are the post-graduating courses arranged by the large manufacturing firms.

Having arrived at some definition, however incomplete, of the engineer and his activities, we can now proceed to the author's process of "finding" him. Here I am not inclined to agree with the author that we must find the "head and shoulders" above the average man. Cream always rises to the top, and he will find himself. It is rather the good average man we have to discover, and allot to him that sphere of engineering most suited to his inclinations and ability. In this respect the author's proposal is a good one, with these additions: that the sifting process of suitable youths from early school days should not be confined to the schools, but should be continued in the universities, and finally to their practical and business lives. There is not much advantage in recording a boy's school performance or a young man's university attainments if the final results of his after-life remain unrecorded and obscure; then no judgment is possible, and advice as to a boy's future would be uncertain and lack definite value. I do not foresee any real difficulty in devising machinery to produce such records and statistics. Where I foresee real difficulties is in obtaining reliable statistics when a

man has completed his school or university training. I find it very difficult to keep in touch with past students. If the launching of such a "sifting" scheme were contemplated, this is the point which should receive serious attention, and if the work is to be of any value at all the hearty co-operation of employers must be assured. Many of the large electrical manufacturing firms have elaborated a system of records for their apprentices and post-graduate students with a view to advising them as to their suitability at the end of their courses for any of the branches of electrical and mechanical engineering. It will thus be seen that the electrical industries have already made an important step in the direction the author has indicated.

Mr. O. C. Dinerman: The author's "lethal chamber" is rather a drastic procedure to adopt when dealing with men who, owing to certain conditions surrounding them in their early days and adolescence, such as environment, health, etc., have not been able to reach his standard of citizenship. There are many men and women who, by some selective natural process, cannot exercise their individualism to the full, frequently owing to a matter of ancestry. Bunyan, seeing a manacled man, said to his friend, "There, but by the grace of God, walks John Bunyan." I think we should be more lenient to those men and women who fail to realize their duties in life and give full service, and endeavour to understand the reason of their shortcomings and, understanding, to forgive. "To understand all is to forgive all." Thus may some of us help to steer them into their proper channel in life. Our aim should be to bring up the average into a high state of efficiency. Dealing with the finding of engineers, the author's method of selection has many drawbacks. The whole matter of occupation must, in the very nature of things, be plastic. One can safely say that, in the main, engineers are not born, they are made. It is a quite different calling from that of a painter or poet; it is a mechanical art and, as such, can be acquired to a high pitch of perfection. A boy may have a strong penchant for engineering up to a certain age, and suddenly drop it; on the other hand, he may follow that bent and be a mild success. Rather let selection be free, but once having taken it up then is the time to concentrate upon it and endeavour, by sheer hard work and enthusiasm, to make a success of it. It is the singleness of purpose in any mechanical art that makes for success. Some there are who are born engineers. Nature breeds a genius now and again, and then breaks the mould. We must not forget that many successful engineers began life in other professions and trades, and achieved fame for their administrative powers, inventiveness, etc. In regard to the sales engineer, there are many qualities that go to make him up. I should say that adaptability, service (and lots of it), energy, self-reliance, good judgment, enthusiasm and cheerfulness are enough to make any one successful. Two or three of these would suffice. The sales engineer should also be able to sense the requirements of the district he works in and duly report. He should be able sometimes to give broad hints to his works in such matters as design, advertising, etc., and always think of himself as part of the organization and working with it. He should not bore his customers, and should avoid the sin of limitation. Enthusiasm is a quality which, being of the spirit, engulfs most others. It is amazing how enthusiasm put into a relatively dull occupation enables us to see some latent pleasure in it. But most of us are in congenial occupations which should give us scope for the exhibition and development of our true selves, and however hard the work is, it will afford us the highest pleasure. All work done well produces a feeling akin to joy. We can express our creative spirit no matter in what sphere. The service of our fellow members should be the chief goal. The humble worker becomes a mighty craftsman when his soul speaks through his labour. That is the acid test of character. Amid the constant flux of things, honest work is the one finally enduring, and if there is no other immortality there is one along the line of our daily duties. Apart from the great masters, let me give an illustration: A village craftsman, a worker in wood or clay, dead for centuries, his grave flattened as the surrounding land, perhaps built upon, yet behold his work lives after him, his tables, his chairs, clocks and pottery, a sensuous feast for the eye, a symphony in graceful curves. At the time a simple village worker, now nameless. His creative spirit found expression through his craft; his the achievement, ours the harvest. Play the game for its own sake, and let the prize go to anyone who may desire it. Our own work in industry should be played and won on points, and, at the end, show not only the material result which is the prize of victory, but a team happier and more prosperous than others. That is the game of industry and no unworthy game for men to play. Strive for the common good, for the glory of achievement, and the material reward must come as a *sine qua non*; whether success or failure comes at last, the effort brings the reward. For the successful and happy man is he who serves best, who is great by being humble, who believes all things, hopes all things, and endures all things, not that others may love him, but rather that he may learn to love them.

> "Man hath his daily work of body or mind
> Appointed, which declares his dignity
> And the regard of Heaven on all his ways,
> While other animals inactive range."
>
> MILTON, *Paradise Lost.*

Colonel H. C. Fraser: The supply and training of young men for the electrical industry are on a higher level to-day than they have ever been. Candidates are better trained at the universities and in the workshops, and are turned out more capable of competing with modern conditions than has been the case previously, and I think that a survey of the younger members of the personnel of industry to-day gives one the greatest hope for the future. On the question of the selection of engineers, the author goes right back to the rights and duties of life and the rise in modern engineering. Dealing with the selection of suitable boys for the profession, be it engineering or any other, the first and most important point to my mind is the training which a boy receives in his home. After all, a boy goes through the hands of his mother to start with and then it is that the foundation of his powers of observation and imagina-

tion, which are all-important to him in after-life, are first taught, and I believe that the credit is due to the mother rather than to the father. The boy then goes to school where he is generally further developed and learns to play the game and eventually passes on to the university, and his period of university training is, as Mr. French said, the time when he gets an idea of creative action. He is brought into touch with a corporate body with all its activities and deems himself of some account in the world. There is, however, a modern tendency to lay too much stress on the university training and not enough on workshop training. The ideal, I think, is a sound university training, but without a knowledge of the working man he will be lost in after-life and will lack that knowledge which cannot be obtained on a slide rule. My remarks have been confined more especially to the upbringing of engineers, as I consider that is the most important part of their lives.

Mr. W. H. Wraith: The engineer's view of life concerns us all from the highest to the lowest. If he does his duty he is benefiting the whole community.

Mr. W. F. Cooper: When I went to school my tendencies were not towards engineering, as I was on the literary side of the school. In such subjects as mathematics and chemistry I occupied one of the lowest positions at the end of the term. On the other hand, I was always interested in engineering and, as a result, have taken it up as a career. I have not regretted this. I think that to a great extent I have made up for the lack of mathematical knowledge that I showed at school. This lack was a hindrance to me, especially at the university.

Mr. J. W. J. Townley: The author has rather narrowed down his proposals for the selection of the engineer, but I think it will be agreed that no great achievement can be carried out by one type of individual alone. Great results are obtained by the co-operation of very different types of mind, and in no profession is this more marked than in our own. There is the man who is specially adapted for scientific research; he is capable of producing certain results but in many cases not capable of applying them. These results, however, are usually applied by another and more practically-minded type, whose duty in life appears to be making use of the tools put into his hand by the research man. A very necessary type, too, is the engineer with literary abilities, of which we have a very good example in the author of this paper, and I think we are very short of that type of man in the engineering profession, with the result that the value of our work is not always recognized, because it is not often adequately described. I would suggest, therefore, that it is not entirely a good thing to be too restricted in the selection of boys to train as engineers, provided always that they have some liking for engineering matters. The author refers to the desirability of the engineer taking his part in public life, and this unfortunately the engineer very rarely does, and thus, when a commission or committee is set up to inquire into any problem it consists usually of lawyers and business men, who call the engineer in as an expert adviser or witness. There is no particular reason why the engineering profession should not be well represented on such committees or commissions, and I am sure, knowing the type of men we have in the engineering profession, they would contribute something to the solution of some of our large national problems.

Mr. R. A. S. Thwaites: At the top of page 199 the author says: ". . . the essential importance of never doing a thing ourselves if we can find someone else to do it well for us." At first sight that seems to be a direct incentive to sheer laziness, but rightly applied I think that is the essence of successful organization. Most of us know men—clever men, perhaps brilliant men—who try to make a one-man job of work which should be really tackled by an organization, and I think that this when rightly worked out is really the foundation of some of those very large organizations that have been built up by, say, the late Lord Leverhulme, and other similar heads of industry. There is an old saying that the man at the top should never be busy—in other words, he should have time for coping with emergencies, studying conditions, and organizing those who serve under him.

Mr. M. Wadeson: The "common good" is mentioned in the paper in many places. One of the first things to do is to decide what is the common good. What may be the "common good" in one era may not be in another. It may be that the index of the sum of knowledge at the present time will only be the index of the sum of ignorance in the future. On the question of selection of the engineer, the author says that we must observe the nature of children at an early age. In my opinion that is nearly impossible. It is only in exceptional cases that any reliable indication of predilection in a particular child will show itself at an early age. Further on in the paper the author speaks of the "head-and-shoulders-above-his-fellows" man. I take it he means a genius. Genius has been defined as "an infinite capacity for taking pains." Throughout the paper the author advocates taking pains in whatever is done. This capacity for taking pains is a trait which can be developed in anybody, and since engineers are, after all, ordinary people, they are not necessarily all geniuses. The "head and shoulders" people would do quite as well in any other walk of life to which they were called as in engineering. The author mentions that some boys have no liking for one thing but that they show a distinct liking for another. I think it is inherent in young people nearly always to show a liking for what one might call manual work, but it does not follow that when they get to more mature years their likings will not be changed to a very great extent. The engineer is an ordinary person with a specialized training. The ordinary training or the opportunity for the ordinary training should be given to everybody, and the specialized training should be undertaken at a later date when the career definitely settled on was that of an engineer. On page 199 the author says: "Engineers have gone on inventing, often enough not realizing that the results of their work might be used for merely commercial ends." I take it that if any invention has a commercial value then it must be considered that the community as a whole wish for it, and therefore I cannot see what his objection is to an invention having a commercial value.

Mr. H. Moss: When I first saw the subject of the paper I thought that the author was going to deal with

the matter on an entirely different basis, in fact I thought that he was going to deal with it from the practical point of view. I think that we, as a body of engineers, know to a great extent what our duties are in life, but we do not get our honest dues. The whole paper bristles with what may be termed social-reform matters which cannot be discussed in a limited time. The author says on page 198 that an engineer should study everything connected with the running of this life. If he were to do this, however, he would have no time for his business. I am quite in agreement with the view that the engineering industry of this country ought to have more representatives on our governing councils. When I say "governing councils" I refer to municipal bodies and Parliament, because I feel there are many capable men in our ranks who would be a very valuable addition to these bodies.

Mr. H. W. Walker: In regard to the training of an engineer, and particularly the selection of an engineer, a little anecdote that I heard some time ago may be of interest. The parents of a boy, probably about 12 to 14 years of age, intended him to become an engineer. Mathematical problems worried him very much, and someone who was visiting the house drew his attention to the fact that he must persevere and do all he could to train himself in mathematics and become a good engineer. "Well," said the boy, "if engineers have to bother with that sort of thing I would rather leave it alone and be an engineer like father." This remark of the boy indicates how careful parents need to be in selecting a suitable profession for their children. The paper opens up a line of thought which I hope will be further developed, as such developments would be a great blessing to the rising generation, and prevent so many square pegs being forced into round holes.

Mr. T. H. Seaton: A previous speaker has dilated on the advantages of a university training for the engineer, but in my opinion there is something wrong with the present system of university training. It is often looked upon as being an end in itself, whereas it is really only a means to an end. If a boy is destined to be an engineer it is best that he should start his practical training either on works or in the shops as soon as possible. At 16 or thereabouts he will find that the men will take an interest in him and teach him willingly. He will learn something of their lives, difficulties and aspirations, and the knowledge thus gained by personal contact will be of inestimable value to him in after-life if he has to control men. A man who has been to the university comes on to the works or into the shops when he is practically a man and rarely seems to pierce the natural reserve of the workmen. Personally, I took advantage of the technical courses of a university during my practical training, and found that an excellent method of obtaining the most value from the theoretical side. This is the day of great amalgamations and there is a danger of their failing by neglect of the personal equation. Men are put into positions of authority, labelled, and submerged by a flood of forms, statistics and returns, often rarely coming in contact with the men they control. The workman feels the loss of that personal contact with his chief, and that in many cases the latter does not understand his point of view. I feel sure that if we could get more of the personal element into industry and recover the confidence of the men, many of the industrial troubles of the present day would rapidly disappear.

[The author's reply to this discussion will be found on page 229.]

NORTH-WESTERN CENTRE, AT MANCHESTER, 1 DECEMBER, 1925.

Mr. J. Frith: I propose to say a little about the selection and training of the young engineer. It is gratifying to feel that our parents and guardians took such trouble over finding out that we really had the root of the matter in us. I wish that more schoolmasters were like the author's friend and tried to help the boy's parents to start him in the right calling. Too many boys have been made engineers because they took the kitchen clock to pieces. Mathematics or physics is the sure foundation to build upon. I say "or" because the two are *very* rarely found in the highest degree in one individual. They are not attainments so much as types of mind. If the boy shows any signs of being able to profit by it, by all means let him go to college, and, I think, straight from school. For, although I see to the full the arguments in favour of some works experience first, I think that continuity is of even more importance. Continuity of the habit of brain working, especially in the evenings, and, perhaps more important still, the continuity of works when he does get there. My advice to the college is: Don't spend many valuable hours in trying to teach the boy what he will pick up in much less time in the works, but teach him what he may never again have the opportunity to learn, the broad principles underlying the nature of things and not merely of the things which are to bring him bread and butter. The popular idea of the college-trained youths swaggering into the works and proceeding to teach the staff how the works should be run and, furthermore, demanding a large salary for doing it, has very little foundation in fact, but is largely a bogy set up to be knocked down amid the cheers of the "practical man." My experience is more that the college student approaches the works with a very real humility and is very willing to begin at the bottom of the ladder; but that having been to college he will be both quicker in the uptake and will see further round a problem than the man who has been trained entirely in the works. I should like to say a word of encouragement to the engineer who wants to get out of the rut and try new ways of doing things. I know only too well that all the inducements are in the other direction. Get off the beaten track ever so little and difficulties spring up. It is so much easier to do things in the old, tried way and to play for safety, than to be original. If the pioneers had done this where should we be? The motor-car trade and, more forcibly, the war have taught us that there may be many other ways of attaining

the desired end than those prescribed by orthodox engineering.

Mr. B. Mouat Jones: Professional bodies, it seems to me, normally talk a great deal, and quite rightly, about their work and its result, without paying much attention to the relationship of that work to the general scheme of things. In my opinion it is desirable that at comparatively rare intervals they should have a sort of mental stocktaking and put questions to themselves as the author has done. This applies to all professional bodies. I agree with practically everything the author has said; but favourable criticism does not, as a rule, add to the vigour of a discussion, and I have therefore endeavoured to find one or two points on which I do not quite see eye to eye with him, although I do not think there is any serious difference between us. What I have to say is really by way of amplification. Under the heading of "The Finding of Engineers" he says, "It is the head-and-shoulders-higher-than-their-fellows people whom we want specially to discover." I am inclined to think that is not quite so. Those people are the people who discover themselves; they do not want so much help as the average person who is not going to be a leader or a first-class man. I also disagree with the statement on page 195: "Strictness at the beginning may reduce the number of those who become engineers; but that is what is needed." I think that engineering training is, in itself, as good a training as any for the purpose of performing the functions of good citizenship, and is a better training than most. I believe that the more men we have who are trained as engineers the better, whether they finally become engineers or not. I sometimes put it to my students that merely because they have had an engineering training, it does not follow that the only thing they can do is engineering, that a man who goes to Oxford or Cambridge, say, and learns all about philosophy, history, Latin or Greek, considers he is fully capable of doing anything and does it very well; but I am certain that a person trained as an engineer could do it just as well and possibly better. That is why I like to say sometimes that I feel the more trained engineers we have the better, even if they do not necessarily become engineers, or even if they do not happen to be engineers of first-rate ability. If they get into other walks of life it is a very good thing for those other walks. To limit artificially the number of those who are going to be engineers seems to me a very dangerous thing to do. The economic situation is likely to do it automatically. The supply and demand in regard to engineers will always be roughly in consonance, although there will always be a small lag, according as the demand increases or decreases. I suggest it would be a fatal blunder to limit the number of engineers by any process of merely selecting those who are going to be first-class men. There will always be a great need for the rank and file of good average engineers of second- and third-rate ability. The author enjoins upon us the necessity for recognizing the "essential importance of never doing a thing ourselves if we can find someone else to do it well for us." That is very important. But if all engineers are leaders and first-class men, the first-class men will have to do second- and third-class work and will cease to do first-class work. I want to put in a plea for the finding, utilizing and training of the second- and third-class men, and not to lay too much stress upon the finding of the first-class men, who, I think, will normally find themselves. In connection with the discovery of future engineers while still of tender years, the author says on page 195, "In pursuit of our aim we must discover the inmost nature of children at an early age." That rather scares me, as it suggests that we should apply intelligence tests and psycho-analyses to these young children. What he really means is that the headmaster should be in a position to say which boys are suitable for certain professions. That is useful so far as it goes, but it is also very dangerous, particularly in this way. To begin with, the percentage of boys who show any particular bias in any direction up to the time they leave school is remarkably small. A very great proportion do not show any particular bias. They are by definition the average boys, and I rather fear that anything done to determine a career on the lines suggested by the author and Dr. Johnston might lead to the neglect of the average boy and to difficulties with the brilliant one. It must not be forgotten that a boy at school who may show a very great aptitude in a particular direction often turns out, in later life, to be a duffer in that direction, and vice versa. The ordinary boy often turns out to be much better than the brilliant fellow at school. Dr. Johnston has said some rather curious things as to his method of choosing the careers of boys. In choosing a boy for engineering he wants the boy who can inspect a structure and tell instinctively what parts are in a state of tension or pressure, and what must be done to ensure stability. I do not think any man can do that. He may think it is done by instinct, but his instinct is the result of long training and experience, and if I felt that engineers were going to build bridges by instinct, and locomotives in the light of faith, I should take to walking. A boy who can do that sort of thing by instinct is a freak or a victim of over-specialization, and has lost a great deal of the other things he ought to have been doing. I think that we run a great danger of over-specialization if we adopt such means as those for deciding what careers boys should follow. When a boy is found who shows a particular aptitude in some direction do not discourage him, but do not encourage him too much in that direction, because it may not in the long run be the thing for which he is really fitted. Another point to remember is that a very large number of people who become engineers cease to be technical people and become more or less administrators. To judge from statistics taken from the College of Technology and the Leeds University, between 50 and 60 per cent of engineering students who go into industry become administrators. In those positions technical knowledge is a very desirable and useful asset, but they want a very great deal more. They want those things which we shall not necessarily get by selecting boys who can inspect a building by instinct. In conclusion, I am in entire agreement with Mr. Frith's remarks on college training.

Prof. Miles Walker: Believing that the true life is the life of service, I am afraid that our day schools do not bring that point sufficiently before the boys. They are also deficient in general training in ethics;

it is left too much to home influence, and the mind of the boy is not turned to those important ethical principles which are really at the basis of good society. In my school-days, when the question of a suitable profession was discussed, the point usually stressed was, how much can be earned? How far any particular profession was of use to the community was hardly discussed at all. This matter is not one to be talked over in a pious way; we must make a definite attempt to bring into the education of all young people the fact that the future of civilization really turns upon bringing them up to believe that they must give rather than get. The mind of the young child is so supple that it will turn one way or the other, and we can see in many actions of children that they are just as delighted with doing something to please somebody else as they are to get something for themselves. If they get on the wrong track it is simply because the general tendency of education as a whole is in the wrong direction. The question of service to the community is particularly important to the engineer, because the monetary remuneration he obtains is, as we all know, altogether inadequate when we consider his long training and the amount of mental effort which he has to put into his work in order to achieve success. In discussing with a youth whether he should take up engineering as a profession, we can put the matter to him in a very much truer light if we remember that the service of humanity is, after all, the main object of his existence. I have in mind many cases, but I shall refer merely to two, and I sometimes narrate these two incidents to young men who are thinking about a profession. A young man succeeded his father in a grocer's shop. He did not even make the effort of starting the shop, but he was well-behaved and, I dare say, conducted the grocery business exceedingly well. In about ten years' time he was making £2 000 a year, was possessed of a very fine motor-car and house, and was a very respected citizen. About the same time, and at the same age, another young man took up engineering as a profession. He worked very hard to get an engineering degree, and afterwards went into a manufacturing concern. In a few years' time he was receiving about £350 a year, and after ten years about £750. He thought that he was doing well, and so he was from an engineer's point of view, for he held an important position in a big manufacturing concern. His friends regard him as a successful and clever engineer; but everyone will agree that his monetary remuneration is quite inadequate, although at the same time I must say most emphatically that the monetary remuneration is unimportant. Let these two men arrive at the age of 50 and look back upon their past life. The grocer is respected by all people, gets into nice society, and everything is going on well; but what has he to look back upon as his life? What has been his life? Now consider the engineer. When he is old he goes to the works and is respected by all those in it. He has designed machines which have been running for 20 years and have perhaps generated millions of units. How many thousands of homes has he helped to light? How much labour has been saved? That old man, I say, is the happier of the two.

Mr. A. P. M. Fleming: I am going to confine my remarks to the Section of the paper dealing with the finding of the engineer, which, after all, is only a mathematical equation. We have on one side the requirements of the job, and on the other the latent capabilities of the man. We have to balance the two. Those who are responsible for the training, such as Mr. Mouat Jones, have a comparatively easy job, but those of us who are occasionally meeting the products of the universities, the very raw material they turn out, have a fairly difficult job. The real problem is the other side of the question: What are the latent characteristics of the man? It does not matter whether we are dealing with a man who has been to the university or one who comes from an elementary school and climbs up; they both reach the same level if they are made of the right stuff. Whether we are dealing with first-, second- or third-class men, the real problem is to know what their real capabilities are, and I do not believe that we shall get very much help from the schoolmasters. It is not because they are unwilling or because their sympathy is not there. I had occasion lately to discuss this point with 10 leading schoolmasters from the elementary schools in this city, and when I began to probe them as to what they could do in regard to guiding youths I realized that, after all, engineering is only one of scores of vocations, professions or jobs within a $\frac{1}{4}$-mile radius of the school, so what chance has the schoolmaster of knowing, except in a very elementary way, the requirements of all those jobs? Here in Manchester we are in advance of most cities in trying to find a way to equate the capabilities of the very young people who leave school at 14, 15, or 16, for the jobs that are open to them. A very definite effort is being made, but it is entirely inadequate, and we must not expect too much from it. Neither do I think that there will be much help from intelligence tests and the work generally of the psychologists, although one appreciates the attempt to solve the problem on scientific lines. There is a need of some means for getting into contact with boys and girls at about 13 years of age and beginning, not to influence them in the choice of their future work, but to guide them as to what they are most likely to come to, and, in fact, to give them a chance of finding out their bearings for themselves. Dr. Johnston is quite unique in the efforts he makes and the sympathy he shows in trying to place his boys, but that is not practicable in most schools and with most headmasters. Whatever may be said about the expense of the present educational system, I believe that it would be well worth while, though it would involve considerable expenditure, to devise some means by which advice could be given to quite young people at an early age as to their careers. With the present economic conditions, once a youngster gets into a job he finds it difficult to move from that particular trade. So the importance of getting him right at the start is very great; and if a mistake is made he will probably be discontented and a source of dissatisfaction both to himself and to everybody around him. That particular feature of the paper is of great importance and bristles with difficulties. On the question of training, I would urge that a boy should complete his training in the

works if he is going to manufacture, because he has become identified with some work or job, he knows the people around him, and if he is worth his salt he has prima facie made a niche for himself. If he breaks off at that point to return to college he is throwing away a very valuable asset. The outstanding point that one looks for in connection with young people coming from the university is personality. The man who has not to refer to a book whenever he is faced with a new proposition, the man who can fall on his feet like a cat and go on without even looking round, is the type of individual we look for to carry on the work of engineering when the rest of us drop out. The question of imagination is also important. It must be imagination tempered with a good deal of experience; in fact, what is wanted is the individual who has his head in the clouds but keeps his feet very solidly on the ground.

Prof. G. Stoney: The author says: "Unless each of us is striving to increase the common good he were better dead." Does he mean that we should kill off all the old people, invalids and incapables? It is undoubtedly true that an engineer is born, not made. We can make them only to a certain extent, and only the fitter ones should enter the profession. To be an engineer a man must have an eye for proportion—a great many never get that—and must be able to make things simply and cheaply. The engineer is a man who does for a shilling what another person does for a pound, and no theoretical training will give him that power, although such training is a great help. Another point which the author touched upon was that besides dealing with machinery he must be able to deal with men. A successful engineer must be able to influence others who are under him and be able to induce the directors and others over him to see that his schemes are good. Without that he will never get on. There is a difference of opinion as to whether the shop or the college should come first. I myself plead for a certain spell of shop practice associated with part-time study. Many of my best men have first gone through our day-apprentice course, under which for two years they came on Mondays to the college and spent the rest of the week in the shop. Others have gone to evening classes to continue their education before entering college. There is no need for a total break between the school and the university; with shop practice in between they can carry on, especially by means of the day-apprentice class which, I think, is one of the greatest boons we have in this city. The young man who comes into the works at, say, 16 years of age is much more adaptable to shop life. He rubs up against the workmen, and the workmen are much more ready to speak to him and show him things. He gets that most valuable factor, the opportunity of knowing the British workman, without which he will never be able to get on in the world. A large part of one's work is dealing with the British workman, appreciating his position and feelings. The capacity for drawing safe deductions from experiment and experience and for seeing what limits there are is most important. This is absolutely necessary if progress is to be made. If a man is not able to make safe deductions he is nothing more than a "walking slide rule." The author mentioned that extrapolation is dangerous. Without it, however, we cannot make any real progress and go from a smaller thing to a large one. I have seen turbines go from 50 h.p. or 32 kW to 50 000 kW with extrapolation, and in 20 years electrical engineers have made it possible for alternators at 3 000 r.p.m. to rise from 750 kW to something like 20 000 kW. Would that have been possible without extrapolation? The man who can safely extrapolate is the man who makes real advances. I am glad to see that the author calls attention to the importance of a wide knowledge. It is curious how often a knowledge of things totally outside one's general line of work becomes of immense value. During the war I had to provide for the billeting, clothing and feeding of large numbers of men, and I was largely occupied during the first year of the war in turning old warehouses and old workshops into billets. A small knowledge of sanitary engineering, though entirely outside my usual work, became of immense value.

Alderman W. Walker: I do not agree with the author when he says that a schoolmaster should decide what careers the boys at his school ought to follow in their after-life. For such a scheme to be successful the schoolmasters of this country would have to possess a fairly precise knowledge of all the principal industries and the qualifications and mental equipment required by those entering them, if they are to have a reasonable chance of success. The intuition and the ability to judge correctly cannot, I think, be taken for granted as being either a natural gift, or an acquired accomplishment of schoolmasters as a class; yet, without these, an attempt to place such a momentous decision in their hands could not be successful. To-day most parents do take an interest in their children, and give much thought to what their future careers should be. They listen to a boy's ideas, they can watch his tendencies, and the father can usually get good advice from friends engaged in a particular career to which consideration is being given. Parents are anxious not to make a mistake and can often bring factors into consideration of which a schoolmaster does not know. Obviously he should be consulted. I think that the figures which Mr. Jones gave us of the percentage of ex-students from Manchester and Leeds who, trained as engineers, are to-day, to the extent of 50 per cent, engaged on the administrative side, were most valuable. These figures are very significant but I am not astonished to find the percentage is so high. It proves how necessary it is that during the period of training the engineer-to-be should have an opportunity of getting an insight into the administrative side of the industry. I am afraid it is one of the weak points in most schemes of training that the opportunities for gaining that insight are infrequent and very often not to be obtained at all. I have been engaged with others in drafting a scheme for the training of power station engineers. When we had completed our first draft we sent it to the boards of the 13 districts into which the United Kingdom is divided. These 13 boards consist of representatives of employers and of the technical staffs, and we asked them for their comments. We have finally worked out a scheme which gives two lines of approach to the status of power station engineer. One of them is for the boy who starts in an elementary school.

Such a boy will go for one term to a secondary school, then to a manufacturing works for a period of 5 years, after which he will spend two years as trainee in a power station. The other is for the boy with a public school education followed by a three-years' university or technical college course, and then either one or two years (that point is not quite settled) in a manufacturing works, finishing his training by two years in a power station. Those who have been trained by both methods respectively must then pass the Associate Membership Examination of the Institution of Electrical Engineers to qualify as power supply engineers on the register which will be kept by the National Joint Board for the industry. As years go on it will be very interesting to note what percentage of the men who have gone through these respective courses will make good by obtaining the higher positions in the profession. It will certainly be some test of the value of the two methods of training, but to-day it has not come into being. Another point brought out by Mr. Jones is one with which I strongly agree, viz. that youths who have had a college training which has taught them to think and draw deductions and to make proper use of information, will probably be more successful than those who have not had such an education. For example, how many students have gone through the School of History at the Manchester University and have subsequently made good in industries and in walks of life entirely detached from history. They were taught to think, to investigate. to use and develop their mental powers, and that is the key to their success in life. They have been able to apply those methods to other problems. It is this fundamental training, added to the purely technical training, which counts for much. It is one of the tragedies of the profession to find large numbers of men who, whilst highly successful as technical advisers, will never be able to take high and administrative posts. They have not the intuition which enables them to visualize what line any given development will follow nor the commercial sense to perceive the ultimate effect of a line of action decided upon at the present. When the main decisions have been taken and the policy has been decided they are then able to deal with the purely technical points. I think that employers in the industry should give more opportunities to the younger members of the technical staff to get an understanding of the organization, administration and commercial sides. Opinion as to the necessity of having works experience is unanimous, judging from the fact that not one of the 13 district boards did not lay down as being essential to the career of the power supply engineer that he should have had a period of training of 5 years in one case and 2 or 3 in the other in the works of a manufacturing engineer before coming into the electrical supply industry, the idea being (and I agree with it) that a youth in a power station who has not been in an engineering works and there learned how the plant is made, methods of manufacture and the handling of machines and the use of erecting tackle, is not likely to become a successful power station engineer.

Mr. J. W. Thomas: I should like to say a word or two on several aspects of the paper that have not yet been touched upon to any extent. Very little has been said about the engineer's due, and it is the point which interests me most. As Prof. Miles Walker has remarked, it is not the predominating feature in the engineer's life but it is an important one. The engineer plays a great part in industry; in fact, as the author reminds us, civilization would practically come to an end if the engineer ceased to function, and because he performs that useful function he is entitled to due consideration. I do not think the engineer has ever expected, and does not now expect, anything unreasonable in the way of reward or recompense for his work, but he does ask for a return that will enable him to live a decent and respectable life. Perhaps he is too much engrossed in his work to give sufficient thought to what he is getting for it, but, after all, like all other human beings he has to live and is therefore entitled to something that is commensurate with his worth. He does not require a very large salary, because his happiness is in his work and does not depend primarily upon his reward, but he requires sufficient to bring up his family respectably and under decent conditions. When that has been settled an engineer will do his work much better, for no man can do his work effectively while he is embarrassed by financial difficulties. I can say quite confidently that there are many engineers, certainly in the electricity supply industry, who are doing their work with more efficiency and greater contentment to-day because their remuneration has been settled on a satisfactory basis. The engineer's due does not, however, consist merely in his financial reward, but in the recognition of his status in the community as a professional man. Though to perform his work he requires as much skill, training and knowledge as members of other professions, he does not get from the community the same recognition and status that they enjoy, nor is it regarded as being necessary that he should be governed in his professional life by those rules and codes of conduct which are the outstanding features of the older professions. There is no reason why engineers should not have the same professional standing and be accorded the same prestige as the members of the professions of law and medicine, seeing that not only do they require careful training but that they give to the community equally important service. Their lack of status in the past has been due partly to their own inertia, but chiefly to a lack of faith in themselves. They do not think sufficient of their service to the community. I mean to imply by this not that they ought always to be sounding their own trumpets, but that they ought to have a larger and juster view of their own worth. If the responsibilities of an engineer in charge of a large power station which controls the lighting, power and transport of a city, be compared with the work of a lawyer in his office, or even of a doctor, it will be agreed that the engineer deserves at least the same standing and recognition as they enjoy. I am in agreement with the author in regard to the choice of men for the engineering profession. I disagree with some of the previous speakers because I believe our methods of choosing men for the profession, or of allowing them to enter it, are much too haphazard. The difficulties of choosing men are undoubtedly great, but they

are not insuperable. They are only great because we have not the data to work upon, and I am quite convinced if we had more data—something on the lines suggested by Alderman Walker—we should be able to prevent many people starting on an engineering career who would be better advised not to. My own experience has been comparatively short, but I know four men who have taken engineering degrees, two of whom are now practising in medicine and two are engaged in the cotton trade. I have no doubt that many members present have similar knowledge of people who have started well in the engineering profession but have found it uncongenial and have then turned aside to some other walk in life. It seems rather serious that they should have gone so far and then be lost to the profession, when a little more systematic selection might have avoided it. Turning to another point, I am convinced that there is plenty of room for the engineer in public life. I always regard him as the true thinker in the community, a man who is bold in conception, is not afraid of taking risks, and who can see a problem and tackle it. That is the kind of man who is wanted to solve many of our industrial and economic problems. If I may refer to another profession, the lawyer who dominates our public life is not, by his training, a man calculated to tackle a problem on new lines; he is not essentially an innovator. Admittedly he has an important function in society inasmuch as he gives form and expression to the views of the community, but he is apt to look to the past for his solutions, whereas the engineer is always tackling problems on new lines. If engineers would not keep their noses so closely to the grindstone, but would take a larger view of things, and see that there were big public questions to which they could make an effective contribution, I think our industrial and economic life would be the better for it.

Mr. M. Hird: The author has instructed us fully in our duties, the chief of which, and the one that has had the most attention paid to it in the discussion, is in regard to the choice of the engineer. There is a great difference of opinion as to how the engineer should be chosen, but it is generally agreed that we want the very best that is obtainable. We must make the choice; no one else can do it for us. The citizens of Ancient Rome at one period of their history used to keep Greek slaves to do their reading and writing for them and it was supposed to be bad form to have the accomplishments of a slave. We are in the same position as those learned helots, as we might call them—we have made all the apparatus of latter-day civilization and handed it over to other people to use. The reason why we do not get our status talked about, as mentioned by Mr. Thomas, seems to be that the whole of the products of our work ultimately passes into other hands. It has been mentioned that half of our number go into administrative work after having had their engineering training, but I think that in spite of all the labour questions, works committees, welfare schemes and the like, we have all had our training in dealing with the raw material provided by Nature. Nature is honest, even if at times she is somewhat pigheaded. This in itself makes it difficult for us, as a class, to deal with humanity —which is pigheaded as well. We cannot avoid taking some responsibility for the ultimate results of our handiwork, and I think that one reason why we feel so helpless before this sort of question is that we have paid so little attention to questions of this class. I suggest it is our duty to think more about the ultimate results of the work we are doing, and in the course of time if we give these questions serious consideration we shall be able to speak as a body and what we say should command respect.

Mr. T. E. Herbert: Far too seldom are we asked to study ideals and to get down to the fundamental problems of life. The author has considered the special case of the engineer, but would it not be better to say, in set terms, that we want everyone to do the work that he is best fitted to accomplish? Such work involves his natural aptitudes, and in doing it he will find not only the greatest measure of usefulness to the world in general but the greatest happiness to himself. The author says, in effect—quite rightly in my view—"First catch your engineer young," but apparently he thinks the schoolmaster is the right person to make the selection. I agree that a schoolmaster is a member of a very important profession, but the work of finding out what are the real capabilities of a youngster seems to me to be entirely a job for the medical man who has specialized in psychology. In my opinion the new science of pyscho-analysis developed by Freud, Jung, Adler and others will advance to such an extent that from the hands of medical specialists one will ultimately be able to get a correct forecast of what profession a boy should follow. This, however, is essentially work for the specialist physician. The body and mind are, of course, related and we must get the right people in the right places, and not round pegs in square holes. The governing motive in getting through life may be simply money, or it may be fear alone that drives a person to perform his duties. In either case he will not perform his work with happiness to himself, and if he is not happy in his job then I do not think that very much can be expected in the way of results. With regard to the training of engineers, one point which should be emphasized very strongly is the vital importance of the human touch. In all but the very early stages the majority of engineers are called upon to guide and direct human effort. The ideal to be attained has been described as:—

> "Souls tempered with fire,
> Fervent, heroic, and good,
> Helpers and friends of mankind."

The mental attitude may be correct but it needs a considerable amount of training in the administrative side of the work to achieve a successful application of the principle. A little later in the paper the author refers to a subject which interests me very greatly, i.e. the need for an accurate knowledge of English and power of expression so that reports, letters and statements may convey to the recipient a perfectly clear idea of what is intended. On the other hand I think that the young engineer should acquire the judicial frame of mind referred to by Alderman Walker, and should

appreciate the dignity of his position. The use of extravagant language is perhaps an error into which young people are prone to fall. If an engineer enters into a newspaper controversy with a professional colleague he ought to remember that by using wrong methods in that controversy he brings his profession into the profoundest contempt. Such a controversy does untold harm to our profession and that is perhaps why in so many cases a so-called business man instead of an engineer is found in administrative control of an essentially engineering concern. It may be that some engineers have no administrative ability whatever, but I do not think it is fair to say that because a man is an engineer and knows his work he is *ipso facto* unfitted for supreme control. Take, for instance, such a job as that of a director of a railway company. The very last thing that any director of a railway company has is a knowledge of civil, electrical or mechanical engineering. I do not see why that sort of thing should continue to the same extent as it has obtained in the past. It may have been our own fault and if we have people in our profession who do not realize the proper use of the English language and the proper attitude towards their professional brethren then very serious damage to the prestige of electrical engineers will result.

Mr. J. B. Hartley: In the first Section of the paper, dealing with the rights and duties of life, the author mentions that we should try to do a little bit more than our duty. That reminds me of the need for enthusiasm. We can never do more than our duty if we cannot maintain our enthusiasm; we all enter the profession with it, but somehow many of us lose it. Whether it is our fault, the fault of the modern industrial system, or the fault of the people who employ us, it is difficult to say. The man of real enthusiasm puts his soul into his work, not because he loves his work for itself, but because the idea behind the work has made him captive. A so-called matter-of-fact man, who prides himself upon taking things as they are, who has no use for theories, dreams or speculations of any kind, is never an enthusiast; in fact he scorns enthusiasm as a stigma of an ill-balanced mind. We have all met the man who is sure that an ounce of common sense is worth a ton of enthusiasm. No great ideal ever tempts him from his moorings. He may be a faithful, industrious, intelligent worker all his days, but his career in his profession or business will be commonplace and uninteresting. Such men often make the best of neighbours and citizens but they do nothing to make the earth a better place on which to live. Enthusiasm is one of the most dynamic of all human qualities. In a sense it is the ideal descended on earth to battle with realities; men instinctively recognize its high origin and easily surrender to its influence. That is why we say that enthusiasm is contagious. A business organization lacking enthusiasm does not, I am sure, get out of its men 50 per cent of their potential efficiency. We all start with enthusiasm but many of us lose contact with this very effective driving force. It is not always our fault; it may be due to the men who have control of us. Executive officials do not always help to keep an organization loyal and enthusiastic. New positions should, whenever possible, be filled by the promotion of employees rather than by going outside for new men. Managers often handle their men stupidly, not seeking to make each employee feel contented and hopefully ambitious. Each employee should feel that his welfare is of interest to his employers and that they are determined that the merit of not a single one should be overlooked. So far as men are concerned, I think we often get the wrong mental attitude towards our work. There is one degrading conception of our work which should be avoided by engineers. Many engineers speak of their positions as "jobs." This conception often leads a man to think of his work as being a more or less disagreeable occupation for 8 or 10 hours a day. The typical man with a "job" very soon begins to think that he is overworked and underpaid, and is glad when the day is over, for the job means hard work and no pleasure. He also has a habit of thinking that mere length of service alone entitles him to promotion or increased remuneration. He usually has a special grudge against his immediate superior, the man who directs his work. He is sure that he works harder than his superior but that his work is not appreciated. There is a sense in which every task is a gold mine. The man who works for the gold in the task rather than the amount in the pay envelope is the one who eventually makes most progress. In Section (5) the author reminds us that we should be ready for opportunities. It is, I believe, a familiar human weakness to think of ourselves as not being in just the right place. We are prone to think that opportunity, like happiness, lies in some distant place, and if we could only get there we should be successful and content. Actually the best opportunities often turn out to be close at hand. This is perhaps naturally so, for we are familiar with near-at-hand conditions and know their possibilities. As Thomas Carlyle has said: "Our grand business is not to see what lies dimly at a distance, but to do what lies clearly at hand."

Mr. L. H. A. Carr: Many of the questions raised by the author are very profound. He refers to the right to live, but is there any right to live without a corresponding right and duty to work? There is an essential difference between ourselves and the members of some of the other professions which have been mentioned during the discussion, and this difference must be taken into consideration in discussing our due and our duty. This difference is due to the fact that an engineer does not carry out single-handed the ideas of his brain. In almost every case a large number of workers are required to carry out his designs. Consequently the present system of organized industry has arisen in which the majority of engineers are not individual practitioners, but are closely allied to a large number of workers of all classes in order to form an industrial unit. Further, and largely arising out of the same facts, the engineer's duty is not served directly to, nor is his due received directly from, individual members of the community who require his services, as is the case in many other professions. This brings up the whole question of the organization and financing of industry, which in a sense is a side issue to the subject of the paper, and yet is one that would have to be thoroughly discussed in considering how the engineer's duty to the community can best

be carried out. Among the necessary qualifications for the embryo engineer, the author has omitted to mention good health and a strong constitution. He suggests that more use might with advantage be made of engineers in connection with the solving of the many problems with which industry is faced. This view is held by many other engineers who have already formed professional organizations, one of the objects of which is to promote such practices. One other duty of the engineer has not been mentioned in the paper. In feudal times the inhabitants of a village were almost entirely dependent on their overlord, and, whether he realized it, or whether he shirked it, his was the responsibility for seeing that they did not starve in bad times. I feel that this responsibility has, to a large extent, come down to us, and that we are responsible to the workpeople in our industry for getting sufficient work into our factories to keep them from penury and starvation.

Mr. A. E. Clarke (*communicated*): I have often thought that the papers read before the Institution have been too much confined to the technical and professional side of engineering, with consequent neglect of that equally important phase, the contact of the individual with the world at large and the reactions that spring therefrom. It has been well said that "it is a consolation that life is still the same essentially as it always has been, and that we are still the sons of men, and not the children of machines or systems." It is also interesting to note the accuracy with which the character of the modern engineer was forecasted in the apocryphal Bible by the writer Ecclesiasticus. Writing of the activities of the farmer, graver, ploughman and so on, he proceeds thus :—

> "Without these a city cannot be inhabited.
> And they shall not dwell where they will, nor go up and down.
> They shall not be sought for in public counsel.
> Nor sit high in the congregation.
> They shall not sit in the judge's seat.
> Nor understand the sentence of judgement.
> They cannot declare justice and judgement.
> And they shall not be found where parables are spoken.
> But they will maintain the state of the world,
> And all their desire is in the work of their craft."

The whole excerpt fits the engineer, the last two lines being particularly applicable. This, then, is the man whose duty and due are under discussion. Should not the "duty" come before the "due" in the title of the paper? It is only by the performance of duties that dues or rights become established. Also, the last sentence in Section (1) should be altered to read "There is no duty without its corresponding right," and it is in the spirit expressed in this word inversion that many, if not all, of our industrial troubles to-day may be solved. Once this principle has been clearly grasped, and is in process of resolute enforcement, confidence between man and master, community and individual, will be established and most of our difficulties will disappear. It is said that the spirit of the engineer is expressed in the single sentence "I will," i.e. he is essentially an objective thinker as opposed to the subjective thinker, who says "I am," and it is because of this that the engineer's activities permeate the whole of the world to-day. There is hardly any action which can be taken or thing that can be handled that has not been influenced at some stage by the work and thought of the engineer, and accordingly civilization, as we understand it to-day, is largely founded on, and is certainly maintained by, his efforts. His duties, therefore, are very arduous, for on his energy depends all the good that has survived from the past, and the development for the good of humanity at large of all resources which may become available in the future. Such a responsibility should make him very humble, and should serve to strengthen his determination never to cease to strive for the truth, speaking in the widest sense, both objectively and subjectively, as a member and perhaps guider of the human race, perpetually straining towards one goal, the betterment of humanity. His dues are therefore clearly established before the whole world, though, because of his peculiar concentration on his art, there has yet to grow up in the body politic a true appreciation of his worth. But if engineers will be true to themselves and indeed strive wholeheartedly, honestly and continuously to do their duty, not as mere engineers, but as conscientious members of the race of man, then there can be no doubt that appreciation will eventually arise, and they will be called on "to decide the courses and steer the ship of civilization to fairer seas." Signs of that change are already visible, and engineers are being consulted more and more widely upon all manner of diverse subjects. I do not mean to say by this that engineers are omniscient, because they must always remember that even to-day they are like Carlyle's minnow, which, although it knew every crick and cranny of the little piece of water in which it swam, had no conception at all of the mighty external forces of rain and sea which might at any moment in a (to him) terrible cataclysm sweep him and his world away to nothing. We are the minnows, the creek is our tiny world and the mighty influences are those forces which we do not even begin to understand, which work with æons as their unit of time. Up to the present the work of the engineer in public life has been but small, for the clear and simple reason that he deals with inanimate things and forces of which to some extent he knows the properties and can calculate the interactions, and which, within certain well-known limits, he can direct and guide to perform different kinds of acts. If he be a true engineer at heart, his work is of such surpassing interest and engages his attention so fully that he has neither time nor desire to enter the mazes of public life. Even if he be inveigled away eventually from his bench or his desk and is confronted with the *genus homo* with all its psychologic limitations, he finds that this particular being will not run true to formulæ and he becomes possessed of an impatience, evolved from his very training and experience, which eventually causes him to turn away from such recalcitrant material and return to his well-beloved, well-understood and obedient forces of Nature. This is a limitation which engineers in the future will have to surmount, and

it is refreshing to find such stress being laid on this point both here at home and in many countries abroad, particularly America. In that country I understand that concurrently with technical courses at the universities, courses in natural philosophy, economics and certain branches of psychology are included. Years ago a paragraph appeared in *The Spectator* which struck me as being inherently unsound. It was as follows:—" The design of learning is, I take it, either to render a man an agreeable companion to himself, to teach him to support solitude with pleasure, or, if he is not born to an estate, to supply that defect and furnish him with the means to acquire it." If the whole of the objects be included in one course of education then there is little to cavil at, but to take either part separately and to compare each with the principles enunciated by the author reveals at once the infinitely greater charity and broadness of conception of the author's scheme. Stress has been laid on the selection of engineering students and trainees, and rightly so, but I do think that when advising prospective engineers, greater stress should be laid on the extremely arduous nature of the training necessary, both physical and mental, and the long years between the ages of 20 and 30 which return little to the devotee and demand all his endurance. Many young engineers seem to give up hope and lose enthusiasm between those ages. To the chosen, such years act as a kind of weed-killer and exorcise all the weak elements of character and endurance with which they may be cursed. Nevertheless, a deal of heart-searching and, perhaps, bitterness might be spared if greater stress in advice were laid on that period and students were warned of what to expect before they entered the ranks of the profession. Employers should treat men during those years with much consideration, encouraging their efforts and guiding their steps gently towards the shining light beyond. Another equally important matter is the selection of the trainers of students. It has often seemed that college professors, the experience of many of whom is confined almost entirely to practice in college or school, must necessarily lack certain qualities which are of supreme importance to the budding engineer. The dispensation of knowledge on the subject of the great and unchanging fundamentals of engineering may be safely placed in their hands—that is their training—but it does appear that better ends would be served if on that stock were grafted a selection of modern practising engineers who would deal with engineering in its most recent applications in industry and would bring to bear on the students some of those great qualities which have lifted them to their present heights.

Mr. W. J. Medlyn (*communicated*): In Sections (3) and (4) the author quite rightly stresses the importance of technical knowledge, but very little is said about the need for training in administration. It is true that many engineers are required to be technical experts without having to exercise powers of administration to any considerable extent, whilst the duties of other engineers may be chiefly administrative. The discussion has brought out the fact that a very large proportion of trained engineers do ultimately take up important administrative posts; and in this connection I think the following brief extract from an address delivered in 1907 by Mr. James Pigg, then chairman of the North-Eastern Centre, could be usefully placed on record:—" Another essential qualification of the engineer is the power of organization. Organization can only be effectively carried out when a clear view of the end to be attained is combined with a thorough knowledge of the means available. Effective organization implies a knowledge of the tools; the aptitude to judge a good tool from a bad one, or the ability to improve it. These tools are for the most part men. The engineer must therefore be a good judge of men, and know in what way they may be most effectively used for his purpose; how, in fact, they may each be fitted properly into the mosaic which it is his business to form." From the observations in the present paper I gather that the author is in full agreement with the remarks I have quoted, but it seems to me to be well worth while to emphasize the importance of these qualifications. There is, of course, room for the best men of both types to rise to positions of eminence. Whether the technical expert or the engineer-administrator reaps the greater reward for his labours is perhaps a matter for speculation, but on the whole I am inclined to think that the greater possibilities for advancement lie with the administrator. In both cases, of course, success can only be achieved through hard work and self-sacrifice.

Mr. T. Petrie (*communicated*): The author's two main themes, put very baldly, are that engineers must be born to be made; and that when they are at the height of their powers they should turn more to public affairs than they do. With regard to the first, it is probable that every boy at one stage of his life has wanted to be an engineer—or at any rate an engine-driver—and it always seems a wonder to me that more do not start engineering training than is actually the case. With regard to the second, I think the same may be said of all the intellectual professions—except perhaps the Law. The whole of one's active mind is absorbed in keeping abreast with one's profession, and the time devoted to outside work means a loss of efficiency as a professional engineer in the strictest sense of the words. Nevertheless, we have had two engineers as Lord Mayors of this city within the last three years, and both of them are exceptional men. I should like to stress a third theme for the fundamental duties of an engineer. He should never take anything for granted—not even a formula. His training should be such that he learns not only his fundamentals but also how to think for himself, so that when new problems arise he is equipped to meet them with an open mind. Our immediate predecessors of the Victorian era, if they had a fault, were rather prone to accept blindly the lead of the big men—even shops tended to be run on the principle that what was good enough for their grandfathers was good enough for them. The consequence was that new ideas—in other words true progress—tended to be stifled, to the general loss of the community. I am afraid that the big men were as much to blame as the others—at any rate Herbert Spencer, replying to some new argument, is reported to have said: " That can't be true, for otherwise my ' First Principles ' would have to be re-written —and the book is already stereotyped."! How far is

this attitude true to-day? We all pride ourselves on modern progress and broadmindedness—but I should like to stress this aspect of the question and to suggest that if they want to represent all that is highest in their profession, engineers should always think things out for themselves and then act on their convictions.

The Author's Reply to the Discussions at London, Liverpool, Newcastle, Leeds, and Manchester.

Mr. T. Carter (*in reply*): Mr. Dunsheath says that the Papers Committee may have had some misgivings about accepting "a paper so unorthodox as this." I certainly had misgivings as to its reception, for it might have been thought by those who heard it to be more suited to the pulpit than to the reading-desk of the Institution and its Local Centres; but the volume and the sympathetic tone of the discussion are the best proofs that there is a place in the Institution for the stirring up of thought on fundamental issues, and I trust very sincerely that others, far more versed in these great matters, and far better able to deal with them than I am, will from time to time submit them to us for consideration. I believe that the Institution, with its ever-increasing weight of influence, could so shape and educate public opinion that a proper view would come to be taken of the rightful place and standing of engineers in the community. The mere existence of our Institution, and of other kindred Institutions, is evidence, to those who understand it, of the real importance of the matter; and it might be possible to do a great deal through the Engineering Joint Council to secure a fuller study of the whole question of how to use our human resources adequately. The paper, and the discussions arising out of it, have necessarily dealt in a very general way with what are really the mere outlines of the subject; and my reply must be on equally general lines. Had I unlimited time and ability to think out all that has been said, and had I unlimited space to fill, there would even then not be an end of what could be written. But there are limits, and it is well; for there is the day's work to do, and we may not cease from it while we consider how to do it. Is not that all the more a reason for the early acquisition of a clear view of fundamental principles, so that, as far as in us lies, we may deal with the unending chain of events instinctively in the best way?

I propose to make one reply to these five discussions, and if I do not specifically mention the name of every person who took part in them, it will not be thought, I am sure, that I have not heeded what he said. He will find, I hope, that I have referred to the essential things in his remarks. It has been interesting to discover, amongst much agreement with the principles laid down in the paper, that questioning and controversy have centred round a few definite points. I think the thing that has impressed me most is the readiness with which one person after another has assented to views that are nothing but sheer idealism and counsels of perfection. Matter-of-fact and prosaic as are the work of engineers and their attitude to its problems, there is in far more of them than might be expected—deep down perhaps, and rarely seen at the surface—a poetic outlook that will surely save the profession from ever becoming a merely materialistic affair. Thus we may escape the all-too-common tendency to be taken in by "that great engineer, Satan," the eternal adversary of God and man, who lays his snares so cunningly. He is the champion of the second-best: "Doth Job fear God for nought? . . . Thou hast blessed the work of his hands. . . . But put forth Thine hand now, and touch all that he hath, and he will renounce Thee to Thy face." What could more perfectly express the dullness and deadness that sometimes steal over us than these lines by Humbert Wolfe, taken from *The New Statesman*?

IN THE CITY.

In the City they sell and buy,
And nobody ever asks them why.
But since it contents them to buy and sell,
God forgive them! They might as well!

Mr. Swinburne carried the discussion to a place of wide outlook; he raised the whole question of the kind of education that will make the men and women the world needs, and he brought into view no less a thing than democracy itself. In spite of the change in the attitude of the educated towards the uneducated—a change that may perhaps be symbolized by quoting, on the one hand, the command: "Be silent, all flesh, before the Lord," and, on the other, the pleading petition: "Come unto Me, all ye that labour, and are heavy laden, and . . . learn of Me"—it is to be feared that democracy has far to go before it ceases to deserve Mr. Swinburne's definition of it. It is an epigrammatic definition, and must be read accordingly; but it is not quite clear whether the governors are meant to be described as the greatest fools amongst a community of fools, or whether they are to be looked upon as the least foolish of the fools, great, though fools; great, if they are indeed real and noble leaders, in spite of the tincture of folly that they cannot escape. I hope it may be believed that the second is the true alternative. Although it is necessary to admit the inevitability of a pessimistic view of much that is human, and although it may be no more than a feebly flickering and perhaps apparently quite illogical hope that yearns for a brighter goal, I trust that we may cherish the little spark as often as we find it. Who knows when it may break out into a great conflagration of soul-searching and purifying enthusiasm? You remember how, in Hans Andersen's tale of "The Flax," the children "sang over the dead ashes:

'Snip, snap, snurre,
Basse lure:
The song is ended!'

But the little invisible beings said, 'The song is never ended; the most beautiful is yet to come.' Only the children could neither hear nor understand this, nor should they; for children must not know everything."

I had naturally to confine the paper to problems peculiar to engineering, but it is quite true that in its essentials it applies to all callings. I am sorry that Mr. Day is disappointed on this account, because it seems to me that unless the engineer is facing life fundamentally from the same standpoint as the rest of men, he will be living in a world so different from theirs that he will have less in common with them than he ought to have. I quite agree with Mr. Day that what is desirable for the engineering profession is equally desirable for all others, and I would emphasize Mr. Herbert's point that what we want is that everyone should do the work he is best fitted to accomplish. The order of words in my title has been criticized: duty, it is said, comes before due, and I gather too that my definition and discussion of the engineer's due is thought by some to be not practical enough. Apart altogether from the fact that an inquiry as to whether or not the engineer is duly paid for what he does would be quite inappropriate to this occasion, I think that there is a far wider view to be taken of both the points that have been raised. Due, I suggest, begins at birth, before any duty can have been done to form a claim for due. The engineer baby (no one knows as yet that fact about him) has his due in the bodily and mental food, the clothing, and the shelter that his parents, or failing them the community, try to give him. It is only as he grows up that he realizes that duty is the counterpart of due, and, if he is a decent citizen, does his duty. In return for that, he continues to receive his due, that is, his opportunity for a proper life, as long as he is serving the community to the utmost of his strength. So, though due and duty are inseparably linked, I put due first because it is first in time. My reason, too, for saying that rights have corresponding duties rather than that duties have corresponding rights, which is also true, is that to-day it seems that many are clamouring for their rights and forgetting their duty altogether. So I want very definitely to stick to the order of the words in my paper. Then, as for the engineer not getting a salary commensurate with his deserts—a subject, as I have said, that may not be discussed in detail here—I would say that his surest way of getting all that he should have in that direction is to see that he and, as far as he has influence, every other engineer strive primarily to make it absolutely clear to the whole community that they put the interests of the nation before the interests of their profession, and that they equally count their profession greater than the individual engineer, infinitely important as every human soul is. If this seems to be a distant goal, I can only say that I believe that disinterested service will tell in the end, and will establish the engineer on a far safer basis than anything else will. Here, as so often, the longest way round is the shortest way home. This seems to me to answer Mr. Hurlbatt's point about the group and the individual: to consider the interests of the group, or rather the whole, is to me the soundest way of advancing the interests of the individual. I fear that I am expressing my meaning crudely; it is put perfectly in the words: "Be not therefore anxious, saying, What shall we eat? or, What shall we drink? or, Wherewithal shall we be clothed? . . . Seek ye first the kingdom of God, and His righteousness, and all these things shall be added unto you."

I agree with Mr. Wadeson that we must decide what is the common good, difficult though it is to discover it. If we say that it consists of all that helps the race rather than hinders it, we do not say more than is obvious; the real problem is to get a wide enough view of things to foresee whether they will help or hinder. Prof. Stoney asks whether I would kill off all the old, the ailing, and the feeble. Emphatically no! There are old people without whose guiding we should be lost; there are those whose bodies ail and yet whose courage is an inspiration; there are feeble folk whose presence is a benediction. All these are somehow contriving to increase the common good, so let them live, and do not cease to thank God for them! If there be a rubbish heap somewhere in the universe, it is not they who will be cast upon it in the last reckoning. But, after all, I do not think that I proposed to kill off anyone, by means of the lethal chamber or otherwise. It is not advocating the slaying of a man to say he were better dead; nor is it suggesting the use of the lethal chamber to say that it would be more comfortable than life. Again, when I described some rocks as unclimbable, I meant them to be thought of as unclimbable, and not as climbable with difficulty. Those who have referred to this have scarcely misunderstood me, and I am grateful to them for having made explicit what I said only implicitly. The same thanks are due to those who have mentioned the essential importance of never doing a thing ourselves if we can find someone else to do it well for us. The managing director does not lick and stick on the stamps that frank his office correspondence; that is an obvious illustration of the principle, and it is according to our skill or want of skill in devising less obvious applications of it that we shall be free for bigger things than we have been doing, or, on the other hand, stuck in a morass of clogging details.

A good deal has been said about my reference to free meals and other free things (which, as has been pointed out, are not really free at all, though it may be recalled that they are not usually paid for, in the ordinary sense, by those who receive them). Had I put the word "education" inside quotation marks, as I have just done here, or described it as "education, so called," my meaning might have been clearer. It is because we are inclined to regard these things as sufficient, as solving our problems, as ends rather than as means, that I suggest that they are likely to lead to so inadequate a use of our human resources that they are only to be thought of as bringing death to the nation in the end. I agree with Mr. Vernier in what he said about doles, but I feel sure that he agrees too that they are a very dangerous expedient and a most regrettable necessity.

I am glad that Prof. Scholes has given the American definition of engineering, because, although human activities are really amongst the great sources of power in nature, it is perhaps well to mention them separately. To direct and organize them aright calls for all that is most skilful and cultivated in the engineering brain, and I have tried to indicate in the paper some of the

things essential for success. I gladly add to these the others that have been mentioned in the discussions: enthusiasm, imagination, general knowledge of men and of human character, the possession of the human touch, good health, a strong constitution, the enlightenment that comes from foreign travel, and the acquisition, somehow, of common sense, by which, though I am never quite sure, I suppose is meant that most uncommon thing, a nice appreciation of the universal judgment on affairs. Equally gladly will I add the sales engineer to the list of persons making up the total of our profession. I agree with Mr. French's classification of the sales engineer, and I pass it on to Mr. Allan, feeling sure that it entirely meets the point that he raised. My own reference to the perennial question of the engineer-salesman was rather to the problem of who he is to be: that is, whether the qualities described by Mr. French are sufficiently often found combined in one person to make the supply of sales engineers equal to the demand, and whether, if they are not so found, the man who will sell goods best is the engineer as such, or the salesman as such. I think that this is a very real problem, and I believe that its solution is to be found along the lines indicated in the paper. Mr. Allan and I really agree with each other, and I most cordially endorse what he and Mr. Dinerman say about the extraordinarily useful results of the activities of the first-class sales engineer. Mr. Crompton asks me to add the mains engineer to the list also. I intended him to be included amongst those who run power stations, using the word "run" in the widest sense; but if that is not clear, I am quite willing to mention him specially.

I suppose that many papers could be written on the very wide subject of the finding of engineers, and I think that it has been referred to in the discussions more than any other question. Because there is so much that might be said, I must be as brief as I can in my comments. I value exceedingly Mr. French's proposal for the extension of the principle of collecting information about the characteristics of persons: if we could study representative men from the cradle to the grave, we should undoubtedly gain valuable data. I think his classification of engineers is most illuminating; it is the kind of thing that defines our aims and objects, and I am certain that it will be treasured by many readers. The difficulty of getting information about people in later life might be overcome—I say "might" advisedly, for most of us are quite unnecessarily casual about these matters—by explaining to students as they leave a school, a college, or a university, that they can be of service to their successors by continuing to furnish particulars of their doings and achievements to some central recording place. It is all very well to say that this kind of geometrical precision is impossible: perhaps it is in its complete details, but if it is desirable, as I believe it is, its impossibility as a whole is no reason for our not seeking to secure some measure of it. As I said in the paper, we must cease to be haphazard; and if by patient thought for the next few years we can discover how to do so we shall indeed have accomplished a great thing. I should not have dared to say what I did about finding out what is in children by intelligence tests, by vocational tests, and by continuous observation, had I not had in my possession the record of Dr. Johnston's successful achievement. It seems to me that it answers those who say that this cannot be done: a beginning has been made, and what with negative suggestions and positive suggestions, all carefully considered in the light not of a kind of laboratory analysis of the boys but of a friendly attention to their characteristics from year to year, there must be many men in a more suitable niche to-day than they would otherwise have been. I agree with those who would not trust the selection to schoolmasters as we know them now: most emphatically I agree. But if the demand for this kind of thing arises generally, the process of natural selection will gradually bring into the teaching profession those who are capable of doing what is wanted. It would be a great change; but it would not be any greater than, for example, the change in the methods of the medical profession in the last few centuries. These are not things to be reached to-day, or to-morrow, or even next week; but we shall not come nearer to them by saying that they are impossible. Our realization of their present impossibility is the first step towards their future achievement.

What has been said about the head-and-shoulders-higher-than-their-fellows people is interesting, and has brought out many valuable points. It may be recalled that I did not suggest discovering these to the exclusion of the second-class and third-class people; but I do think that we ought not merely to let them discover themselves. Cream, Mr. French says, always rises to the top; but it does not do so if we keep on agitating the milk and never give it a chance in the turmoil. We must provide facilities for the best men to rise to the top, and even if we discover them merely by letting them discover themselves, we still want to discover them. I said, too, that only by watching all will the best be found; and it is in the process of watching all that the second-best will be found too. It is clear that at Highgate every boy is helped as far as possible, and as far as he will accept help, and, given the right kind of observer, I am sure that the boy who needs least pushing will get it, and, on the contrary, much help will be given to those who need it most. We must get away from looking at things as they happen to be now, and transfer our gaze to things as we think they ought to be; thus will change follow change from less to greater perfection. All the more because, as the discussion has suggested, the first-class engineer might be almost a first-class anything, do we want to find out if he is just a little better engineer than he is something else, and say to him: Here is your finest calling. I would not make known the results of intelligence tests to all those who are tested. The data of mass tests are for the guidance of the teacher rather than for the information of the taught. But if I had to discuss the possible future careers of older boys with each of them personally, having had the opportunity of watching their individual characters and qualities, I should be quite prepared, at least by way of suggestion, to acquaint them with the results of my observations. Mr. Day asks me what I would do with the rest of the people. They, I imagine, will be those to whom I have referred as going through life doing mostly as they are

told, and they will have to be distributed amongst whatever occupations are in need of them, very much as they find room where they can now. Only, under a more careful system, they would be more efficiently employed. I quite agree that the question of population is wrapped up in all of this, but that is a problem that will apparently have to be tackled and solved somehow in any event.

I am still inclined to think that a restriction of the number of those who become engineers would be useful. That is not the same thing, however, as a refusal of an engineering training to some who will not become and do not intend to become engineers. Whatever they make of their lives eventually, it will always be useful to those who can afford it to have had an engineering training. It is reasonably certain, in my mind at least, that a smaller number of better-trained men would bring about an increase in efficiency. I agree that economic demands will regulate the supply, but with a lag, as Mr. Mouat Jones says. If the lag can be reduced by keeping records, I must say that I would advocate the keeping of records, for when the lag operates towards the throwing out of employment of those who have been trained at great cost, it is an undesirable thing. Hence the proposed register mentioned by Alderman Walker, Mr. Thomas, and others, is likely to be of immense use and importance, and the general question of the registration of engineers, mentioned by Mr. Marshall, should not be forgotten.

Under the heading of the training of engineers, many things have been said relating to the varieties of engineering education, with which my paper deliberately did not deal; I welcome them, because they add to the completeness of the discussion as a whole. I think that Mr. John's suggestion for a closer contact of teachers with practical work is particularly interesting and valuable, and ought to be seriously considered by those who have power to arrange these matters. I know that in some schools teachers are set free for travel periodically for a term of two, with beneficial results to themselves and to those whom they begin to teach again on their return. Of great importance, too, is the training scheme formulated by the Electrical Power Engineers' Association in co-operation with the representatives of the supply undertakings for the purposes described by Mr. Crompton, Alderman Walker, and others. Nothing could more completely ensure the smooth working of the supply industry, which is so vital to the general prosperity of the nation; it is a tremendous step forward, and one on which the industry is to be sincerely congratulated.

The great question of students living at home or away from home was raised: is it not true that some homes are far and away the best places for their children to be in, whereas other homes, or, better said, houses, are not fit for any children to inhabit? Reference has also been made to the relative share of parents and teachers in education. It is far from easy for even the most careful parent to get reliable information as to the best training and preparation for any kind of career for his children; and, if the schoolmaster were expert along the suggested new lines, he could render invaluable aid. With the best will in the world, parents are often puzzled, and their friends cannot always help them, nor ought they to be expected to be able to assist in complicated details. The schoolmaster need not know all the intricacies of all the possible vocations, professions, or jobs: these are roughly divisible into groups, and for many of them the general lines of preparation are alike. Here again, it is nothing to the point that the problem is difficult; it is far more pertinent to say again that one notable attempt is being made, with some success, to solve it, and that what can be done in one place can be done elsewhere. It should at least be easy to keep a potential Beethoven out of engineering, which is always something; and, little by little, finer distinctions will become possible and will be drawn.

I agree with what was said by Mr. Maccall, Mr. Dickinson, and others, about the value of internal examinations. They are obviously in a category quite different from external examinations, and the more their results are judged in the light of the general work of those who sit for them, the more will they be really a part of the record of achievement that is so much more desirable a basis of judgment. It is, indeed, in the long run, and the older a man grows, the only possible basis of judgment. So far as the general curriculum of a university or college training goes, I feel sure that the course suggested in Section (4) of the paper will satisfy the demand for instruction in broad principles, in administration and organization, in the kind of economic problems to which Mr. Dickinson specially refers, and in the ways in which the engineer must be prepared to deal with his fellows in all his relations with them. Obviously no more than a mere beginning of all this can be made in an academic place. Experience is the only certain instructor in the last details, but a little initial guidance will make the later learning easier by far than if the engineer came into contact with administrative problems quite unprepared. One thing that can scarcely be acquired at all in a college is skill in dealing with men: Mrs. Matthews, Mr. Fleming, and others have pointed out how essential it is to learn this from personal contact with those who are employed in works; and still others have reminded us that men do not act according to any formula. I mention these points once more because of their tremendous importance, and I suggest that if the engineer finds that the laws of man are painfully different in character from the laws of nature, there is all the more incentive in that for him to try to bridge the gulf and to improve the laws of man. Mr. Carr has rightly emphasized the intimate way in which we are bound up in our fortunes and misfortunes with many others, between whom and ourselves there is continual mutual dependence, and he has also shown how great a responsibility we may have for the welfare of others in times of distress. Let us be thankful for everything that convinces us afresh of the impossibility of one suffering without bringing hurt to all, or, on the other hand, of one advancing without bringing gain to all; and let us clearly realize the fallacy underlying any attempt to separate us and to make us stand alone or in sections and classes alleged to have opposing interests. Several people have remarked on industrial problems, and their hints of

possible solutions of some of them are welcome additions to the discussion. The subject must be left there so far as the present occasion is concerned, for, tempting as it is to discuss it further, its controversial aspect arises all too readily.

Mr. Anson refers to the conflicting opinions of experts. Are not these due to the impossibility that any one of us can possess complete knowledge and understanding of any problem? And if experts of equal eminence differ, does not that merely show the enormous complexity of the particular question before them? The final difficulty is how to find a comprehensive answer; that is, how to combine the partial answers of the several experts into a coherent whole. This is never easy, and usually it can only be done according to the special circumstances of each case; but it is at least certain, as Mr. Swinburne will doubtless particularly support me in saying, that to leave the settlement to the vote of electors or of their elected representatives is usually the way to ensure the kind of decision that might be equally logically obtained by putting all the possible answers, written on slips of paper, into a hat, by getting the first stranger who passed by to draw out one of them, and by adopting that as the true solution.

I want to emphasize once more the value of reading the works of great writers. A sense of the melody of rightly chosen words will add to the harmony of our whole life, and will increase the resources of our thought. What would not many of us give to be able to find words so apt as in this poem by A. Doris L. Wilson, printed recently in *The Poetry Review*?

EPITAPH.

All loveliness she sought.
Disgrace, despair
Struggled to dim the courage of her eyes,
And Poverty, seeing her spirit flame,
Bruised her with deadly pain
Till Death the Healer came.

* * * * *

And now she sleeps, her calm brave face,
Small chin, grave lips and eyes a long, long space
So still.
So still she lies
She cannot know this earth hath given
A sweeter bed to her beneath wide heaven,
She cannot know the rains will fill
Her folded hands and hair
With grass and cowslip fragrant there,
Nor can she hear
Increasing year by year
The brook that dusks and gleams past fern and firs.
Only long quietness and night are hers.

Prof. Stoney rightly says that extensions and progress come by extrapolation; but I do not think that that makes extrapolation less dangerous. All pioneering is extrapolation, and pioneers are taking risks all their lives. So long as the risks are recognized and understood, their power to hurt is lessened. But let us realize that they exist, and let us not complain too much if the larger machine, designed by extrapolation, does not turn out quite so good as was expected.

Dr. Ferranti's remarks about the need for persuading people to come to the help of the engineer who has something serviceable to propose to them and to carry out with their aid, are a useful comment on what I said about the results of an engineer's work being used for merely commercial ends. The emphasis in my sentence is on "merely," and the commercial exploitation of the work of engineers, in ways that probably they themselves never intended, would have been impossible had they been possessed of the qualities that would have allowed them to obtain help, as Dr. Ferranti suggests, and had they then been able themselves to develop their own work along the lines of their own desire. This leads us to recall once more the need for the cultivation of personality, and for the acquisition of the power of effective contact with other men.

I would particularly thank Mr. Bridges for having pointed out for me that the exceeding of mere duty is the lubricant that will ease the creaking of the mechanism; I am, indeed, specially grateful to him for all that he has contributed to the discussion. I hope that no one who sees this will fail to read what he has written on the subject of the second mile. It is action on that kind of principle that makes life a magnificent thing and prevents it from ever being a mere dreary routine of soul-destroying tasks. The more we appreciate the truth of this, the more shall we agree with Prof. Miles Walker when he points out that the service of humanity should be the main object of existence. There are some who give that they may receive, and there are others who receive that they may give. According to his nature is the thought of each man about his due and his duty; but in our inmost heart we know where blessedness lies.

I began by mentioning something said by Mr. Dunsheath. I find myself, as it happens, closing with a reference to another thing hinted at in his remarks: I mean the realization that change is the essence of life. Death itself, indeed, is but a passage to a new state, and cannot cut off the undying part of us from somehow sharing in all that is still to come.

Death! There is not any death, only infinite change;
Only a place of life which is novel and strange.
Change! There is nought but change and renewal of strife,
Which make up the infinite changes we sum up in life.
Life! What is life, that it ceases with ceasing of breath?
Death! What were life without change, but an infinite death?

As I lie on my bed, and the sun, like a furnace of fire,
Burns amid the old pines in the west, ere the last ray expire,
Can I dream he will rise no more, but a fathomless night
Shall brood o'er Creation for ever, and shut out the light?
It is done, this day of our life; but another shall rise,
Day for ever following day, in the infinite skies
Day following day for ever!

Day following day, with the starlit darkness between;
Or, maybe in a world where Dawn comes ere our Sunset has been,
Day following day for ever!

For ever! though who shall tell in what seeming or where?
In what far-off secret space of God's limitless air?

TEES-SIDE SUB-CENTRE: CHAIRMAN'S ADDRESS

By E. EDWARDS, Associate Member.

(ABSTRACT *of Address delivered at* MIDDLESBROUGH, *23rd November*, 1925.)

ELECTRICITY SUPPLY.

It is the prerogative of a chairman to discourse on a variety of subjects, and the opportunity is often used to survey the progress made in the whole field of electrical engineering during the preceding year. This is invariably a fascinating subject, as each year is a record of astonishing progress, not only in this country but throughout the world. A few years ago the difficulty of electrical engineers was to interest the man in the street in the possibilities of electricity. This aim has now been realized to a large extent and people everywhere are awake to the benefits bestowed on the community by the unlimited use of electrical energy. It would appear that we are now on the flood tide of popularity and that during the next few years the use of electricity will increase by leaps and bounds. One has evidence of this if one compares the present financial standing of various supply undertakings with that of, say, three years ago. The shares of the leading London supply companies show a capital appreciation of approximately 50 per cent, with a corresponding increase in dividends. The provincial companies also show a substantial improvement in their financial position, which, considering the depression in trade generally, is very encouraging.

There appear to be three definite stages in the development of every new industry. We have seen them illustrated in the case of railways, telegraphy and electricity supply. First, there is the initial boom when people rush to invest in the new industry and numerous companies are floated, some of them sound and others the reverse. This initial boom is followed by an inevitable reaction, when only the companies formed on sound lines can survive and the failure of many of the weaker ones brings the whole industry into disrepute with the investing public. This phase in turn passes away and, if it is worthy of doing so, the industry will gradually regain its prestige and develop on a surer foundation. It is to be hoped that the electrical industry has now reached this stage and, provided it is not made the catspaw of political parties but is left untrammelled to work out its own salvation, I am confident that the next decade will see unprecedented developments.

Before I finish with the general aspect of electricity supply there are two directions in which development so far has been rather backward in this country. I refer to railway electrification and rural electrical supply. It seems to me that these two aspects are largely complementary. The countryside is covered in every direction with a network of railways, and few places are situated more than a dozen miles from a railway station. When these are electrified, does it not seem feasible that the electrical network which will follow the railway network shall be used to give a supply of electricity to hamlets and towns which otherwise could not be supplied economically? Incidentally, these local supply networks would help to carry the huge capital cost that railway electrification involves. Still, even under existing conditions, there is evidence of a new spirit in rural electrification. Small villages in various parts have their electric generating plant driven by water power, where available, or by oil engines. The equipment is often primitive and inefficient and the cost per unit high, up to a shilling in some places, but, even so, these small undertakings are a boon to village life.

Under such a scheme as I have suggested above, power would be available at economic rates all over the country. We might thus hope to see a revival of village industries and a gravitation of population from the congested city slums to the village greens.

ELECTRICITY IN STEELWORKS.

I do not propose to deal further with the general aspect of the electrical industry, although it would be of great interest to outline the developments in different directions during the past year. I propose to confine my further remarks to the applications of electricity which more particularly concern this district and which are presumably of greater interest to the members of this Sub-Centre.

Foremost among these applications is undoubtedly the use of electricity in iron- and steel-works. We have had able papers on this subject, but somehow I feel that engineers not actually engaged therein have not a true idea of its magnitude and importance. By the courtesy of some of our members I have been able to compare the generating systems at four typical local works and I find that the maximum load varies from 6 000 to 12 000 kW and that the units generated in one works alone exceeded 30 millions per annum. When it is remembered that there are eight or nine works of a similar capacity on Tees-side, members will understand what I mean. These works have large generating plants of their own, using some form of waste heat from metallurgical processes; they are generally self-contained systems with their high-tension transmission lines, transformer substations, switch-houses and distribution centres scattered about the works. These systems have generally grown from very small beginnings, and the process is one of evolution rather than revolution. In the works with which I am connected the first electrical plant was a Brush arc-lighting dynamo supplying about

40 arc lamps in series at 2 000 volts. Then followed a small high-speed reciprocating steam set supplying a few small two-phase motors at 250 volts. Other similar sets followed and later a mixed-pressure turbine was installed. During the war this peaceful evolution almost became revolution, and a high-pressure three-phase system was inaugurated, supplied from gas-engine-driven generators. To-day this system is quite up to date and all the electric power used in the works, besides a large amount transmitted to an allied works, is generated entirely from blast-furnace gas.

This instance is typical of many others and the process is by no means completed. As steam-driven plant becomes worn out and obsolete it is being displaced everywhere by electric drive. The automatic possibilities of the latter often lead to the displacement of the skilled attention which is necessary with steam drive, and the economies resulting from the change invariably show an excellent return on the capital expenditure involved.

As the electrical plant has gradually evolved from small beginnings, so has the responsibility for its maintenance increased. In the early days it was under the nominal control of the works engineer and was actually looked after by a wireman or electrician whose technical knowledge was generally limited. To-day the situation is quite changed and the electrical man has as much responsibility as, if not more than, the engineer of the average public supply undertaking. His responsibilities are certainly more varied, because he not only has charge of the generation and distribution of the electric power, but is also responsible for its utilization, with its manifold applications. The only part he is spared is the commercial responsibility, with its dealings, pleasant and otherwise, with the electricity committee on the one side and consumers on the other. On the other hand he is not free from financial responsibilities, especially at these times when capital expenditure has to be cut down to a minimum and working costs are scrutinized to the last penny. He is often discouraged by having a scheme, which promises an excellent return on the outlay, turned down because the capital expenditure involved is at these times prohibitive. It is encouraging, however, to find that the management of large works is recognizing more and more the possibilities of electricity and the vast economies that its adoption can secure. I think it was the late Andrew Carnegie who said that it was always a feast or a fast in the steel trade. When trade is booming it is impossible to shut down a plant for the length of time necessary for extensive alterations, and in times of depression, such as those through which we have lately been passing, there does not seem to be the necessary confidence in the future to tempt the directors of these companies to sanction heavy capital expenditure.

During and since the war several steel plants have been put down in this country on modern lines and are marvels of efficiency. Labour-saving has been considered throughout and electric drive is practically universal. They compare favourably with any works on the Continent or in America. Apart from these few instances the average iron- and steel-works is very out-of-date and, in my opinion, such works cannot hope to survive in the struggle for existence, which is more intense to-day than ever, unless they are prepared and able to remodel their plants on up-to-date principles, making use of every means to cheapen production and eliminate waste. If the estimated saving resulting from some new process be sufficient to repay the capital expenditure within a reasonable time, the scheme should be adopted, although it may mean the ruthless scrapping of plant which has by no means reached the end of its useful life. Only by such means can our steel industry hold its own, and in such a process electricity is bound to play a predominant part; and the time is approaching when the steelworks will become a "function of the electric motor."

Some two years ago I read an informal paper before this Sub-Centre, in which I tried to prove that if the so-called waste heat evolved in the conversion of iron ore to finished steel were properly utilized in the generation of electric power, theoretically not only would the power requirements of the works be satisfied but there would be a margin for use elsewhere. It must be understood that this balance will only hold good when the works are operating under ideal conditions. Actually these conditions vary continually, and while at times there will be a large surplus of power, at others the power demand will exceed the supply. In practice, therefore, it is essential that the power system of a fully electrified works be linked up with a separate source of power to make up the deficiencies and level up the load curve. The ideal arrangement is parallel running with a large public supply system such as we have in this district. By this means not only will the periodic shortages of power in the works be supplied, but an outlet will be obtained for the surplus energy which would be available at certain periods.

For such a scheme to be attractive an equitable charge must be arranged, not only for all energy supplied to the works, but also for the outgoing units. I feel that there is room for effective co-operation on these lines, with mutual advantage to both parties, not to speak of the resultant conservation of our national resources. Where this co-operation is for some reason not practicable, consideration might be given to other means of utilizing the surplus power available at certain periods. An instance of this would be some electrochemical process where large variations in the supply of energy would not be detrimental to the working of the process. What must be remedied is the loss of potential energy now going on at many of the iron- and steel-works.

I wish now to speak on a few points of practical interest to the steelworks engineer.

Large Gas Engines.

I am still convinced of the superiority of gas engines over steam turbines for use with blast-furnace gas. Over four years' experience with large gas engines has confirmed my faith in their reliability and efficiency.

Two gas-engine driven sets of 1 000 kW capacity have generated 47½ million units since the beginning of 1922 without a serious breakdown. During the last two years, since a routine of systematic cleaning has been adopted, there has been practically no interruption to supply. Although up to now I believe the largest

vertical gas engine built is of only 1 000 kW capacity, horizontal sets have been built up to 5 000 kW and one set of this size has recently been installed at Staveley. The thermal efficiency of an engine of this size will be about 28 per cent, which is much higher than any obtainable from steam-turbine plants.

As far as my experience goes, it is an advantage if the gas engines are run in parallel with a steam-turbine station, especially on a fluctuating load such as rolling-mill drives. The flywheel effect of the high-speed turbine is naturally much greater than that of the low-speed gas engine, and exercises a steadying effect on the load. I have never noticed "hunting" with gas engines when dealing alone with a load of this character, but the variation in speed and voltage becomes pronounced. The cost of lubrication of gas engines is fairly heavy, but this can be reduced by a proper system of oil filtration.

Alternating Current *v.* Direct Current.

I do not propose to-night to touch upon the vexed question of alternating current versus direct current for steelworks, except to mention that personally I have found the former satisfactory except for isolated duties such as magnets. Where the primary system is alternating current I do not consider that the advantages of the d.c. drive warrant the expense and complication of conversion. Where direct current is essential for exceptional duties it can be provided by small converting sets supplying merely the particular plant in question.

Transmission System.

The correct layout of the transmission and distribution system in a large works is a matter which needs very careful consideration. The future policy in the way of extensions is generally very nebulous and often a large demand is required at short notice. It is, therefore, wise policy to allow for a good margin over the immediate requirements and to make the distribution system as flexible as possible.

The primary transmission should be kept high; 6 000 or even 11 000 volts would be an economical voltage for a works covering a large area. If possible the sub-stations should be self-contained buildings properly designed for the purpose in hand, although too often an odd corner of an existing building is considered by the management to be sufficient for the purpose.

Duplication, wherever possible, is essential for that reliability which must obtain in steelworks, and it must never be forgotten that a certain proportion of the plant runs for many months without stoppage, even at holiday time. Duplication on the low-tension side is equally desirable, and I have found a system consisting of a number of ring mains the cheapest way to secure that end.

Power Factor of Steelworks.

The power factor of a steelworks is generally accepted as being very low, but it need not be as bad as it is painted. Steelworks engineers have to be very conservative in their outlook and provide motors with an ample margin of power for the work in hand. They also have a predilection for ample air-gaps and, in their opinion, maximum reliability is a greater merit in a motor than maximum efficiency and power factor. On many duties in a steelworks, such as cranes and roller drives, the motor has to be constantly reversed, sometimes up to 500 times an hour, and it is essential that the inertia of the moving parts be kept as low as possible, with the result that low-speed motors are favoured, with a further lowering of efficiency and power factor.

Whilst in full agreement with this policy I find that there are in most sections of the works certain constant running drives in favourable situations where a reasonably high-speed motor of high efficiency and power factor can be installed, and on certain heavy drives auto-synchronous machines can be used with advantage. By judicious management the power factor of most sections of the plant can be kept at, say, 75 per cent. In the case of the typical works load I mentioned earlier it varied between 0·7 and 0·75. Still, in some cases, further power-factor improvement is desirable and the installation of static condensers should be considered, particularly if extensions are under consideration, when their use can often effect a saving on mains and transformers greater than the cost of the condensers themselves.

Steelworks Motors.

I have mentioned the question of steelworks motors and this is a matter of sufficient importance to warrant further comment. Special types of d.c. motors for steelworks use have, of course, been manufactured for several years, and have given satisfaction, but it is only comparatively recently that their counterpart in a.c. machines has been brought out. I think that we owe their development to a great extent to a well-known local steelworks engineer, who has encouraged their manufacture for some years.

The latest development is a squirrel-cage rotor with high-resistance end connections which give satisfactory starting torque with a reasonable starting current. It is not necessary to enlarge on the advantages of this type of motor with its consequent simplification of control gear. For small sizes up to, say, 25 h.p. a simple stator reversing-switch is all that is necessary; for larger sizes reversing stator contactor-gear is advisable. Motors of this type are now being largely used for crane work, where the resultant freedom from complication of wiring is a great advantage. So far these motors have stood up well to the exacting steelworks conditions. When it is remembered that on slip-ring motors about 80 per cent of the breakdowns occur in the wound rotor it will be seen that the rugged squirrel-cage type should make for that reliability which is a *sine qua non* of steelworks requirements.

Whilst on the subject of motors I should like to mention a matter which has been discussed previously at Institution meetings. I refer to their standardization. It does seem to me that it is time some definite move was made in that direction and I would suggest that it is a suitable subject for the attention of the British Engineering Standards Association. I see the difficulties that stand in the way, but I think that it would be quite possible for the different manufacturers

to standardize certain dimensions which would make motors of the same rating interchangeable. It is not expedient that the purchaser should be bound to one particular make because he requires a motor to be a duplicate of one already in commission.

A feature of present-day motor design is the increasing popularity of ball and roller bearings, and certain makers are now fitting these exclusively on their standard machines. The doubts and suspicion with which their introduction was received by maintenance engineers have been largely dispelled.

I am glad to report an improvement in the conditions under which motors have to operate in steelworks. The old days of cast gears and overhung pinions are passing, and machine-cut gears and outboard bearings are standard practice in modern plants. In the lay-out of new schemes consideration is given to the facility of changing motors where necessary.

Electric Locomotion.

The question of electric locomotion in steelworks is one that has attracted attention for many years, but, as far as I know, electric traction has not been adopted for general use in any steelworks in this country.

At first sight the suggestion is very attractive and it would seem that large economies could be obtained from its adoption, as the steam locomotive in the average works is a very inefficient piece of apparatus. When one goes into the matter more deeply one finds difficulties almost insuperable at present. A network of overhead trolley lines is out of the question, as they would have to be erected at an absurd height to give the necessary clearance for the jib cranes which are continually moving about the works. The only possible solution is a battery locomotive, preferably in combination with overhead collectors for use on those particular tracks where they can be permitted. The better acquainted an electrical man becomes with the conditions under which the works locomotive has to operate, the more disinclined will he be to advise the management to experiment with a battery locomotive. There are certain duties, however, such as haulage of coke from ovens to blast furnaces, or slag from furnaces to slag tip, where an overhead system might be feasible and where electric traction is well worth consideration.

Electrical Staff.

Finally, a word as to the electrical staff. They must be taught that safety in operation is a first requirement, and suitable rules and regulations for the proper operation of the plant must be strictly enforced if this is to be secured. They must learn that the proper earthing of apparatus is as important as the proper connection to the line. They should be encouraged to take an intelligent interest in the working of the plant and to obtain the technical knowledge which will enable them to acquire that interest. Only by such means can the *esprit de corps* be gained which is necessary to get the maximum efficiency out of the plant.

In conclusion I would congratulate my fellow members that we are engaged in a profession that offers such boundless opportunities for our powers. Our young men may see visions and our old men may dream dreams, but none can foretell the future of the electrical industry. Certain it is that it is at present, if not in its infancy, at any rate in its strong and vigorous youth. As yet there is no sign of a halt in its triumphant progress, and I feel that its past triumphs will sink to insignificance compared with those the future holds in store.

PROBLEMS IN CONNECTION WITH TWO PARALLEL ELECTRIFIED CYLINDRICAL CONDUCTORS.*

By ALEXANDER RUSSELL, M.A., D.Sc., LL.D., F.R.S., Past President.

(*Paper first received* 19*th May, and in final form* 7*th October,* 1925.)

SUMMARY.

Electrostatic problems in connection with two unequal parallel cylinders, and with single-core cables when the axes of the cores are parallel but not coincident with the axes of the outer cylinders, are considered. The solutions are given by formulæ the numerical value of which can be readily evaluated. Novel relations are given connecting the capacity between any two cylinders with the capacities between two equal cylinders and with the capacities of cylindrical condensers.

When there are two parallel cylindrical conductors with an alternating difference of potential maintained between them, it is well known that electric currents flow in them. The magnitude of these currents can be computed in certain cases and are found to be in agreement with their observed values. It is also known that when we have two equal conductors and the dielectric between them is a gas at a known temperature and pressure, then the corona or the sparking potential can be computed when we know the value of the maximum potential gradient between them. In addition, the electrostatic force between the conductors can be computed in certain cases.

In treatises on electrostatic theory it is generally considered sufficient to give the capacity formulæ for two equal parallel conductors and for a concentric main. One or two give the formulæ for the forces between the cylinders and for the maximum potential gradient in the dielectric of a concentric main, but practically none state clearly the limitations of the formulæ they give. It has seemed to the author, therefore, that it would be useful to point out the limitations in the ordinary theory owing to the assumptions made, and to give a résumé of the ordinary mathematical formulæ. It is shown that in many cases the solution of problems when the cylinders are unequal in size, or when the axis of the core is not concentric with the axis of the sheath, can be written down at once from the ordinary formulæ for equal cylinders and concentric mains.

THE CAPACITIES OF CYLINDERS.

We first of all suppose that the cylinders are of infinite length, so that the field surrounding them is not disturbed by the irregular electrical distribution at their ends. We suppose that the charges per unit length of each cylinder are equal in magnitude and of opposite sign. These assumptions greatly simplify the problem, as the equipotential surfaces are all cylindrical and all cut another set of cylinders orthogonally. Finally, it is customary to define the capacity per unit length between the two cylinders as the ratio of the positive charge per unit length to the difference of potential between the cylinders. The reason for adopting this definition is, doubtless, that it is a quantity readily measured in practice. It seems to the author that it would be helpful in practice to call the ratio of the charge per unit length on one of the cylinders to its potential the "capacity" of that cylinder, or, if it is preferred, the "capacity of that cylinder in the presence of the other cylinder." This quantity can be calculated quite as easily as the capacity between the cylinders, and a knowledge of its value is instructive.

The assumption that the electric charges on the two cylinders are equal and opposite is a serious one. This is not always true in practice, and it is highly desirable that simple formulæ should be found by means of which the capacities, the maximum potential gradient, and the forces, could be computed in the general case. Maxwell showed that if (q_1, v_1) and (q_2, v_2) be the charges per unit length and the potentials of the two cylinders, then

$$q_1 = k_{11}v_1 + k_{12}v_2, \quad \text{and} \quad q_2 = k_{22}v_2 + k_{12}v_1 \quad . \ (1)$$

where k_{11}, k_{22} and k_{12} are constants which depend on the radii of the cylinders, their distance apart and the inductivity of the medium between them. These constants are called the "capacity coefficients," and if their algebraical values could be readily found we should have practically the complete solution of the problem. So far as the author knows, no formulæ that would be useful from the engineering point of view have yet been given for them. In this paper we practically consider only the case when the charges on the two cylinders are equal and opposite.

Some of the formulæ given below have been published before, but the methods of obtaining them have been simplified. Novel relations connecting the capacities of cylindrical condensers with the capacities of other cylindrical condensers and with the capacities of parallel cylinders are also given.

THE PROBLEM OF TWO ELECTRIFIED CYLINDRICAL CONDUCTORS.

Let us first consider the case of two parallel cylindrical conductors external to one another. Let their circular sections be as shown in Fig. 1. Let C be the centre of the circular section whose radius is a, and D be the centre of the circle whose radius is b. We shall denote the distance CD between the axes of the cylinders by c. Now it is known by geometry that two points A and B

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

(the inverse points) can be found such that CA . CB $= a^2$ and DB . DA $= b^2$. It is easy to show that the circle described on AB as diameter will cut the two circles orthogonally. Thus if r be its radius, we have

$$c = \sqrt{(a^2 + r^2)} + \sqrt{(b^2 + r^2)}.$$

Hence $$cr = 2\{s(s-a)(s-b)(c-s)\}^{\frac{1}{2}} \quad . \quad . \quad (2)$$

where $$2s = a + b + c.$$

By logarithms, the value of r can be calculated very readily from (2) in every case.

It is found useful to introduce two new quantities α and β, which are defined by the equations

$$\sinh \alpha = r/a \quad \text{and} \quad \sinh \beta = r/b \quad . \quad . \quad (3)$$

Hence $$cr = ab \sinh(\alpha + \beta) = ab \sinh \omega \quad . \quad . \quad (4)$$

if we denote $(\alpha + \beta)$ by ω. It also follows that

$$\cosh \omega = \frac{c^2 - a^2 - b^2}{2ab} \quad . \quad . \quad . \quad . \quad (5)$$

and CA $= a\epsilon^{-\alpha}$, CB $= a\epsilon^{\alpha}$, DB $= b\epsilon^{-\beta}$ and DA $= b\epsilon^{\beta}$

Let us now suppose that the charge on the cylinder whose centre is C is q per unit length, and that the charge

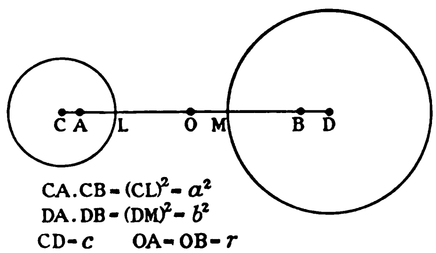

FIG. 1.

on the other cylinder is $-q$ per unit length. Then if v be the potential * at any point P between them, we have, assuming the medium to be a vacuum,

$$v = 2q \log(\mathrm{BP}/\mathrm{AP}) \quad . \quad . \quad . \quad . \quad (6)$$

It is well known that the locus of a point P which moves so that BP/AP is a constant is a circle. Thus the equipotential surfaces are cylinders surrounding A and B respectively.

If P is a point on the cylinder whose centre is C and if v_1 be its potential, we have

$$v_1 = 2q \log\left(\frac{\mathrm{BP}}{\mathrm{AP}}\right) = 2q \log\left(\frac{\mathrm{BL}}{\mathrm{AL}}\right) = 2q \log \frac{a\epsilon^{\alpha} - a}{a - a\epsilon^{-\alpha}} = 2q\alpha$$

Thus $$\frac{q}{v_1} = \frac{1}{2\alpha} \quad \text{and similarly} \quad \frac{-q}{v_2} = \frac{1}{2\beta} \quad . \quad . \quad (7)$$

These ratios are the capacities of the two cylinders in the presence of one another. We shall denote these capacities by $C_a(a, b, c)$ and $C_b(a, b, c)$.

The capacity $C(a, b, c)$ between the two conductors is given by

$$C(a, b, c) = \frac{q}{v_1 - v_2} = \frac{1}{2(\alpha + \beta)} = \frac{1}{2\omega}$$
$$= \frac{C_a(a, b, c) \cdot C_b(a, b, c)}{C_a(a, b, c) + C_b(a, b, c)} \quad . \quad (8)$$

* A. RUSSELL: "Alternating Currents," vol. 1, p. 163.

When engineers refer to "capacity" they usually mean the ratio which we denote by $C(a, b, c)$.

It is interesting to notice that

$$C_a(a, b, c) = \frac{1}{2\alpha} = \frac{1}{2 \log(a/\mathrm{CA})}$$

and $$C_b(a, b, c) = \frac{1}{2 \log(b/\mathrm{BD})} \quad . \quad (9)$$

Hence $C_a(a, b, c)$ is the capacity per unit length of the concentric main whose outer radius is a and inner radius CA. Similarly we have

$$C(a, b, c) = \frac{C_a(a, b, c) \cdot C_b(a, b, c)}{C_a(a, b, c) + C_b(a, b, c)} = \frac{1}{2 \log\{ab/(\mathrm{CA} \cdot \mathrm{BD})\}}$$

We also have

$$C(a, b, c) = \frac{1}{2\omega} = \frac{1}{2 \log_{\epsilon} m} \quad . \quad . \quad . \quad (10)$$

where $$m = \frac{d}{2} + \sqrt{\left(\frac{d^2}{4} - 1\right)}$$

and $$d = \frac{c^2 - a^2 - b^2}{ab}$$

THE ELECTRIC FORCE BETWEEN THE CYLINDERS.

The energy stored in the field

$$= \tfrac{1}{2}C(v_1 - v_2)^2 = q^2/(2C) = q^2\omega$$

where C stands for $C(a, b, c)$.

Hence if F be the force between the cylinders

$$F = \frac{\partial}{\partial c}(q^2\omega) = q^2\frac{\partial \omega}{\partial c}$$

Now by (5), $\sinh \omega \dfrac{\partial \omega}{\partial c} = \dfrac{c}{ab}$, and thus by (4), $\dfrac{\partial \omega}{\partial c} = \dfrac{1}{r}$.

We thus get the interesting theorem that

$$F = q^2/r \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

It follows that, when the charges on the cylinders are equal and opposite, the attractive force between them varies inversely as the radius r of the smallest cylinder which cuts them both at right angles. This is true whether the cylinders are external to each other or one is internal to the other. The value of r for a given pair of cylinders is easily computed from (2). In (11), F is in dynes, q is in electrostatic units, and r is in centimetres. (A coulomb equals 3×10^9 electrostatic units.)

THE MAXIMUM POTENTIAL GRADIENT BETWEEN THE CYLINDERS.

It is well known that the electric field between the cylinders (Fig. 1) is the same as that produced by two electrified wires cutting the paper perpendicularly at A and B respectively and having charges $+q$ and $-q$ per unit length. The potential gradient (electric force) between the cylinders will have its greatest numerical values at the points L and M where the line joining the centres of the two circular sections intersects

them. If we denote the potential gradient at L (Fig. 1) by R_L, we have

$$R_L = \frac{2q}{\mathrm{AL}} + \frac{2q}{\mathrm{BL}} = \frac{2q}{r}(1 + \cosh \alpha) \quad . \quad . \quad (12)$$

Similarly $$R_M = \frac{2q}{\mathrm{BM}} + \frac{2q}{\mathrm{AM}} = \frac{2q}{r}(1 + \cosh \beta) \quad . \quad (13)$$

It follows that if a is less than b, R_L is greater than R_M.

We would naturally expect that the sparking potential between the cylinders in a gas would be determined by the value of R_L. When the radius of each of the cylinders is a it is known that the spark takes place or the corona occurs when R_L is given by a formula of the type

$$R_L = \mathrm{A} + B/\sqrt{a} \quad . \quad . \quad . \quad . \quad (14)$$

where A and B are constants. It would be very interesting to know whether (14) applies when the cylinders are unequal. A research to determine this would be of considerable theoretical value.

From (12) we get

$$R_L = \frac{2q}{r}\left\{\frac{(c + a)^2 - b^2}{2ca}\right\} = \frac{2q}{a}\sqrt{\left[\frac{s(s - b)}{(s - a)(c - s)}\right]} \quad (15)$$

Similarly $$-R_M = \frac{2q}{b}\sqrt{\left[\frac{s(s - a)}{(s - b)(c - s)}\right]} \quad . \quad . \quad (16)$$

Since $q = C(a, b, c)\,(v_1 - v_2)$, see (10), we have

$$q = \frac{v_1 - v_2}{2 \log_e m} \quad . \quad . \quad . \quad . \quad (17)$$

where $$m = \frac{d}{2} + \sqrt{(\tfrac{1}{4}d^2 - 1)}$$

and $$d = \frac{c^2 - a^2 - b^2}{ab}.$$

Thus R_L can be found from (15) and (17) when the difference of potential $(v_1 - v_2)$ is known, provided that the charges on the cylinders are equal and opposite.

If we denote LM by x, and if x be not great compared with a or b, we have

$$R_L = \frac{v_1 - v_2}{x}\left\{1 + \frac{2b - a}{6ab}x\right\} \quad . \quad . \quad (18)$$

approximately. When the cylinders are equal

$$R_L = \frac{v_1 - v_2}{x}\left\{1 + \frac{x}{6a} - \frac{x^2}{180a^2} + \frac{43x^3}{55\,296a^3}\right\} \quad (19)$$

approximately.

For instance, when $x = a$,

$$R_L = \frac{v_1 - v_2}{x} \times 1{\cdot}1618$$

The true value of the multiplying factor is $1{\cdot}1617$. It will be seen that provided x is not greater than a, formula (19) can be used for all practical purposes. When $x = 2a$, the factor given by (19) is $1{\cdot}319$ instead of $1{\cdot}315$.

Cylindrical Condenser.

Let the sections of the cylinders perpendicular to their parallel axes be as given in Fig. 2.

Then if A and B be the inverse points, we have $\mathrm{CA}\,.\,\mathrm{CB} = a^2$, $\mathrm{DA}\,.\,\mathrm{DB} = b^2$, and, if c be the distance DC between their centres, b must be greater than $a + c$. A circle described on AB as diameter cuts both circles orthogonally.

Let $\quad \mathrm{AB} = 2r = 2a \sinh \alpha_1 = 2b \sinh \beta_1$.

Then $\quad c = \sqrt{(b^2 + r^2)} - \sqrt{(a^2 + r^2)}$,

and thus $$cr = 2\sqrt{[s(s - a)(s - c)(b - s)]} \quad . \quad . \quad (20)$$

where $\quad 2s = a + b + c$.

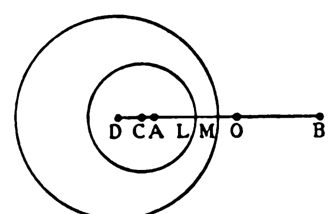
It readily follows (*l.c. ante*) that

$$v_1 = 2q\alpha_1 \quad \text{and} \quad v_2 = 2q\beta_1. \quad . \quad . \quad (21)$$

Hence $$\frac{q}{v_1 - v_2} = \frac{1}{2(\alpha_1 - \beta_1)} = \frac{1}{2\omega_1} = K(a, b, c)$$

where $$2 \cosh \omega_1 = \frac{a^2 + b^2 - c^2}{ab} = d \quad . \quad . \quad (22)$$

and $K(a, b, c)$ is the capacity per unit length of a cylindrical condenser whose inner radius is a, and outer



$\mathrm{CA}\,.\,\mathrm{CB} = (\mathrm{CL})^2 = a^2 \quad \mathrm{DA}\,.\,\mathrm{DB} = (\mathrm{DM})^2 = b^2$

$\mathrm{DC} = c \quad \mathrm{OA} = \mathrm{OB} = r$

Fig. 2.

radius b, and c is the distance between the axes of the cylinders.

Thus $$K(a, b, c) = \frac{1}{2 \log_e m_1} \quad . \quad . \quad . \quad (23)$$

where $m_1 = \frac{1}{2}d + \sqrt{(\frac{1}{4}d^2 - 1)}$ and d is given by (22).

Proceeding as before, we find that the attractive force F between the cylinders is given by

$$F = q^2/r \quad . \quad . \quad . \quad . \quad . \quad (24)$$

and that $$R_L = (2q/r)(1 + \cosh \alpha_1) \quad . \quad . \quad . \quad (25)$$

and $$R_M = (2q/r)(1 + \cosh \beta_1) \quad . \quad . \quad . \quad (26)$$

We also have $$\frac{q}{v_1} = \frac{1}{2 \log (a/\mathrm{CA})} \quad . \quad . \quad . \quad . \quad (27)$$

In these formulæ $$\cosh \alpha_1 = \frac{b^2 - a^2 - c^2}{2ac} \quad . \quad . \quad (28)$$

and $$\cosh \beta_1 = \frac{b^2 + c^2 - a^2}{2bc} \quad . \quad . \quad (29)$$

When x is small, we have

$$R_L = \frac{v_1 - v_2}{x}\left\{1 + \frac{2b + a}{6ab}x\right\} \quad . \quad . \quad (30)$$

approximately.

CAPACITY COEFFICIENTS FOR EXTERNAL CYLINDERS.

From (1) and (7) it follows that, whatever the charges on the cylinders are, we have

$$k_{11} = \frac{1}{2\alpha} + \frac{\beta}{\alpha}k_{12} \quad \text{and} \quad k_{22} = \frac{1}{2\beta} + \frac{\alpha}{\beta}k_{12} \,. \quad (31)$$

The problem of finding the three capacity coefficients of the two cylinders is thus reduced to that of finding a capacity coefficient of one of them.

In all cases we have

$$v_1 - v_2 = (q_1 + q_2)(\alpha - \beta) + (q_1 - q_2)(\alpha + \beta) \,. \quad (32)$$

For instance, when $q_1 = q_2 = q$, we have

$$\frac{q}{v_1 - v_2} = \frac{1}{2(\alpha - \beta)} \quad . \quad . \quad . \quad . \quad (33)$$

which can be readily computed.

Similarly when $q_2 = 0$,

$$\frac{q_1}{v_1 - v_2} = \frac{1}{2\alpha} \quad . \quad . \quad . \quad . \quad . \quad . \quad (34)$$

THE INDUCTIVITY OF THE MEDIUM.

If the inductivity (specific inductive capacity) of the medium in which the cylinders are immersed be λ, then the formulæ given above for the capacities have to be multiplied by λ. The formulæ for the electric force between the cylinders have to be divided by λ, and the formulæ for the potential gradient are unaffected.

CAPACITY RELATIONS BETWEEN CYLINDRICAL CONDUCTORS.

The formulæ given above enable us to write down many simple relations connecting the capacities of external cylinders with each other and with the capacities of cylindrical condensers. These relations are instructive and interesting. They are also useful in practice as, in many cases, they enable the capacities to be computed more readily.

From formulæ (10) and (23) we see that the capacities C and K only depend on the ratios of a, b and c. Hence, if p be any number, we have

$$C(a, b, c) = C(pa, pb, pc) \quad \text{and} \quad K(a, b, c) = K(pa, pb, pc) \quad . \quad (35)$$

Thus, for external cylinders,

$$\begin{aligned} C(a, b, c) &= C\left(\frac{r}{\sinh\alpha}, \frac{r}{\sinh\beta}, \frac{r\sinh\omega}{\sinh\alpha\sinh\beta}\right) \\ &= C\{\sinh(\omega - \alpha), \sinh\alpha, \sinh\omega\} \\ &= \frac{1}{2\omega} = \frac{n}{2n\omega} \\ &= nC\{\sinh(n\omega - \alpha), \sinh\alpha, \sinh n\omega\} \quad (36) \end{aligned}$$

where n is any number.

Similarly, we find that

$$\begin{aligned} K(a, b, c) &= mK\{\sinh(m\omega_1 + \beta), \sinh\beta, \sinh m\omega_1\} \\ &= \frac{1}{2\omega_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (37) \end{aligned}$$

Hence for all values of m, n, α, β and ω, we have

$$\begin{aligned} &nC\{\sinh(n\omega - \alpha), \sinh\alpha, \sinh n\omega\} \\ &\quad = mK\{\sinh(m\omega + \beta), \sinh\beta, \sinh m\omega\} \\ &\quad = \frac{1}{2\omega} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (38) \end{aligned}$$

This is a very general formula.

The following particular cases of (38) are useful :—

$$\begin{aligned} C(a, b, c) &= C[1, 1, \sqrt{\{c^2 - (a - b)^2\}}/\sqrt{(ab)}] \\ &= K\{(c^2 - a^2 - b^2)/ab, 1, 1\} \quad (39) \end{aligned}$$

and

$$\begin{aligned} K(a, b, c) &= K\{(a^2 + b^2 - c^2)/ab, 1, 1\} \\ &= C[1, 1, \sqrt{\{(a + b)^2 - c^2\}}/\sqrt{(ab)}] \quad (40) \end{aligned}$$

The formulæ (39) and (40) enable us to convert at once the problem of computing the capacity between any external or internal cylinders into the simpler one of finding the capacity between two equal cylinders.

We also have

$$\begin{aligned} C(1, 1, d) &= \tfrac{1}{2}K(d, 1, 1,) = \tfrac{1}{2}C[1, 1, \sqrt{(d + 2)}] \\ &= \tfrac{1}{2}C[a, b, \sqrt{(a^2 + b^2 + dab)}] \quad . \quad (41) \end{aligned}$$

where a and b can have any values.

For example, if we put $d = 142, a = 10$ and $b = 1$, we get at once

$$C(1, 1, 142) = \tfrac{1}{2}C(1, 1, 12) = \tfrac{1}{2}C(10, 1, 39)$$

For all values of c less than $a - b$, we find that

$$K(a, b, c) = C\{a, b, \sqrt{[2(a^2 + b^2) - c^2]}\} \quad . \quad (42)$$

and for all values of c between $a + b$ and $\{2(a^2 + b^2)\}^{\frac{1}{2}}$, we have

$$C(a, b, c) = K\{a, b, \sqrt{[2(a^2 + b^2) - c^2]}\} \quad . \quad (43)$$

For all values of m

$$C(a, b, c) = C\{ma, b/m, \sqrt{[c^2 - (a+b)^2 + (ma+b/m)^2]}\} \quad (44)$$

and

$$K(a, b, c) = K\{ma, b/m, \sqrt{[c^2 - (a+b)^2 + (ma+b/m)^2]}\} \quad (45)$$

It is also easy to show that

$$\begin{aligned} K(a, b, o) &= nK\left\{\frac{a^n}{b^n} + \frac{b^n}{a^n}, 1, 1\right\} = 2mC\left\{1, 1, \frac{a^m}{b^m} + \frac{b^m}{a^m}\right\} \\ &= C\{a, b, \sqrt{[2(a^2 + b^2)]}\} = 1/\{2\log(a/b)\} \quad (46) \end{aligned}$$

For example,

$$\begin{aligned} C(70, 10, 100) = K(70, 10, 0) &= 1/(2\log 7) \\ &= 0 \cdot 2569924 \ldots \end{aligned}$$

Dividing this number by 900 000 we get the value of $C(70,10,100)$ and of $C(7,1,10)$, in microfarads.

In general, we have

$$\begin{aligned} &K(a, b, c) \\ &= K(d, 1, 1) = K(d^2 - 1, d, 1) = K(d^3 - 2d, d^2 - 1, 1) = \ldots \\ &= 2K(d^2 - 2, 1, 1) = 3K(d^3 - 3d, 1, 1) = \ldots \\ &= 2K(d^2 - 1, 1, d) = nK(m^n, 1, 0) = 1/(2\log m) \,. \quad . \quad (47) \end{aligned}$$

where $d = (a^2 + b^2 - c^2)/ab$ and $m = \frac{1}{2}d + \sqrt{(\frac{1}{4}d^2 - 1)}$

Theorems similar to (47) in connection with $C(a, b, c)$ can be readily written down.

If we put $d = 2 + x$ in (41) we get

$$K(2 + x, 1, 1) = 2C(1, 1, 2 + x)$$
$$= \frac{1}{4 \log \{\frac{1}{2}\sqrt{x} + \sqrt{(1 + \frac{1}{4}x)}\}} = \frac{1}{4 \sinh^{-1}\sqrt{x}} \quad . \quad (48)$$

When x is not greater than unity we can use the formula

$$K(2 + x, 1, 1) = 2C(1, 1, 2 + x)$$
$$= \frac{1}{2\sqrt{x}}\left\{1 + \frac{x}{24} - \frac{17x^2}{5\,760} + \frac{137x^3}{276\,480} - \ldots\right\} \quad (49)$$

For instance, using this formula and (41), we get

$K(2\cdot 01, 1, 1) = 2C(1, 1, 2\cdot 01) = 5\cdot 002082 \ldots$
$K(2\cdot 5, 1, 1) = 2C(1, 1, 2\cdot 5) = 0\cdot 72136 \ldots (0\cdot 72135)$
$K(3, 1, 1) = 2C(1, 1, 3) = 0\cdot 5196 \ldots (0\cdot 5195 \ldots)$

The true values are given in brackets.

When $x/(a + b)$ is small, we have approximately

$$C(a, b, a+b+x) = \sqrt{\left[\frac{ab}{8(a+b)x}\right]}\left\{1 + \frac{a^2+b^2-ab}{12ab(a+b)}x\right\} \quad (50)$$

and

$$K(a, b, a-b-x) = \sqrt{\left[\frac{ab}{8(a-b)x}\right]}\left\{1 + \frac{a^2+b^2+ab}{12ab(a-b)}x\right\} \quad (51)$$

For example,

$C(98, 10\cdot 8, 109) = 2\cdot 4688 \ldots$
and $K(109, 98, 10\cdot 8) = 24\cdot 748 \ldots$

Denoting, as before, the capacity of the a cylinder in the presence of the b cylinder by $C_a(a, b, c)$, we have

$$C_a(a, b, c) = K(c, a, b). \quad . \quad . \quad . \quad (52)$$

For example,

$$C_a(1, 7, 10) = K(10, 1, 7) = \frac{1}{2\omega_1}$$

where $\cosh \omega_1 = \dfrac{10^2 + 1^2 - 7^2}{20} = \dfrac{26}{10} = \frac{1}{2}(5 + \frac{1}{5})$

Thus $\omega_1 = \log 5$, and therefore

$C_a(1, 7, 10) = 1/(2 \log 5) \quad = 0\cdot 3106674 \ldots$
$C_a(7, 1, 10) = 1/(2 \log 1\cdot 4) = 1\cdot 4860013 \ldots$
and $C\ (1, 7, 10) = 1/(2 \log 7) \quad = 0\cdot 2569924 \ldots$

To find the capacities in microfarads, we divide these numbers by 900 000. Notice that all the logarithms given in this paper are to the base ϵ. To convert common into Napierian logarithms we multiply by 2·3025851.

High Frequency Self-Inductance.

If $L_e(a, b, c)$ denote the high-frequency self-inductance per unit length of two external parallel cylinders, then *

$$L_e(a, b, c) = 2\omega = 1/C(a, b, c) \quad . \quad . \quad (53)$$

and if one cylinder surrounds the other,

$$L_i(a, b, c) = 2\omega = 1/K(a, b, c) \quad . \quad . \quad (54)$$

Hence we can write down theorems similar to those connecting the electrostatic capacities of the cylinders.

CIRCUIT CONSTANTS IN TRANSMISSION-LINE CALCULATIONS.*

By A. C. A. CALDWELL, B.E., Associate Member.

(*Paper first received 2nd October, 1924, and in final form 10th December, 1925.*)

SUMMARY.

In this paper the use of "circuit constants" for the calculation of transmission-line problems is dealt with in an elementary way, in the hope that many who perhaps would not have the time or patience to follow the original papers of Messrs. Evans and Sels may be encouraged to use their very powerful and useful methods.

To avoid having to refer to textbooks for the elements of complex algebra, a few notes on its use have been included.

The formulæ for calculating the constants of series and parallel circuits are developed; and the determination of the particular values of the constants for transmission lines, and for transformers, is dealt with in detail.

Following this, methods for dealing with more complex cases of lines supplying more than one substation, and branching lines, are dealt with. An actual example of an existing transmission line is worked out in detail.

INTRODUCTION.

For the purpose of calculating the performance of long-distance high-voltage transmission lines and networks, it is essential that capacity effects and the effects due to step-up and step-down transformers be taken into account. Hitherto it has been usual to calculate the characteristics of a transmission line with considerable pains and then to treat the transformers separately and more or less approximately, though their effects may easily be of the same order of magnitude as those produced by the line itself.

Again, it has been suggested that the transformer resistance and reactance may be added directly to the line resistance and reactance. This method also lacks accuracy, especially when high voltage and long distance make it imperative that the charging currents of both the line and the transformer be taken into account. To be able to take full and accurate account of both the line and transformers is therefore most desirable. That this may be done without undue labour and complication has been shown by Messrs. R. D. Evans and H. K. Sels in two papers on "Transmission Line Circuit Constants" and "Transmission Lines and Transformers." † While indicating the general method and stating the general formulæ necessary, the reader is left by these authors with very little in the nature of concrete example or instructions for applying the method to everyday uses. The method is, however, of very great practical value, and the following notes are an attempt to elaborate the practical details arising when the method is applied to simple and also to more complex cases in actual practice. The author has found the methods as developed herein of great service in predetermining voltage variations on the large power schemes now under development by the Public Works Department of New Zealand, particularly in connection with the Mangahao, Arapuni and Lake Coleridge transmission systems.

The use of circuit constants in transmission-line calculations is well known * and widely used, and it is by making use of these and similar constants for the transformers that any ordinary combination of lines and transformers may be treated as a whole and exact solutions obtained for any condition of loading.

USE OF COMPLEX NUMBERS.

Throughout these calculations complex numbers and complex algebra are used, and a few words covering the ordinary operations that will be continually employed may not be out of place.

Two methods of notation are in use and both have their special applications, and the elementary rules for the manipulation of both forms must be thoroughly mastered.

Assuming some vector of reference, a vector may be defined with respect to it :—

(1) By means of its projection on and at right angles to the vector of reference, the usual notation for a vector of length $\sqrt{(a^2 + b^2)}$ being $a + jb$, where a denotes the length of its projection on the axis of reference and b the length of its projection on an axis at right angles to the first, where j is an operator denoting a rotation of 90° in an anti-clockwise direction and is defined as $\sqrt{(-1)}$; j^2 therefore has the value "-1" and denotes a rotation through 180°.

(2) By means of its length and the angle between it and the vector of reference, the usual notation being of the form $r\underline{/\theta}$, where r denotes the length of the vector and θ the angle between it and the vector of reference, the symbol $\underline{/\theta}$ generally denoting a rotation through an angle θ in an anti-clockwise direction from the vector of reference, and $\overline{\backslash\theta}$ denoting a rotation in a clockwise direction. The vector of reference is generally taken as the positive direction of the ordinary x axis, so that $(a + jb)$ and $r\underline{/\frac{\pi}{4}}$ denote vectors in the first quadrant, while $(a - jb)$ and $r\overline{\backslash\frac{\pi}{4}}$ denote vectors in the fourth quadrant.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

The following equations define the operations that will be used in this work.

Addition.—$(a + jb) + (c + jd) = (a + c) + j(b + d)$.
Subtraction.—$(a + jb) - (c + jd) = (a - c) + j(b - d)$.
Multiplication.—$(a + jb)(c + jd) = ac + jad + jbc - bd = (ac - bd) + j(ad + bc)$

$$r\underline{/\theta} \times s\underline{/\phi} = rs\underline{/\theta + \phi}$$

Division.—
$$\frac{a + jb}{c + jd} = \frac{(a + jb)(c - jd)^*}{(c + jd)(c - jd)} = \frac{(ac + bd) + j(bc - ad)}{c^2 + d^2} = \frac{ac + bd}{c^2 + d^2} + j\frac{bc - ad}{c^2 + d^2}$$

$$r\underline{/\theta} \div s\underline{/\phi} = (r/s)\underline{/\theta - \phi}$$

Involution.—$(a + jb)^2 = a^2 - b^2 + j2ab$

$$(r\underline{/\theta})^2 = r^2\underline{/2\theta}$$

Evolution.—$\sqrt{(r\underline{/\theta})} = \sqrt{(r)}\underline{/\tfrac{1}{2}\theta}$.

From the above it will be seen that in addition and subtraction it is convenient to use the j notation, while for multiplication, division, involution and evolution it is simpler to use the $r\underline{/\theta}$ notation. Where both multiplication and addition are concerned, however, it is often advisable to retain the j notation throughout and perform the four multiplications necessary for every product of two complex numbers, rather than change to the other notation involving the use of logarithms and tables of trigonometrical functions. This is especially true when a calculating machine is available.

For a fuller discussion of the algebra of complex quantities the reader should see Steinmetz's "Engineering Mathematics."

Circuit Constants.

Coming now to the use of the circuit constants, these may be defined by the general equations of an electric circuit :—

$$E_s = AE_r + BI_r \quad . \quad . \quad . \quad . \quad . \quad (1)$$
$$I_s = CE_r + DI_r \quad . \quad . \quad . \quad . \quad (2)$$

where E_s, I_s are the voltage and current at the sending end, E_r, I_r the voltage and current at the receiving end of the circuit and A, B, C, D the four constants of the circuit, the values of which for different types of circuits are derived below.

The significance of these constants may be visualized thus :—

Putting I_r equal to zero in Equation (1), i.e. the circuit excited but without load, A gives the ratio of E_s to E_r; it is unity for short lines and less than unity for long lines. B is the impedance of the circuit as modified to allow for distributed capacity and reactance, and BI_r gives the impedance drop due to the load.

Putting I_r equal to zero in Equation (2), CE_r gives the capacity current on open circuit. DI_r denotes the load current at the sending end as modified by traversing the line.

* $(c - jd)$ is termed the conjugate of $(c + jd)$.

The above equations may also be stated in the following form to express the receiving-end conditions in terms of the sending-end conditions.

$$E_r = DE_s - BI_s \quad . \quad . \quad . \quad . \quad . \quad (1a)$$
$$I_r = - CE_s + AI_s \quad . \quad . \quad . \quad . \quad . \quad (2a)$$

As previously stated, the first aim of this method of treatment is to reduce the circuit or network to an equivalent simple circuit with one set of constants embracing the whole of the individual lines, transformers, etc.

The necessary equations for determining the general constants of circuits in series and parallel are derived as follows :—

Let the voltages, currents, and constants of three circuits in series be as shown in Fig. 1, where the

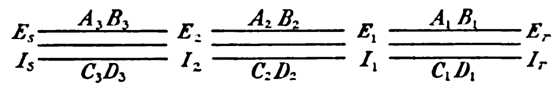

Fig. 1.

separate circuits will generally be either sections of transmission lines with dissimilar characteristics, or sections of transmission lines and transformers.

It is desired to find the general constants A_0, B_0, C_0, D_0, of the circuit as a whole that will express E_s and I_s directly in terms of E_r and I_r.

The equations of the three sections of the circuit are:—

$$E_1 = A_1E_r + B_1I_r; \quad I_1 = C_1E_r + D_1I_r \quad . \quad (3)\ (4)$$
$$E_2 = A_2E_1 + B_2I_1; \quad I_2 = C_2E_1 + D_2I_1 \quad . \quad (5)\ (6)$$
$$E_s = A_3E_2 + B_3I_2; \quad I_s = C_3E_2 + D_3I_2 \quad . \quad (7)\ (8)$$

Substituting the values of E_1 and I_1 as defined by Equations (3) and (4) in Equations (5) and (6) we have :—

$$E_2 = A_2(A_1E_r + B_1I_r) + B_2(C_1E_r + D_1I_r)$$
$$I_2 = C_2(A_1E_r + B_1I_r) + D_2(C_1E_r + D_1I_r)$$

Whence, simplifying, we have :—

$$E_2 = (A_2A_1 + B_2C_1)E_r + (A_2B_1 + B_2D_1)I_r$$
$$I_2 = (A_1C_2 + D_2C_1)E_r + (B_1C_2 + D_2D_1)I_r$$

These two equations define the general constants of two circuits in series thus :—

$$A_0 = A_1A_2 + B_2C_1$$
$$B_0 = A_2B_1 + B_2D_1$$
$$C_0 = A_1C_2 + C_1D_2$$
$$D_0 = B_1C_2 + D_1D_2$$

It should be noted here that in a symmetrical circuit (e.g. a uniform transmission line alone, or with similar transformers at either end) A is numerically equal to D, and the flow of power will produce exactly similar effects regardless of which is the sending and which the receiving end. In an unsymmetrical circuit, however, A is not numerically equal to D (e.g. a transmission line with transformers at one end only) and the direction of flow of power will influence the result.

The general constants for three circuits in series may be found similarly to the above and are :—

$$\begin{aligned}
A_0 &= A_3(A_1A_2 + B_2C_1) + B_3(A_1C_2 + C_1D_2)\\
B_0 &= A_3(A_2B_1 + B_2D_1) + B_3(B_1C_2 + D_1D_2)\\
C_0 &= C_3(A_1A_2 + B_2C_1) + D_3(A_1C_2 + C_1D_2)\\
D_0 &= C_3(A_2B_1 + B_2D_1) + D_3(B_1C_2 + D_1D_2)
\end{aligned}$$

As may be expected, if the two end portions of the circuit are similar (e.g. the transformers at either end of a uniform transmission line), i.e. if $A_1 = A_3$; $B_1 = B_3$, etc., D_0 becomes equal to A_0.

For circuits in parallel the general constants are derived as follows, where the voltages, currents and constants are as shown in Fig. 2.

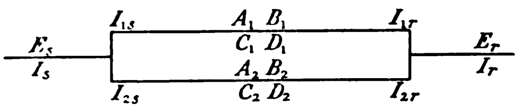

FIG. 2.

The voltage equations of the two parallel circuits are :—

$$E_s = A_1E_r + B_1I_{1r}, \quad \therefore B_2E_s = B_2A_1E_r + B_2B_1I_{1r} \quad (9)$$

$$E_s = A_2E_r + B_2I_{2r}, \quad \therefore B_1E_s = B_1A_2E_r + B_1B_2I_{2r} \quad (10)$$

Adding

$$(B_1 + B_2)E_s = (B_2A_1 + B_1A_2)E_r + B_1B_2(I_{1r} + I_{2r})$$

But

$$I_{1r} + I_{2r} = I_r, \quad \therefore E_s = \frac{A_1B_2 + A_2B_1}{B_1 + B_2}E_r + \frac{B_1B_2}{B_1 + B_2}I_r \quad . \quad (11)$$

From Equations (9) and (11) we have

$$E_s = A_1E_r + B_1I_{1r} = \frac{A_1B_2 + A_2B_1}{B_1 + B_2}E_r + \frac{B_1B_2}{B_1 + B_2}I_r$$

Whence $$I_{1r} = \frac{A_2 - A_1}{B_1 + B_2}E_r + \frac{B_2}{B_1 + B_2}I_r \quad . \quad . \quad (12)$$

Similarly $$I_{2r} = \frac{A_1 - A_2}{B_1 + B_2}E_r + \frac{B_1}{B_1 + B_2}I_r \quad . \quad . \quad (13)$$

Substituting these values in the two current equations we have :—

$$\begin{aligned}
I_{1s} &= C_1E_r + D_1I_{1r}\\
&= C_1E_r + D_1\left(\frac{A_2 - A_1}{B_1 + B_2}E_r + \frac{B_2}{B_1 + B_2}I_r\right) \quad . \quad (14)\\
I_{2s} &= C_2E_r + D_2I_{2r}\\
&= C_2E_r + D_2\left(\frac{A_1 - A_2}{B_1 + B_2}E_r + \frac{B_1}{B_1 + B_2}I_r\right) \quad . \quad (15)
\end{aligned}$$

Adding (14) and (15) we get

$$(I_{1s} + I_{2s}) = I_s = E_r\left\{C_1 + C_2 - \frac{(A_1 - A_2)(D_1 - D_2)}{B_1 + B_2}\right\} + \frac{D_1B_2 + D_2B_1}{B_1 + B_2}I_r \quad . \quad (16)$$

Equations (11) and (16) define the general constants, thus :—

$$\begin{aligned}
A_0 &= (A_1B_2 + A_2B_1)/(B_1 + B_2)\\
B_0 &= (B_1B_2)/(B_1 + B_2)\\
C_0 &= C_1 + C_2 - (A_1 - A_2)\,(D_1 - D_2)/(B_1 + B_2)\\
D_0 &= (D_1B_2 + D_2B_1)/(B_1 + B_2)
\end{aligned}$$

In practice it will be found that the third term in the expression for C_0 can generally be neglected altogether, as it is so small. It will again be noticed that for a symmetrical circuit $A_0 = D_0$.

For two identical circuits the above simplify to :—

$$\begin{aligned}
A_0 &= A_1 = A_2.\\
B_0 &= \tfrac{1}{2}B_1 = \tfrac{1}{2}B_2.\\
C_0 &= 2C_1 = 2C_2.\\
D_0 &= D_1 = D_2.
\end{aligned}$$

The general circuit constants for three circuits in parallel may be found similarly to the above and are :—

$$A_0 = \frac{A_1B_2B_3 + A_2B_3B_1 + A_3B_1B_2}{B_1B_2 + B_2B_3 + B_3B_1}$$

$$B_0 = \frac{B_1 + B_2 + B_3}{B_1B_2 + B_2B_3 + B_3B_1}$$

$$C_0 = C_1 + C_2 + C_3 - \frac{B_2(D_3 - D_1)(A_3 - A_1) + B_3(D_1 - D_2)(A_1 - A_2) + B_1(D_2 - D_3)(A_2 - A_3)}{B_1B_2 + B_2B_3 + B_3B_1}$$

$$D_0 = \frac{D_1B_2B_3 + D_2B_3B_1 + D_3B_1B_2}{B_1B_2 + B_2B_3 + B_3B_1}$$

For three identical circuits the above simplify to

$$\begin{aligned}
A_0 &= A_1 = A_2 = A_3.\\
B_0 &= \tfrac{1}{3}B_1 = \tfrac{1}{3}B_2 = \tfrac{1}{3}B_3.\\
C_0 &= 3C_1 = 3C_2 = 3C_3.\\
D_0 &= D_1 = D_2 = D_3.
\end{aligned}$$

The currents in the individual branches of the circuit may be found from Equations (12) and (13) for two circuits in parallel, and for three circuits in parallel are :—

$$I_{1r} = \frac{B_2(A_3 - A_1) + B_3(A_2 - A_1)}{B_1B_2 + B_2B_3 + B_3B_1}E_r + \frac{B_2B_3}{B_1B_2 + B_2B_3 + B_3B_1}I_r$$

$$I_{2r} = \frac{B_3(A_1 - A_2) + B_1(A_3 - A_2)}{B_1B_2 + B_2B_3 + B_3B_1}E_r + \frac{B_3B_1}{B_1B_2 + B_2B_3 + B_3B_1}I_r$$

$$I_{3r} = \frac{B_1(A_2 - A_3) + B_2(A_1 - A_3)}{B_1B_2 + B_2B_3 + B_3B_1}E_r + \frac{B_1B_2}{B_1B_2 + B_2B_3 + B_3B_1}I_r$$

The constants A, B, C, D have now to be determined for the various types of circuits that are involved in the study of transmission lines.

Transmission-Line Constants.

For the transmission line proper the following data should first be determined (for formulæ see Appendix 1):

R = resistance of one conductor in ohms per mile.
X = reactance of one conductor in ohms per mile.
G = conductance to neutral of one conductor in mhos per mile.
B = capacity susceptance to neutral of one conductor in mhos per mile.

These are the four fundamental physical constants of the line from which the general constants may be calculated as follows:—

Let $Z = R + jX$ = series impedance in ohms per mile;
and $Y = G + jB$ = shunt admittance in mhos per mile.

From here on, all the functions are expressed as complex quantities and with Z and Y expressed in the $r\underline{/\theta}$ notation the next step is to calculate the

Attenuation factor $lm = l\sqrt{(YZ)}$, and the
Surge impedance $n = \sqrt{(Z/Y)}$,

where l is the length of the line in miles.

The general constants can now be defined thus:—

$$A = \cosh lm;$$
$$B = n \sinh lm;$$
$$C = (1/n) \sinh lm;$$
$$D = A.$$

The method of calculating $\cosh lm$ and $\sinh lm$ is as follows:—

Express lm in the form $a + jb$, whence

$$\sinh (a + jb) = \sinh a \,.\, \cos b + j \cosh a \,.\, \sin b$$
$$\cosh (a + jb) = \cosh a \,.\, \cos b + j \sinh a \,.\, \sin b$$

The numerical values of these functions are best calculated by taking values of log sinh, log cosh, log sin, and log cos from tables such as the tables of hyperbolic and circular functions published by the Smithsonian Institute. It should be remembered that a and b are in radians. Tabulated values of $\cosh lm$ and $\sinh lm$ will be found in a paper entitled "The Electrical Properties of Three-Phase Transmission Lines," by E. Parry.*

For many purposes values from these tables will be close enough for the problem in hand, but even if special values are to be calculated the tables will be a valuable check on the accuracy of the work and prevent a gross error from being passed over.

Transformer Constants.

The following data should be known:—

Full-load copper loss per phase in watts.
Reactance or impedance in volts.
Iron loss per phase in watts.
Magnetizing current in amperes.

* *New Zealand Journal of Science*, 1919, vol. 2, p. 127.

These should be in terms of the line to neutral (star) voltage in three-phase systems, and all values are to be calculated as equivalent values at the high-tension star voltage.

Full load should be taken as one-third the capacity of a three-phase transformer or of a three-phase bank. Let I be the full-load current in amperes; then

$$R = \frac{\text{copper-loss watts}}{I^2} = \text{equivalent series resistance in ohms.}$$

$$X = \frac{\text{Reactance volts}}{I} = \text{equivalent series reactance in ohms.}$$
$$= \sqrt{\left[\left(\frac{\text{Impedance volts}}{I}\right)^2 - R^2\right]}$$

$$G = \frac{\text{Iron-loss watts}}{E^2} = \text{equivalent shunt conductance in mhos.}$$

$$B = \sqrt{\left[\left(\frac{\text{Magnetizing amps}}{E}\right)^2 - G^2\right]}$$
$$= \text{equivalent shunt susceptance in mhos.}$$

These four constants are exactly similar in effect to those of the transmission line, with the exception that B is in this case an inductive susceptance and is given a negative sign, thus

$$Z = R + jX = \text{series impedance in ohms,}$$
$$Y = G - jB = \text{shunt admittance in mhos.}$$

The change in the sign of B will be easily understood, as in the case of the transmission line it determines the leading charging current whilst in the case of the transformer it determines the lagging exciting current. Consider now the transformer replaced by an equivalent circuit with a series impedance Z and a shunt admittance Y as shown in Fig. 3. The admittance Y is shown

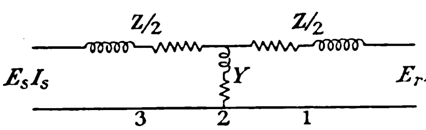

Fig. 3.

connected in the middle of the series impedance, giving a circuit practically exactly equivalent to the actual transformer.

Now the general constants of a series impedance and a shunt admittance are:—

	Series impedance	Shunt admittance
A =	1	1
B =	Z	0
C =	0	Y
D =	1	1

so that the transformer may be considered to be three circuits in series, with the following constants:—

$$A_1 = 1; \quad A_2 = 1; \quad A_3 = 1;$$
$$B_1 = \tfrac{1}{2}Z; \quad B_2 = 0; \quad B_3 = \tfrac{1}{2}Z;$$
$$C_1 = 0; \quad C_2 = Y; \quad C_3 = 0;$$
$$D_1 = 1; \quad D_2 = 1; \quad D_3 = 1.$$

We have, therefore, by substitution in the formulæ for three circuits in series, the general constants for a transformer as follows :—

$$
\begin{aligned}
A_0 &= 1 + \tfrac{1}{2}YZ \\
B_0 &= Z(1 + \tfrac{1}{4}YZ) \\
C_0 &= Y \\
D_0 &= 1 + \tfrac{1}{2}YZ
\end{aligned}
$$

We have now shown how the separate constants for sections of a system may be calculated and combined into one set of general constants. Once these general constants have been determined, the sending voltage and current can be calculated immediately from the known values of the receiving voltage and current.

It is generally convenient to adopt the receiving current vector as the vector of reference. Thus, in treating a three-phase 110 000-volt load of 12 000 kVA at 0·8 power factor, 4 000 kVA is taken as the load per phase and expressed as

$$
\begin{aligned}
I_r &= 62{\cdot}96 \text{ amperes} \\
E_r &= 63\,500\underline{/36^\circ\ 52'} = 50\,800 + j38\,100 \text{ volts.}
\end{aligned}
$$

Transformer Ratio.

It will be noted that so far no mention has been made of the transformer ratio, the problem being treated as if the transformer had approximately a 1 : 1 ratio at no load.

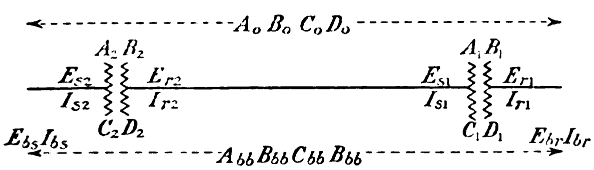

FIG. 4.

For problems dealing only with percentage variation in voltage this will generally be sufficient, but when the definite corresponding values of both sending and receiving voltages are required the actual transformer ratio must be known and taken into account.

How to take into account the ratio will best be illustrated by an example taken from the Mangahao-Wellington transmission lines. Assuming a transmission system as shown in Fig. 4 having as receiving transformers three single-phase 4 000-kVA transformers with constants A_1, B_1, C_1, D_1, and specified to have a ratio of 63 500/6 350 volts at full load, 0·8 power factor, find by trial the values of E_{r1} and I_{r1} that at 0·8 power factor will satisfy the specified conditions, i.e. that their product shall equal 4 000 kVA and that $E_{s1} = A_1E_{r1} + BI_{r1} = 63\,500$ volts. This condition is found to be satisfied by the values

$$
\begin{aligned}
E_{r1} &= 59\,250\underline{/36^\circ\ 52'} = 47\,400 + j\,35\,550 \text{ volts.} \\
I_{r1} &= 67{\cdot}515 \text{ amperes.}
\end{aligned}
$$

If now the symbol E_{r1} is retained to mean the equivalent receiving voltage in terms of the high-tension voltage as used in the formula, and E_{br} the actual low-tension busbar voltage, we have $E_{r1} = 59\,250$ and $E_{s1} = 63\,500$, from which, according to the specification, $E_{br} = 6\,350$.

Therefore $$E_{r1} = E_{br}\frac{59\,250}{6\,350}$$

Similarly if the sending transformers are of 4 000 kVA, single-phase, with constants A_2, B_2, C_2, D_2, and specified to have a ratio of 6 350/63 500 volts at no load, take $E_{r2} = 63\,500$ volts; $I_{r2} = 0$ amperes; $E_{s2} = A_2E_{r2} + B_2I_{r2} = 63\,543{\cdot}6 + j3{\cdot}6 = 63\,544$ volts. As before, letting E_{s2} be the equivalent sending voltage in terms of the high-tension voltage as found from the formula, and E_{bs} the actual busbar voltage, we have $E_{s2} = 63\,544$ and $E_{r2} = 63\,500$ from which, according to the specification, $E_{bs} = 6\,350$.

Therefore $$E_{s2} = E_{bs}\frac{63\,544}{6\,350}$$

It follows that the receiving and sending currents should also be modified in the inverse ratio, so that the equivalent $E_{r1}I_{r1}$ at the receiving end, and $E_{s2}I_{s2}$ at the sending end, shall represent the true power $E_{br}I_{br}$ and $E_{bs}I_{bs}$ respectively.

The following relations will therefore hold :—

$$
\begin{aligned}
I_{r1} &= I_{br}\frac{6\,350}{59\,250} \\
I_{s2} &= I_{bs}\frac{6\,350}{63\,544}
\end{aligned}
$$

If desired, the four values of E_{r1}, E_{s2}, I_{r1} and I_{s2}, in terms of E_{br}, E_{bs}, I_{br} and I_{bs}, may be substituted in the fundamental equations and new constants calculated that will give busbar to busbar voltages directly. The equations would then become :—

$$
\begin{aligned}
E_{bs}\frac{63\,544}{6\,350} &= A_0\frac{59\,250}{6\,350}E_{br} + B_0\frac{6\,350}{59\,250}I_{br} \\
I_{bs}\frac{6\,350}{63\,544} &= C_0\frac{59\,250}{6\,350}E_{br} + D_0\frac{6\,350}{59\,250}I_{br}
\end{aligned}
$$

If A_0, B_0, C_0 and D_0 are the combined constants of the line and transformers the busbar-to-busbar constants would therefore be :—

$$
\begin{aligned}
A_{bb} &= A_0\frac{59\,250}{6\,350} \times \frac{6\,350}{63\,544} = A_0 \times 0{\cdot}932425 \\
B_{bb} &= B_0\frac{6\,350}{59\,250} \times \frac{6\,350}{63\,544} = B_0 \times 0{\cdot}010710 \\
C_{bb} &= C_0\frac{59\,250}{6\,350} \times \frac{63\,544}{6\,350} = C_0 \times 93{\cdot}371746 \\
D_{bb} &= D_0\frac{6\,350}{59\,250} \times \frac{63\,544}{6\,350} = D_0 \times 1{\cdot}072472
\end{aligned}
$$

Transmission Lines Supplying More than One Substation.

The foregoing discussion has shown in detail the methods to be followed in handling simple transmission systems with one generating station and one substation, the equations giving the power-house busbar voltage and current in terms of the substation busbar voltage and current. It often happens, however, that

two or more substations are supplied at intervals along a transmission line, and methods for treating these cases will now be outlined.

To get one general expression for such a system that could be used in practice appears impracticable and all that will be attempted is to show how, knowing the receiving voltage at the remote end of the line and the various loads in kilovolt-amperes and their power factors, the voltage and current at any point on the system may be calculated. The no-load and load conditions will be treated separately.

Let Fig. 5 represent a transmission system with two receiving stations X and Y fed from a sending station Z, the voltages, currents and constants being as shown in the diagram.

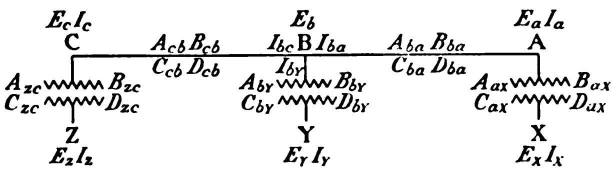

FIG. 5.

Assuming E_x, it is required to find the voltages and currents at A, B, C, Y and Z.

No-Load Conditions (I_x *and* I_y *both zero*).

The voltage and current at A are :—

$$E_a = A_{ax}E_a \quad \text{and} \quad I_a = C_{ax}E_x$$

The voltage and current at B due to the line and the transformer BAX are :—

$$E_b = A_{ba}E_a + B_{ba}I_a \quad \text{and} \quad I_b = C_{ba}E_a + D_{ba}I_a$$

The voltage at Y due to the voltage E_b at B is

$$E_b = A_{by}E_y$$

and therefore

$$E_y = E_b/A_{by} = E_b\overline{A_{by}}/A_{by}\overline{A_{by}}$$

where $\overline{A_{by}}$ is the conjugate of A_{by}.

The current at B due to the transformer BY, i.e. the exciting current at voltage E_b, is $I_{by} = C_{by}E_y$.

The total current at B is $I_{bc} = I_{ba} + I_{by}$.

The voltage and current at C are :—

$$E_c = A_{cb}E_b + B_{cb}I_{bc} \quad \text{and} \quad I_c = C_{cb}E_b + D_{cb}I_{bc}$$

The voltage and current at Z are :—

$$E_z = A_{zc}E_c + B_{zc}I_c \quad \text{and} \quad I_z = C_{zc}E_c + D_{zc}I_c$$

This step-by-step method can be extended to any number of substations. The product of the final values of voltage and current at the sending station Z will give the charging kilovolt-amperes of the system, the power factor being defined by the cosine of the angle between the voltage and current vectors.

It will be of interest to note here that if E and I are the voltage and current at any point, where $E = e_1 + je_2$ and $I = i_1 + ji_2$, then $P = e_1i_1 + e_2i_2$ and $Q = e_1i_2 - e_2i_1$, where P and Q are the energy watts and wattless volt-amperes respectively.

A rather more difficult case may arise where the line branches and supplies one or more substations on each branch. If there is only one substation on the branch line it can be dealt with by calculating the general constants of the branch line and transformers and treating it exactly as the branch BY above. If, however, the branch has more than one substation, the following method may be followed :—

Let Fig. 6 represent a transmission system branching at C and supplying two lines CDE and CBA. Assuming that E_v has been taken as the known point and E_v and I_{cd} calculated as above, it is required to find the

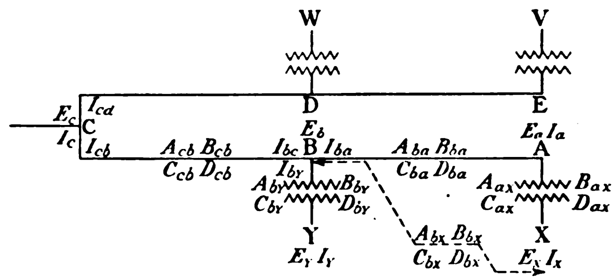

FIG. 6.

voltages and currents at A, B, Y and X as determined by the voltage E_c at C.

Calculate for the line BA and transformer AX the general constants A_{bx}, B_{bx}, etc.

The voltage and total current at B are :—

$$E_b = A_{bx}E_x = A_{by}E_y, \text{ or } E_y = A_{bx}E_x/A_{by}$$

$$I_{bc} = I_{ba} + I_{by} = C_{bx}E_x + C_{by}E_y$$
$$= C_{bx}E_x + C_{by}A_{bx}E_x/A_{by}$$

The voltage and current at C are :—

$$E_c = A_{cb}E_b + B_{cb}I_{bc}$$
$$= A_{cb}A_{bx}E_x + B_{cb}(C_{bx} + C_{by}A_{bx}/A_{by})E_x \quad . \quad (17)$$

$$I_{cb} = C_{cb}E_b + D_{cb}I_{bc}$$
$$= C_{cb}A_{bx}E_x + D_{cb}(C_{bx} + C_{by}A_{bx}/A_{by})E_x \quad . \quad (18)$$

From (17)

$$E_c = (A_{cb}A_{bx} + B_{cb}C_{bx} + B_{cb}C_{by}A_{bx}/A_{by})E_x$$

$$\therefore E_x = \frac{E_c}{A_{cb}A_{bx} + B_{cb}C_{bx} + B_{cb}C_{by}A_{bx}/A_{by}}$$

I_{cb} may be calculated step by step from E_x, or by substituting in Equation (18). The calculations may now be continued from the values E_c and I_c back to the sending station, exactly as previously described.

The above indicates the method for deriving a general equation for no-load conditions. The equations would obviously become very complicated for many substations and the step-by-step method will probably be found to be more useful in practice.

Load conditions.

Referring to Fig. 5, E_x and I_x will be known, from which may be calculated the voltage and current at A, viz.

$$E_a = A_{ax}E_x + B_{ax}I_x; \quad I_a = C_{ax}E_x + D_{ax}I_x$$

and the voltage and current at B, viz.

$$E_b = A_{ba}E_a + B_{ba}I_a; \quad I_b = C_{ba}E_a + D_{ba}I_a$$

A difficulty now arises in finding the current I_{by} at B at the voltage E_b already determined, when only the kilovolt-amperes and power factor of the load at Y are known. A complete solution is not practicable but as the exact value of the kVA is generally not known it will probably be quite near enough to estimate the low-tension voltage E_y (which can generally be done within 1 per cent) and calculate the corresponding value of the low-tension current I_y for the required kVA.

To give a clear understanding of the problem the known and unknown quantities are enumerated below and their relation is shown in the vector diagram (Fig. 7), which is not to scale. Capital subscripts in the following denote scalar values.

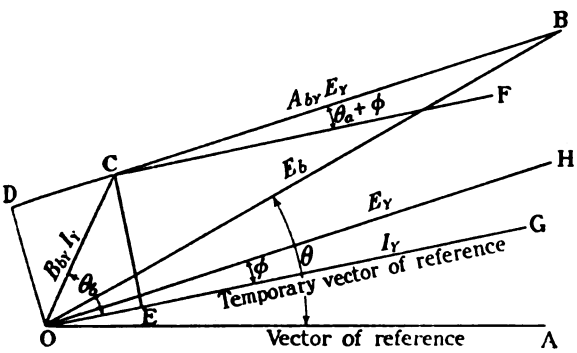

FIG. 7.

The equation to be satisfied is:—

$$E_b = A_{by}E_y + B_{by}I_y$$

where the three vectors are represented in the diagram by OB = CB + OC respectively.

Known quantities:—

E_b expressed as $E_B\angle\theta$.

I_y, numerical value only used as temporary reference vector.

A_{by} and B_{by} expressed as $A_{BY}\angle\theta_a$ and $B_{BY}\angle\theta_b$.

ϕ the phase angle of E_Y with respect to I_Y, i.e. arc cos (power factor).

Unknown quantities:—

E_Y and phase angle $\angle HOA$.

$\angle GOA$ phase angle of I_Y.

Taking OG as the temporary vector of reference, let CF be drawn parallel to OG, OD perpendicular to BC, and CE perpendicular to OG. Then:—

$$OC = B_{BY}I_Y \quad \text{and} \quad \angle COG = \theta_b$$

$$CB = A_{BY}E_Y \quad \text{and} \quad \angle BCF = \theta_a + \phi$$

Now

$$\angle DCO + \angle OCE + \angle BCF = 90^\circ = \angle COE + \angle OCE$$

$$\therefore \angle DCO = \angle COE - \angle BCF$$

$$= \theta_b - \theta_a - \phi$$

Again $\qquad DO = CO \sin \angle DCO$

Therefore

$$\sin \angle DBO = \frac{CO \sin \angle DCO}{OB} = \frac{B_{BY}I_Y \sin \angle \theta_b - \theta_a - \phi}{E_B} \quad . \quad (19)$$

$$BC = DB - DC = OB \cos \angle DBO - CO \cos \angle DCO$$

i.e. $A_{BY}E_Y = E_B \cos \angle DBO - B_{BY}I_Y \cos \angle \theta_b - \theta_a - \phi$

$$E_Y = \frac{E_B \cos \angle DBO}{A_{BY}} - \frac{B_{BY}I_Y}{A_{BY}} \cos \angle \theta_b - \theta_a - \phi \quad . \quad (20)$$

where $\angle DBO$ is defined by Equation (19).

Now $\quad \angle BOG = \angle BCF + \angle CBO = \theta_a + \phi + \angle DBO$

Therefore $\quad \angle GOA = \theta - \theta_a - \phi - \angle DOB$

We can now write:—

Phase angle of $BC = \theta - \angle DBO$

Phase angle of $E_Y = \theta - \angle DBO - \theta_a$ . . (21)

Phase angle of $I_A = \theta - \angle DBO - \theta_a - \phi$. (22)

E_y and I_y are therefore completely determined with reference to the assumed datum I_x.

The voltage and current at B can now be calculated:—

$$E_b = A_{by}E_y + B_{by}I_y \quad \text{and} \quad I_{by} = C_{by}E_y + D_{by}I_y$$

I_{by} is required for finding I_{bc} and continuing the calculation to point C (Fig. 5), and E_b should check with the value first determined, thus proving that the method gives an exact solution for the values E_y and I_y, the only approximation being that of the product E_YI_Y to the assumed value of kVA at Y.

A simpler method of treating a branch circuit with load is to assume the load at the high-tension side of the transformer and to use the inverse forms of the general equations [1 (*a*) and 2 (*a*)] to calculate the low-tension values. The actual low-tension load and power factor can only be approximated to by trial and error, for both will, in general, be different from the high-tension values assumed.

A branch line with only one substation can be treated exactly as above by using general constants for the branch line and its transformers.

The case of a branch line with more than one substation, however, presents considerable difficulty and can only be solved practically by trial and error, beginning with assumed values of E and I at the end of the branch and calculating the equivalent sending voltage at the junction. When the scalar value of this voltage has been determined sufficiently close to the actual value, the phase angles of all the quantities assumed and calculated for the branch circuit will have to be rotated by the amount of the difference between the actual and assumed values of the voltage phase angles at the junction point.

Parallel lines and banks of transformers can be treated by means of the general formulæ as developed in the previous discussion.

In conclusion, I have to acknowledge the assistance rendered by Dr. E. Marsden and the late Mr. L. Birks in reviewing and criticizing these notes.

APPENDIX 1.

Formulæ.

Resistance R = ohms per mile (see tables, e.g. *New Zealand Journal of Science*, 1921, vol. 4, p. 259).

Inductance $L = 741\cdot13 \log_{10}(ks/d)10^{-6}$ henrys per mile,

where s = symmetrical spacing, centre to centre, of conductors;
$= \sqrt[3]{(abc)}$ for unsymmetrical spacings, a, b, c;
d = diameter of conductor in the same units as s;
$k = 2\cdot568$ for single-strand conductor;
$= 2\cdot951$ for 3-strand conductor;
$= 2\cdot756$ for 7-strand conductor;
$= 2\cdot640$ for 19-strand conductor;
$= 2\cdot605$ for 37-strand conductor;
$= 2\cdot590$ for 61-strand conductor.

Reactance $X = 2\pi fL$ ohms per mile,

where f = frequency (see tables as for Resistance above).

Capacity $C = \dfrac{38\cdot83 \times 10^{-9}}{\log_{10}(s/r)}$ farads per mile (phase to neutral),

where r = radius of conductor in the same units as s.

Capacity susceptance $B = 2\pi fC$ mhos per mile.

Leakage conductance G may be taken as

$0\cdot005 \times 10^{-6}$ mhos per mile for suspension insulators.
$0\cdot008 \times 10^{-6}$ mhos per mile for pin insulators.

APPENDIX 2.

Worked Example: Mangahao–Wellington Transmission.

Transmission line, three-phase, 50-cycle, 110 000-volt conductors of 19/13 S.W.G. copper, diameter 0·460 inch, spacing right-triangle 11 ft. 6 in. horizontal, 9 ft. vertical, length 61·5 miles.

Equivalent spacing $s = \sqrt[3]{(108 \times 138 \times 175\cdot2)} = 137\cdot7$ in.

Resistance $R = 0\cdot348$ ohm per mile.

Reactance $X = 2\pi \times 50 \times 741\cdot13 \log_{10} 2\cdot64 \times 137\cdot7/0\cdot46.$
$= 0\cdot6723$ ohm per mile.

Susceptance $B = 2\pi \times 50 \times \dfrac{38\cdot83}{\log_{10} 137\cdot7/0\cdot23} \times 10^{-9}$
$= 4\cdot39196 \times 10^{-6}$ mhos.

Conductance $G = 0\cdot005 \times 10^{-6}$ mhos.

Impedance $Z = R + jX = 0\cdot348 + j0\cdot6723$
$= 0\cdot757\,\angle 62^\circ\,38'$ ohms.

Admittance $Y = G + jB = (0\cdot005 + j4\cdot392)10^{-6}$
$= 4\cdot392 \times 10^{-6}\,\angle 89^\circ\,56'$ mhos.

Attenuation factor m

$$= \sqrt{(YZ)} = \sqrt{(0\cdot757 \times 4\cdot392 \times 10^{-6})}\,\angle \tfrac{1}{2}(89^\circ\,56' + 62^\circ\,38')$$
$$= 0\cdot001824\,\angle 76^\circ\,17'$$

Surge impedance n

$$= \sqrt{\left(\frac{Z}{Y}\right)} = \sqrt{\left(\frac{0\cdot757}{4\cdot392 \times 10^{-6}}\right)}\,\angle \frac{62^\circ\,38' - 89^\circ\,56'}{2}$$
$$= 415\cdot18\,\overline{\backslash 13^\circ\,39'}$$

$lm = 61\cdot5 \times 0\cdot001824\,\angle 76^\circ\,17' = 0\cdot11215\,\angle 76^\circ\,17'$
$= 0\cdot02659 + j0\cdot10895$

$\sinh lm = \sinh 0\cdot02659 \cos 0\cdot10895 + j \cosh 0\cdot02659 \sin 0\cdot10895$

$\log \sinh 0\cdot02659 = \bar{2}\cdot42477$; $\log \cosh 0\cdot02659 = 0\cdot00015$
$\log \cos 0\cdot10895 = \bar{1}\cdot99741$; $\log \sin 0\cdot10895 = \bar{1}\cdot03657$
$\bar{2}\cdot42218$ $\qquad$ $\bar{1}\cdot03672$

$= 0\cdot02643 + j0\cdot10882 = 0\cdot11199\,\angle 76^\circ\,21'$

$\cosh lm = \cosh 0\cdot02659 \cos 0\cdot10895 + j \sinh 0\cdot02659 \sin 0\cdot10895$

$\log \cosh 0\cdot02659 = 0\cdot00015$; $\log \sinh 0\cdot02659 = \bar{2}\cdot42477$
$\log \cos 0\cdot10895 = \bar{1}\cdot99741$; $\log \sin 0\cdot10895 = \bar{1}\cdot03657$
$\bar{1}\cdot99756$ $\qquad$ $\bar{3}\cdot46134$

$= 0\cdot9944 + j0\cdot002893 = 0\cdot9944\,\angle 0^\circ\,10'$

$A_2 = \cosh lm = 0\cdot9944\,\angle 0^\circ\,10' = 0\cdot9944 + j0\cdot002893$
$B_2 = n \sinh lm = 46\cdot496\,\angle 62^\circ\,42' = 21\cdot326 + j41\cdot317$
$C_2 = (1/n) \sinh lm = 0\cdot0002697\,\angle 90^\circ = 0 + j0\cdot0002697$

Transformers sending.—Three single-phase 4 000-kVA 11 000/110 000 volts. Impedance volts = 6·15 per cent. Full-load copper loss = 26 829 watts per transformer. Iron loss = 17 060 watts per transformer. Magnetizing current = 1·411 amperes.

Full-load current $I = 4\,000 \times 1\,000/63\,500 = 63$ amperes.

Equivalent resistance $R = 26\,829/(63)^2 = 6\cdot76$ ohms.

Equivalent reactance $X = \sqrt{\left[\left(\dfrac{3\,905\cdot3}{63}\right)^2 - (6\cdot76)^2\right]}$
$= 61\cdot62$ ohms.

Conductance $G = \dfrac{17\,060}{(63\,500)^2} = 0\cdot00000423$ mhos.

Susceptance $B = \sqrt{\left[\left(\dfrac{1\cdot411}{63\,500}\right)^2 - (0\cdot00000423)^2\right]}$
$= 0\cdot0000218$ mhos.

Impedance $Z = R + jX = 6\cdot76 + j61\cdot62$ ohms.

Admittance $Y = G - jB = 0\cdot00000423 - j0\cdot0000218$ mhos.

$A_3 = 1 + \frac{1}{2}YZ = 1\cdot000686 + j0\cdot000057$
$B_3 = Z(1 + \frac{1}{4}YZ) = 6\cdot76057 + j61\cdot64132$
$C_3 = Y = 0\cdot00000423 - j0\cdot0000218$

Transformers receiving.—Three single-phase 4 000-kVA 110 000/11 000 volts.

Reactance voltage = 8·83 per cent. Full-load copper loss = 30 003 watts per transformer. Iron loss = 14 281 watts per transformer. Magnetizing current = 1·84 amperes.

As above, we have $Z = 7\cdot559 + j89\cdot02$
$Y = 0\cdot00000354 - j0\cdot0000288$

whence
$$A_1 = 1\cdot00130 + j0\cdot000049$$
$$B_1 = 7\cdot56176 + j89\cdot07786$$
$$C_1 = 0\cdot0000035 - j0\cdot000029$$

Combining the three sets of constants according to the equations

$$A_0 = 0\cdot98281 + j0\cdot00441$$
$$B_0 = 34\cdot88740 + j189\cdot99155$$
$$C_0 = 0\cdot000008 + j0\cdot00022$$
$$D_0 = 0\cdot97528 + j0\cdot00497$$

and applying to these the corrections as given under the heading "Transformer ratio" which were calculated for these transformers we have :—

$$A_{bb} = A_0 \times 0\cdot932425 = 0\cdot916393 + j0\cdot004111$$
$$B_{bb} = B_0 \times 0\cdot010710 = 0\cdot373640 + j2\cdot034785$$
$$C_{bb} = C_0 \times 93\cdot371746 = 0\cdot000747 + j0\cdot020448$$
$$D_{bb} = D_0 \times 1\cdot072472 = 1\cdot045965 + j0\cdot005327$$

These four constants when used in Equations (1) and (2) or (1a) and (2a) will give busbar voltages and currents in terms of the busbar voltages and currents at the other end of the line.

The following examples will show the method of applying these constants and the forms in which the results may be obtained. The values of load and voltage are assumed at the receiving-end low-tension busbar, and the corresponding values at the sending-end low-tension busbar are found by one application of the formulæ.

(a) *No-load conditions.*

$$E_{br} = 6\ 350\ ; \quad I_{br} = 0$$

E_{br} is taken as the vector of reference.

$$\begin{aligned} E_{bs} &= A_{bb}E_{br} + B_{bb}I_{br} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1) \\ &= (0\cdot91639 + j0\cdot00411)6\ 350 + j0 \\ &= 5\ 819\cdot1 + j26\cdot1 \\ &= 5\ 819\cdot1 \underline{/0^\circ\ 15'} \text{ volts} \end{aligned}$$

$$\begin{aligned} I_{bs} &= C_{bb}E_{br} + D_{bb}I_{br} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2) \\ &= (0\cdot000747 + j0\cdot020448)6\ 350 + j0 \\ &= 4\cdot744 + j129\cdot845 \\ &= 129\cdot931 \underline{/87^\circ\ 54'} \text{ amperes} \end{aligned}$$

$$\text{kVA} = \frac{5\ 819\cdot1 \times 129\cdot931}{1\ 000} = 756\cdot1 \text{ per phase}$$

Power factor $= \cos(87^\circ\ 54' - 0^\circ\ 15') = \cos 87^\circ\ 39'$
$= 0\cdot0410$
$= 4\cdot10$ per cent, leading

Kilowatts $= 756\cdot1 \times 0\cdot041$
$= 31$ per phase

Reactive kVA $= 756\cdot1 \times \sin 87^\circ\ 39'$
$= 756\cdot1 \times 0\cdot9915$
$= 755\cdot4$ per phase

The kilowatts and reactive kVA could have been found directly from the formulæ on page 248 thus :—

Watts $P = 5\ 819\cdot1 \times 4\cdot744 + 26\cdot1 \times 129\cdot845$
$= 27\ 607 + 3\ 388$
$= 30\ 995 = 31$ kW

Reactive volt-amperes Q
$= 5\ 819\cdot1 \times 129\ 845 - 26\cdot1 \times 4\cdot744$
$= 755\ 560 - 123$
$= 755\ 437 = 755\cdot4$ kVA

(b) *Load conditions.*—Load 4 000 kVA per phase at 0·8 power factor.

$$E_{br} = 6\ 350\underline{/36^\circ\ 52'} = 5\ 080 + j3\ 810$$
$$I_{br} = 629\cdot6 \text{ amperes}$$

I_{br} is taken as the vector of reference.

$$\begin{aligned} E_{bs} &= A_{bb}E_{br} + B_{bb}I_{br} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1) \\ &= (0\cdot91639 + j0\cdot00411)(5\ 080 + j3\ 810) \\ &\qquad + (0\cdot37364 + j2\cdot03479)629\cdot6 \\ &\quad 4\ 655\cdot28 + j\ \ 20\cdot88 \\ &\quad - 15\cdot66 + j3\ 491\cdot46 \\ &\quad \underline{235\cdot24 + j1\ 281\cdot10} \\ &= 4\ 874\cdot86 + j4\ 793\cdot44 \\ &= 6\ 836\cdot9\underline{/44^\circ\ 31'} \text{ volts} \end{aligned}$$

$$\begin{aligned} I_{bs} &= C_{bb}E_{br} + D_{bb}I_{br} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2) \\ &= (0\cdot000747 + j0\cdot020448)(5\ 080 + j3\ 810) \\ &\qquad + (1\cdot045965 + j0\cdot005327)629\cdot6 \\ &\quad 3\cdot7948 + j103\cdot8758 \\ &\quad - 77\cdot9069 + j\ \ 2\cdot8461 \\ &\quad \underline{658\cdot5394 + j\ \ 3\cdot3538} \\ &= 584\cdot4273 + j\ 110\cdot0757 \\ &= 594\cdot7036\underline{/10^\circ\ 40'} \text{ amperes} \end{aligned}$$

$$\text{kVA} = \frac{6\ 836\cdot9 \times 594\cdot7}{1\ 000} = 4\ 065\cdot9 \text{ per phase}$$

Power factor $= \cos(44^\circ\ 31' - 10^\circ\ 40') = \cos 33^\circ\ 51'$
$= 0\cdot8305$
$= 83\cdot05$ per cent, lagging.

Kilowatts $= 4\ 065\cdot9 \times 0\cdot8305$
$= 3\ 376\cdot7$ per phase.

Reactive kVA $= 4\ 065\cdot9 \times \sin 33^\circ\ 51'$
$= 4\ 065\cdot9 \times 0\cdot5570$
$= 2\ 264\cdot7$ per phase.

Summarizing, we have :—

RECEIVING END.

Assumed Values.

Volts	Amperes	Power factor	kVA	kW
6 350	—	—	0	0
6 350	629·6	80 % lag	4 000	3 200

SENDING END.

Calculated Values.

Volts	Amperes	Power factor	kVA	kW
5 819·1	129·9	4·10 % lead	756·1	31·0
6 836·9	594·7	83·05 % lag	4 065·9	3 376·7

The regulation of the line, including transformers, is thus 1 017·8 volts, or 16·0 per cent of the voltage at the receiving end.

APPENDIX 3.

USE OF CALCULATING MACHINE.

One of the commonest operations in these calculations is the evaluation of the sum of two products of complex numbers, e.g. $AE_r + BI_r$. The separate terms may be easily multiplied out on the machine, arranging the four real terms in one column and the four j terms in another, summing each column and taking particular notice of the positive and negative signs.

To obtain the scalar value from the complex form, square each number until the machine shows the sum of the squares of the two components and extract the square root as follows (these instructions are adapted for the Monroe calculating machine but will easily be followed for another make):—

Having the number to be evolved in the lower dial, clear the upper dial and keyboard, point off the number in groups of two each way from the decimal point.

Shift the carriage so that the right-hand column of the keyboard is directly beneath the position in the upper dial corresponding to the number of whole and partial groups in the lower dial.

Beginning in the keyboard column directly beneath the right-hand figure of the first or left-hand group, set up and subtract successively 1, 3, 5, 7, 9, 11, 13, etc., until no further subtractions can be made.

Increase the number on the keyboard by 1, shift the carriage one position to the left and in the keyboard column beneath the right-hand figure of the next group set up and subtract as before 1, 3, 5, etc. In setting up 11 add the left-hand digit to the figure, if any, in the preceding column.

If no subtraction can be made in any one position do not set up the 1 but, making no change, shift the carriage another position, then set up 1 and continue as before. The root appears in the upper dial; the remainder, if any, in the lower dial.

With a little practice this will be found to be a great deal faster than the use of tables of trigonometrical functions.

When trigonometrical functions are necessary it is preferable to work from tables of natural values, using the calculating machine.

THE PERFORMANCE OF AMPLIFIERS.

By H. A. Thomas, M.Sc.

[From the National Physical Laboratory; communicated by permission of the Radio Research Board.]

(*Paper first received* 15*th August, and in final form* 5*th October*, 1925; *read before the* Wireless Section, 2*nd December*, 1925.)

Summary.

The paper describes the researches which have been carried out at the National Physical Laboratory for the Radio Research Board. A standard method of testing the amplification and input impedance of an amplifier is described, and the theory of the load introduced by the amplifier as well as by reaction is shown to agree with the observed results.

Some preliminary experiments on distortion are described, output wave-forms from audio-frequency amplifiers being analysed.

Table of Contents.

Introduction.

An amplifier consists of several valves and coupling components connected in cascade, so that the total amplification effect obtained is the product of the various amplifications obtained in the individual stages. This definition excludes cases where retroaction effects from output to input via inter-electrode capacities or coupling of any type materially affect the overall amplification. In such cases the product of stage amplification is increased or decreased by such "reaction" effect. Although the ultimate output of an amplifier is in the form of power, we may regard all stages except the last as being pure potential magnifiers.

Strictly, each stage of an amplifier should perform the same function, though not of necessity in the same way. For instance, several types of coupling might be employed between two valves used for high-frequency amplification, yet if each stage is designed to amplify high-frequency E.M.F.'s, the whole series of stages would be regarded as an amplifier.

The term, unfortunately, has been extended in practice to apply to any combination of valves used for the purpose of amplifying, note-magnifying and/or rectifying, and any combination of valves fulfilling these varied functions is commercially regarded as an amplifier. For the sake of clarity such an arrangement will be termed an "amplification system," this term being more explicit than "mixed amplifier." The term "amplifier" will be applied only to a combination of components fulfilling the purpose of pure high-frequency or low-frequency amplification. Unless otherwise stated, the terms "amplifier" or "amplification system" will include all battery and output connections, i.e. it is the complete assemblage and not merely the instrument devoid of its outside circuits.

An amplification system must be of one of the following types:—

- (*a*) High-frequency stages followed by a detector.
- (*b*) A detector followed by low-frequency stages.
- (*c*) High-frequency stages, a detector, and low-frequency stages.

In the determination of the behaviour of any given amplification system, it is found expedient to split it up into its independent sections and treat each part separately. The factor of voltage amplification for both high-frequency and low-frequency sections must be obtained at the frequencies required, and the detector law connecting input voltage and rectified output must be stated. The internal behaviour cannot be analysed if an overall input-output expression only is given.

The performance of any amplifier must be expressed in terms of three distinct properties:—

1. Its voltage amplification.
2. Its effect upon the circuit to which it is connected.
3. Its distortion of wave-form.

These three properties are intimately related to each other, but the amount of experimental work carried out has been insufficient for an attempt to be made to correlate any one property with any other. Valve noises, which in a multi-stage audio-frequency amplifier usually determine the limiting number of cascade valves, are a special property of amplifiers and will not be dealt with here. Such noises are more a matter

of valve design. The three essential characteristics are therefore treated separately at present.

A method of determining the voltage amplification of high-frequency or low-frequency amplifiers is described in detail, and the effect of the amplifier on the input circuits is analysed. With reference to the distortion produced by low-frequency amplifiers, the results of some preliminary experiments are given, but more information is needed before a complete study of distortion can be attempted. This Section is therefore very fragmentary, and is given in order to demonstrate the types of distortion met with in practice and to show the magnitude of the distortion that may be anticipated in practical cases.

Section 1. The Measurement of Voltage Amplification.

(*a*) *Practical difficulties.*—At first sight it would appear a comparatively simple matter to inject known E.M.F.'s to the input terminals of the amplifier, and measure these E.M.F.'s for a constant known output, but there are many difficulties which render such an operation exceedingly difficult.

In the first place, since the voltage amplification is critically dependent upon the filament emission and the high-tension voltage, it is desirable to adjust each valve of a cascade amplifier individually to give its optimum voltage factor. In practice, several filaments are bunched together and controlled by a coarse rheostat. It is therefore usually impossible to obtain the maximum output from any given set of triodes. Every disturbance of the original circuit, such as will be produced by the insertion of measuring instruments, will modify the characteristics and, if this insertion takes place between the input and output, the disturbance so produced may be very serious. This forms one of the major difficulties of measurement. Again, actual stage amplification is not constant for all inputs but appears to increase with weak inputs.

The output has either to be determined or kept constant, and, whatever method be adopted, the output must be measured in some way.

The determination of the amplification of the system is of value only when the E.M.F.'s and currents with which it is dealing are of the same order as those encountered in practical operation on a receiving antenna. The current in the telephones for an average type of signal is only of the order of micro-amperes, and such instruments as the Duddell reflecting thermo-galvanometer and electrostatic voltmeters can only be used for loud signals, failing completely to measure the feeble outputs required. Indirect methods such as the valve or crystal rectifier and "slide back" method give rather doubtful accuracy and always introduce not only shunting loads but large earth capacities due to the batteries forming the appendages of such auxiliary measuring circuits.

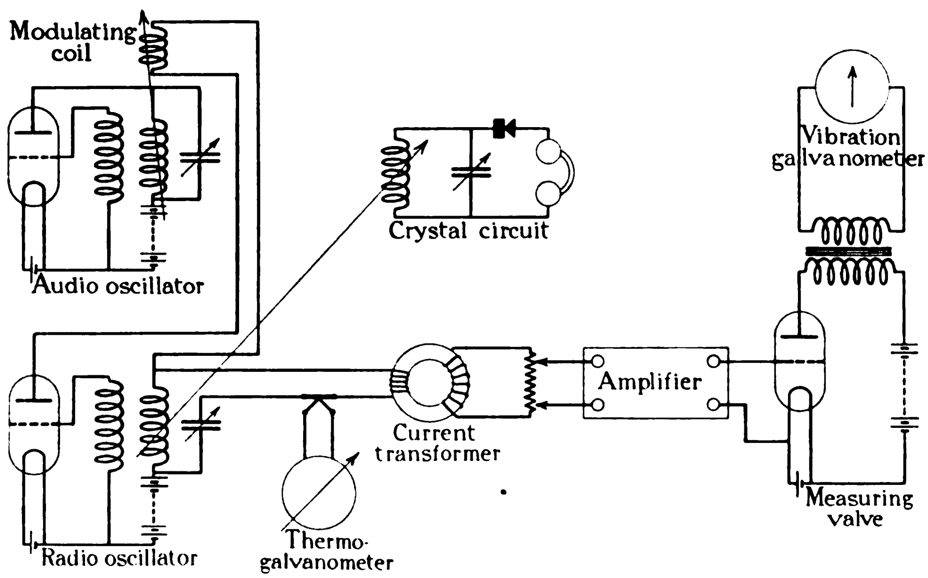

Fig. 1.

The method which has most often been adopted in this class of work consists of telephone comparisons. The difficulty of matching two sounds in intensity is well known, and limits the accuracy of such methods owing to the insensitivity of the human ear to small pressure-changes.

Again, perhaps the most serious difficulty in so matching telephone sounds lies in the fact that the pressure wave delivered to the ear is usually not sinusoidal and the type of wave given under the two balance conditions is dissimilar. It will be shown later that the output wave-forms from even the simplest type of single-stage amplifier are seriously distorted from the original sinusoidal input form, and it is quite true to state that the physiology of the human ear is so little understood that even if a balance is observed between two dissimilar waves, it is difficult to know what such a balance means.

Since such distortions of initial form take place throughout the amplifier, we are left with two methods of measurement :—

(i) The R.M.S. value of the output-current wave.
(ii) The value of the fundamental component of the complex wave.

Most measurements give (i), and it has been found only approximate to consider this value as representing the output. This determination requires also a knowledge of the wave-form to have much significance. However, if (ii) is measured, this does give the true amplification of the original wave due to the system, the harmonics produced being considered merely as the result of secondary effects which can be dealt with separately.

The methods of measuring amplification due to Jordan * and Napier-Smith † suffer by the adoption of a telephone comparison as the final limit of measurement. About 5 per cent is the limit of accuracy with a trained observer, and many observations produce nerve strain upon the operator. The latter method of determination of small mutual inductances at high audio frequencies.

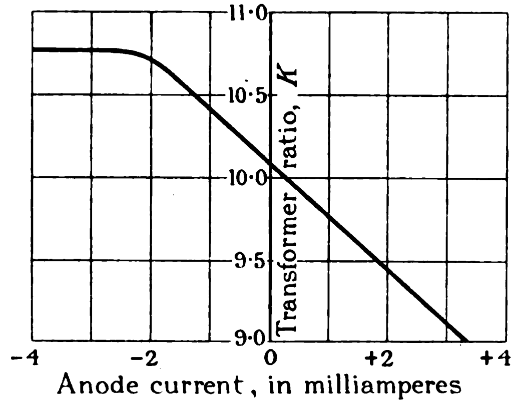

FIG. 2.

(b) *General method.*—The method adopted for measuring output employs a vibration galvanometer in con-

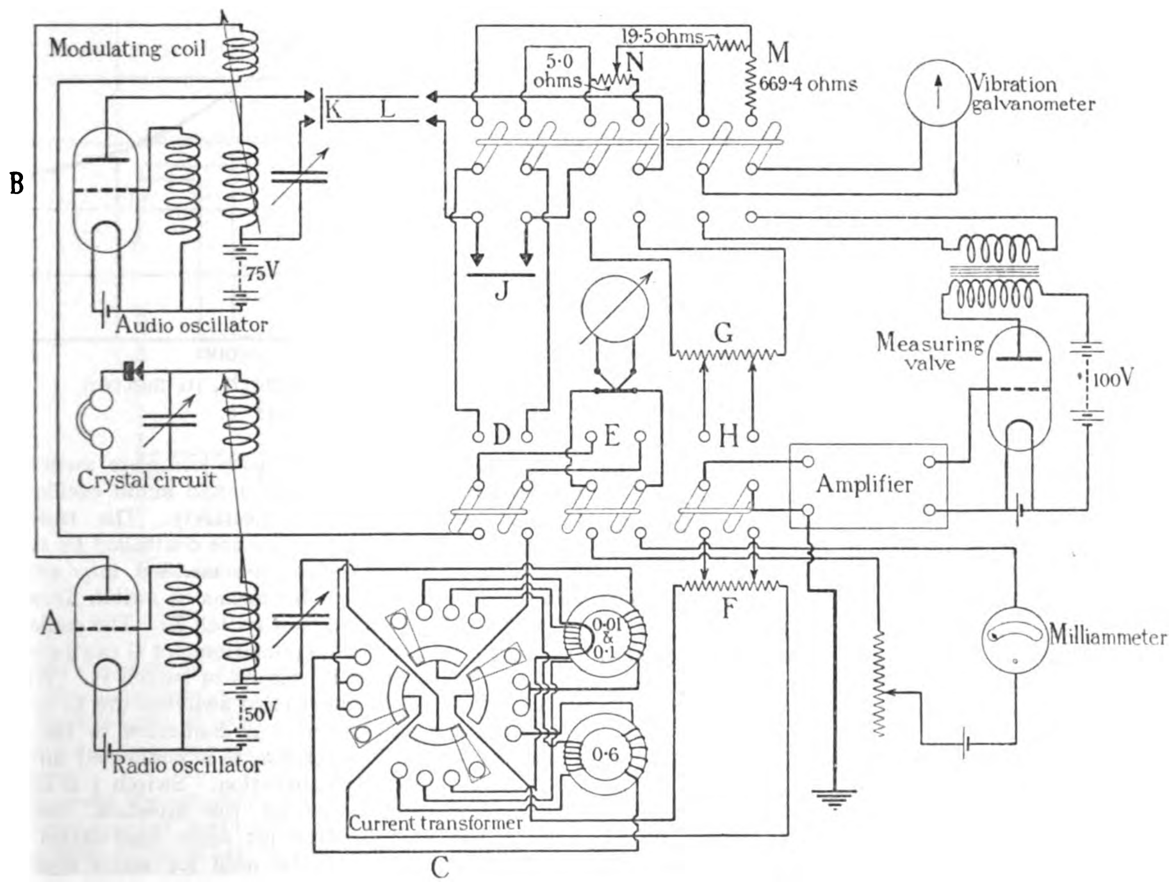

FIG. 3.

known mutuals cannot be applied to cases with very large step-up ratios, owing to the inaccuracy in the nection with a current transformer, the resistance of the secondary of the transformer, which is in series with the galvanometer, being about equal to the sum of the motional and static resistances of the galvano-

* *Proceedings of the Physical Society of London*, 1919-20, vol. 32, p. 105.
† *Ibid.*, 1919-20. vol. 32. p. 116.

meter, the former being the largest portion of the effective galvanometer resistance.

Small, known E.M.F.'s cannot easily be obtained by a series of simple potentiometers, and thus a step-down radio-frequency current transformer * was adopted in conjunction with a calibrated high-frequency resistance potentiometer across the secondary. The current in the primary is measured by means of a thermo-junction and galvanometer. A ratio of E.M.F.'s of $1/10^5$ can be obtained by this method, the accuracy of measurement falling only towards the smaller values of injected voltage.

Since for the measurement of high-frequency amplifiers the output must be of audible frequency to operate the galvanometer, the radio output is modulated by means of an aperiodic coupling coil (coupled to an audio source) in series with the anode of the oscillator valve.

The general scheme of the apparatus is shown in Fig. 1. If the rectifier characteristic is required, a definite percentage of modulation is necessary. This is

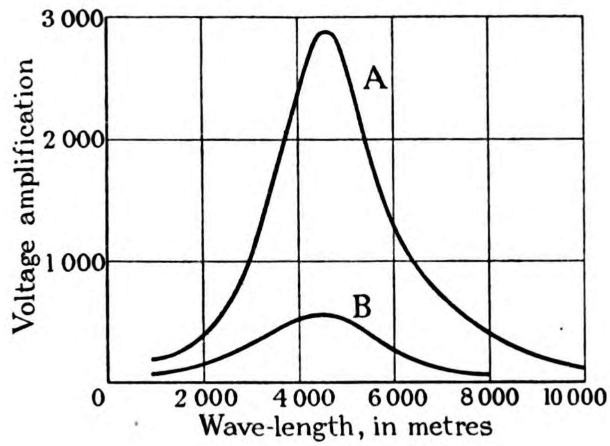

Fig. 4.

provided for by always setting the aperiodic coupling coil to give complete (or 100 per cent) modulation. The method of determining this condition is by means of a local tuned crystal receiving circuit coupled to the radio oscillator. When the source is over-modulated, a second harmonic is easily detectable in the rectified current as observed by telephones, and the point where this just vanishes gives the completely modulated condition. Tests with an electrostatic voltmeter demonstrate that this point can be determined audibly with accuracy.

The galvanometer can be calibrated directly from the audio source, and the current transformer is also calibrated for ratio, the combination forming a method of measuring the output current at the particular frequency of 1 000 which represents an average for telegraphic signals. The calibration of the transformer is dependent upon the d.c. anode current flowing through the primary, as the characteristic working point on the *B–H* curve is altered by such current. Fig. 2 gives the calibration of this transformer and shows what large changes in ratio can be expected from comparatively small polarizing anode currents.

For the determination of high-frequency voltage amplification a constant modulation is all that is required, the calibration of the galvanometer being necessary only for the absolute determination of the rectifier characteristic.

To determine the amplification factor of the audio stages, the audio source is injected directly by means of a potentiometer with a known shunt, and the output is measured as before. It was found that the current sensitivity of the vibration galvanometer varied considerably and thus a quick-switching arrangement was devised by means of which the galvanometer could be directly calibrated from the audio source in terms of a vacuo-junction deflection, which in turn could be instantly calibrated by direct current and a milliammeter. In this way, both input and output can be referred directly to a d.c. instrument, and errors due to inconstancy of calibration are eliminated.

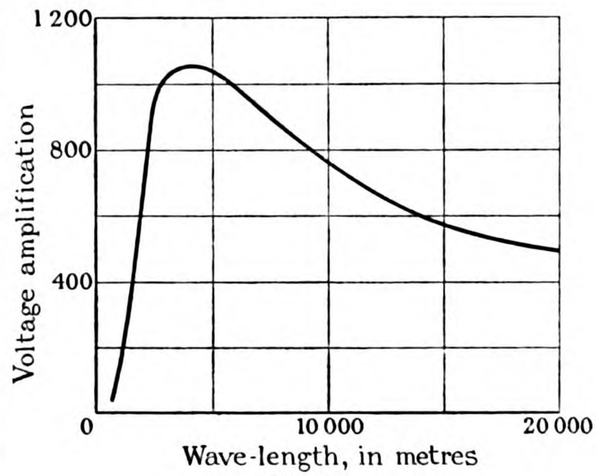

Fig. 5.

The final arrangement with complete switchgear is shown in Fig. 3. The radio and audio oscillators are shown at A and B respectively. The three high-frequency transformer ratios are controlled by switch C. The thermo-junction can be inserted into either the radio or audio source by means of switch D, and can be calibrated by means of switch E. The radio potentiometer F or the audio potentiometer G can be switched on to the amplifier by means of switch H. When the three double-pole interlocked switches are in the lower position the galvanometer is connected to the output, whereas in the top position it is connected directly to the audio source for calibration. Switch J is closed for calibration and works on the interlock. Switch K closes the audio source for radio modulation and L permits the source to be used for audio injection or galvanometer calibration. The standard shunts are shown at M, and the potentiometer N is used for calibration.

Both high-frequency and low-frequency amplifiers forming part of an amplification system can be quickly measured by this means. The only difficulty lies in the direct induction due to the source at a considerable

* D. W. Dye: "Producing Small Voltages at Radio Frequencies," *Journal I.E.E.*, 1925, vol. 63, p. 597.

distance from the amplifier under test. This difficulty was almost entirely eliminated by sheathing all the radio oscillator leads in copper tubing.

(*c*) *Discussion of results obtained.*

High-frequency amplifiers.—So far as high-frequency amplification is concerned, it seems apparent from the results obtained that the net effect of the many factors which can only be approximated in design gives very variable figures for amplification. As an example, two apparently identical 3-stage amplifiers, transformer coupled, were measured, with the results shown in Fig. 4. In curve A, the factor per stage at a wave-length of 4 700 m is considerably greater than the factor of the triode. It is apparent that, in this case, retroaction effects combine to increase the overall amplification, whereas in curve B the phasing is such as to reduce the amplification. Since such retroactive effects form an inherent property of any amplifier and are dependent upon inter-electrode capacities, stray lead capacities and leaks, it is reasonable to expect large variations between amplifiers built to similar specifications.

Fig. 5 gives the overall voltage amplification of a 6-stage resistance capacity amplifier, from which it will be noticed that below 4 000 m the shunting effect due to the self-capacity of the anode resistances seriously reduces the amplification. The more gradual fall at higher wave-lengths is attributed to the fact that the coupling condensers are not large enough at the lower frequencies.

Fig. 6 gives the amplification of a 6-valve untuned transformer-coupled amplifier with various inputs on the grid, from which it will be observed that the amplification appears to fall with increasing input.

It has been stated by several authorities that the voltage amplification falls with weak inputs, but the inputs for which this effect is claimed are of the order of a few microvolts and are smaller than any input measured here. The curve shown in Fig. 6 may therefore bend back to the origin, but no measurements have been taken to confirm this. The evidence for this effect may depend upon distortion which will seriously affect the R.M.S. value of the current and may not be a genuine reduction of amplification of the fundamental. The discrepancies arising due to a neglect of the harmonics present may be, as shown later, very serious.

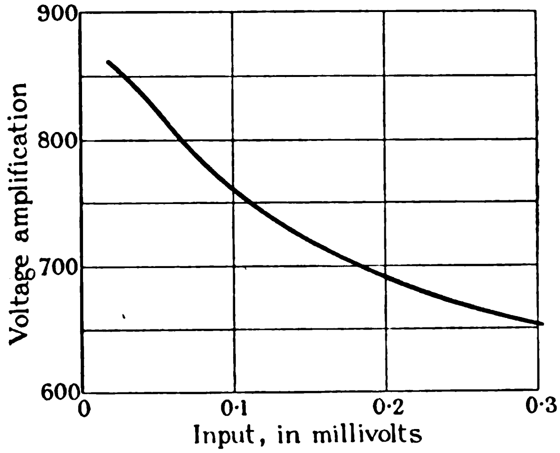

FIG. 6.

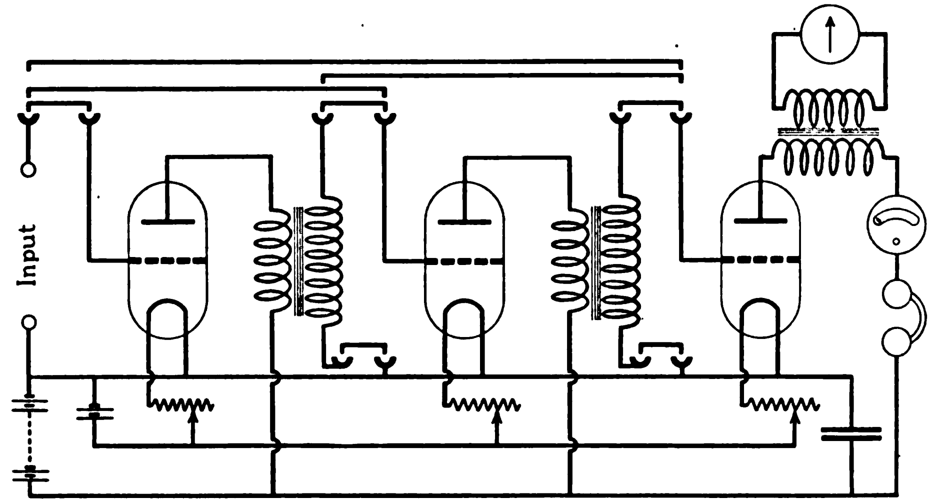

FIG. 7.

The behaviour of the detecting valve has been found in every case to depart only very slightly from the theoretical square law; in fact this law can in most instances be assumed.

Low-frequency amplifiers.—The measurement of the voltage amplification of a low-frequency amplifier presents less difficulty. The inter-electrode impedances at low frequencies are large and their shunting effects almost negligible. Induction can be entirely eliminated with care, and measurements to less than ½ of 1 per cent can be obtained.

Several standard audio amplifiers were tested at a frequency of 1 000, and it was found that the overall amplification of several cascade stages was less than the product of the individual stages. A special experimental 2-stage amplifier was built and with

this it was found that very consistent results could be obtained.

The amplifier output was measured by means of a special calibrated measuring valve as shown in Fig. 7. By means of links and mercury cups, the input could be switched on to the measuring valve, stage 1 and the measuring valve, or stage 1, stage 2 and the measuring valve. The voltage amplification of each stage was in this way compared with the overall amplification of the two stages in cascade. With definite high tension, low tension and grid bias, the amplification of stage 1 was found to be 21·9, and of stage 2, 19·65. When these two stages were coupled together, the first gave 22·2 and the second 19·2, the overall amplification thus being 426 for the two stages in cascade.

This means a gain of 1 per cent on the first stage, due to retroaction from the second and to a weaker input, and a loss of 2 per cent on the second due to the fact that the input wave-form to this valve is now no longer sinusoidal. The overall loss for the two stages is 1 per cent, the theoretical figure being 433, the product of the two initial determinations.

The Smith-Napier method of testing gave 21 for each stage and thus shows good agreement with a poorer sensitivity. The effect of the high-tension condenser of several microfarads was found to be very pronounced, the amplification falling considerably when a smaller condenser was used. This effect is probably due to the resistance of the high-tension battery.

The effect of inserting a small capacity of 100–1 000 $\mu\mu$F between the two windings of the transformer is slightly to increase the amplification, due to the increase in the electrostatic coupling between the windings. A capacity of 1 000 $\mu\mu$F increased the amplification by 5 per cent.

These tests show that it is possible to construct a 2-stage amplifier in which little loss takes place, if the components are judiciously separated. The maximum figure of 420 may be obtained, if separate high-tension batteries be used for each stage without the use of a high-tension condenser. Separate low-tension batteries produce an increase of 4 per cent in overall amplification.

SECTION 2. THE INPUT IMPEDANCE OF AN AMPLIFIER.

(*a*) *Discussion of methods of measurement.*—The effect of the amplifier upon the tuned input circuit is twofold, viz.—

(*a*) To increase or decrease its effective resistance, due to the power taken from (or delivered to) this circuit by the valve amplifier.

(*b*) To alter the tuning of the circuit due to the shunt capacity of the input circuit of the amplifier.

The amplifier may be looked upon as an impedance load across the tuned circuit. To determine this load it is necessary to find the effective change in the high-frequency resistance of the resonant circuit as well as the shift in the resonant frequency due to the amplifier.

The usual method of determining the high-frequency resistance of the tuned circuit consists of inserting a known non-inductive resistance into the circuit and determining the fall of current in that circuit, or the fall in voltage across the circuit. If the voltage across the condenser is V before insertion and V_r when a resistance R is inserted, we have

$$\frac{V}{V_r} = \frac{R_e + R}{R_e}$$

where R_e is the circuit resistance.

Very inconsistent results were obtained with this method, often of the order of 100 per cent. These errors are attributed to the fact that the mechanical shape of the tuned circuit is modified by the insertion, and the effective E.M.F. in the circuit was so varied.

It appears that with large currents and low amplification the E.M.F. can be inserted virtually at one

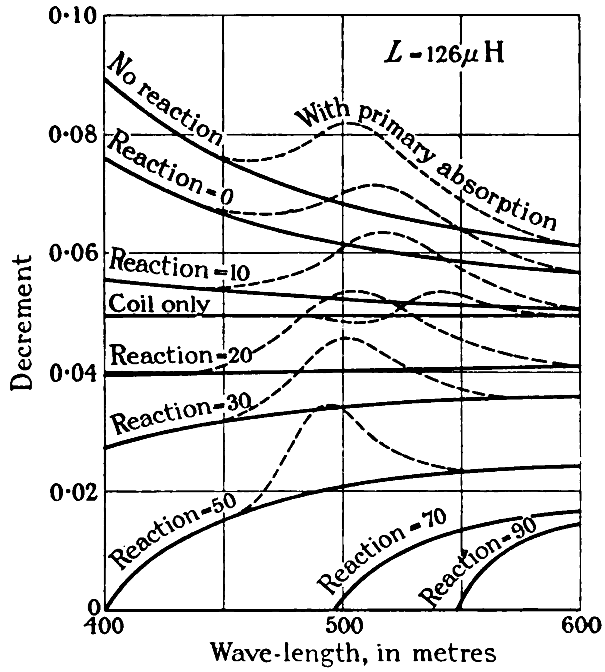

FIG. 8.—Decrement curve: stud 2.

point in the resonant circuit (as in the case of a deliberately inserted inducing coil), thus approaching the ideal theoretical conditions, but when the injected E.M.F. is very small and is picked up by a stray field in the neighbourhood of the amplifier, the injected E.M.F. will vary materially with any changes in the mechanical formation of the circuit. The "feed-back" effect due to retroaction is dependent upon the resistance of the input circuit, and any artificial change in this resistance will modify the amplifier condition.

When a 6-stage high-frequency amplifier is used, the injected E.M.F. is so small that direct pick-up induction from the oscillator is sufficient to give large outputs. In this particular case the injected E.M.F. was of the order of 1 mV to give a weak signal of about 6 μA in the output circuit, the field from a weak oscillator 15 ft. away being sufficient for this output. Such distant injection has the advantage that the tuned circuit is in no way modified by local coupled circuits.

The inserted-resistance method had therefore to be abandoned when such weak signals were being dealt with. A resonant method of determining the high-

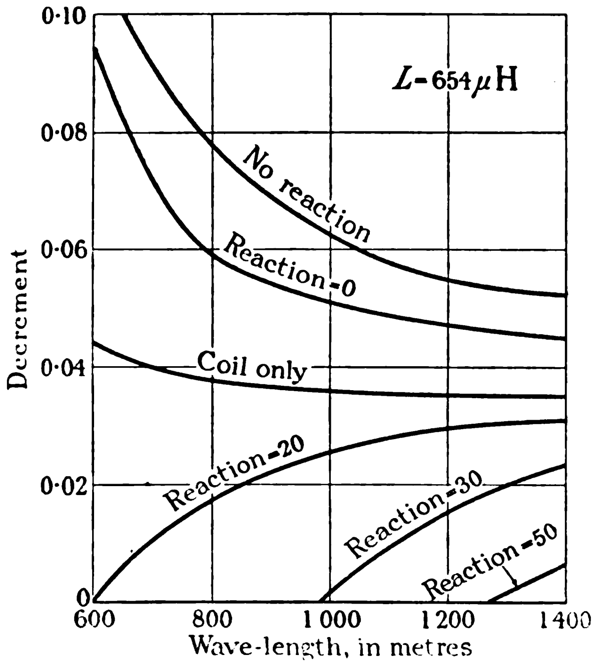

FIG. 9.—Decrement curve: stud 3.

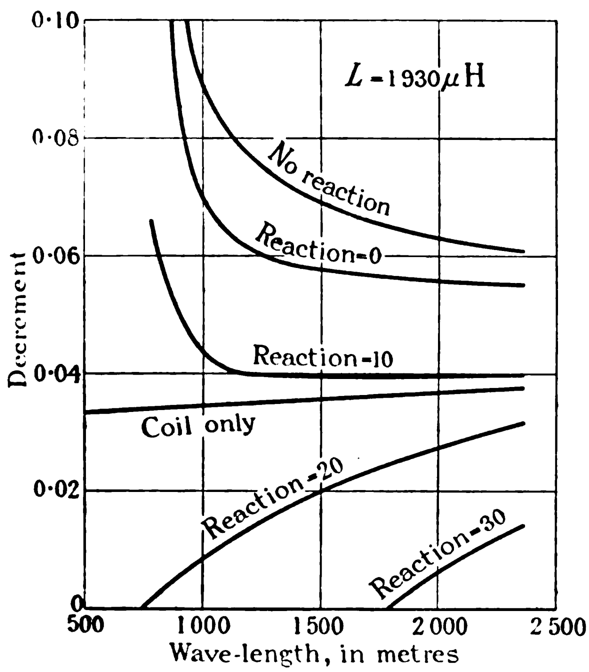

FIG. 10.—Decrement curve: stud 4.

frequency resistance had therefore to be resorted to and it was found that this method gave very excellent results.

(*b*) *The resonance method of measuring the effective resistance of an oscillatory circuit.*—If the resonance curve of a tuned circuit is obtained, the decrement of the circuit is given by either of the following formulæ :—

$$\delta = \pi \frac{C_r - C}{C} \sqrt{\frac{1}{(I_r/I)^2 - 1}} \quad . \quad . \quad . \quad (1)$$

where C_r and I_r are the values of capacity and current

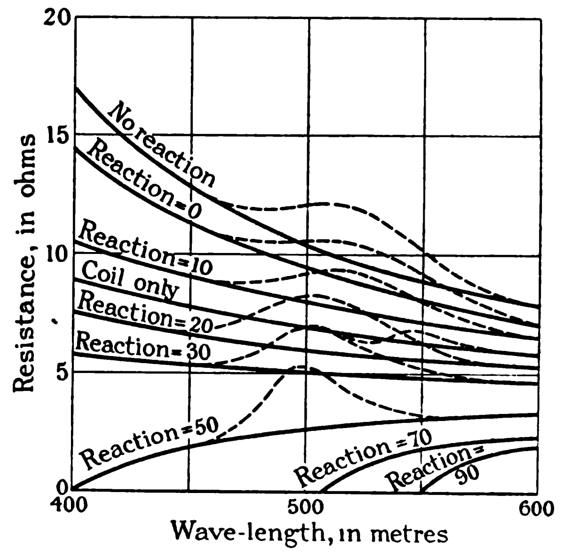

FIG. 11.—Resistance curve: stud 2.

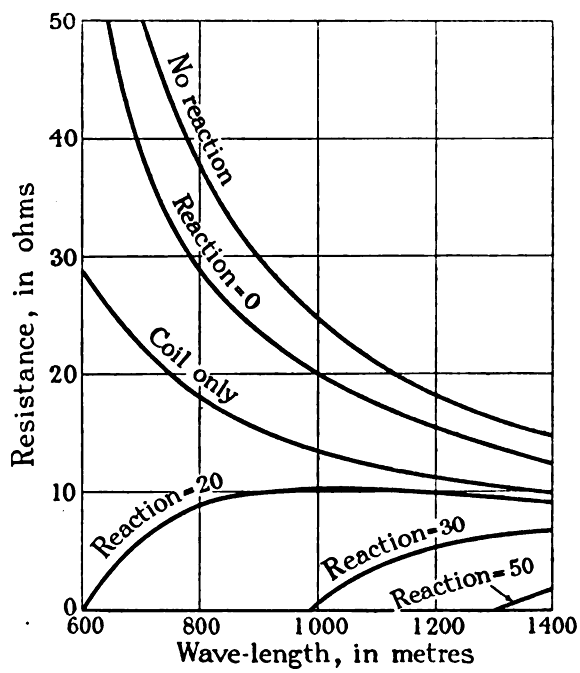

FIG. 12.—Resistance curve: stud 3.

at resonance, and C and I are values at any other point on the curve, or

$$\delta = 2\pi \frac{f - f_r}{f_r} \sqrt{\frac{1}{(I_r/I)^2 - 1}} \quad . \quad . \quad . \quad (2)$$

where f_r and f are the frequencies at resonance and any other point respectively.

If a constant-frequency source be applied to the tuned circuit, and its tuning condenser be altered, a

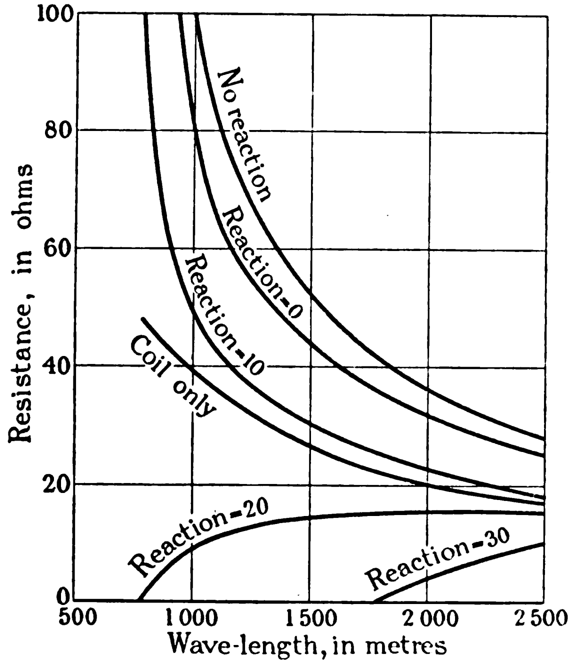

FIG. 13.—Resistance curve: stud 4.

resonance curve can be plotted. This method, however, means a calibration of the tuned circuit condenser, which forms part of the losses to be measured and also

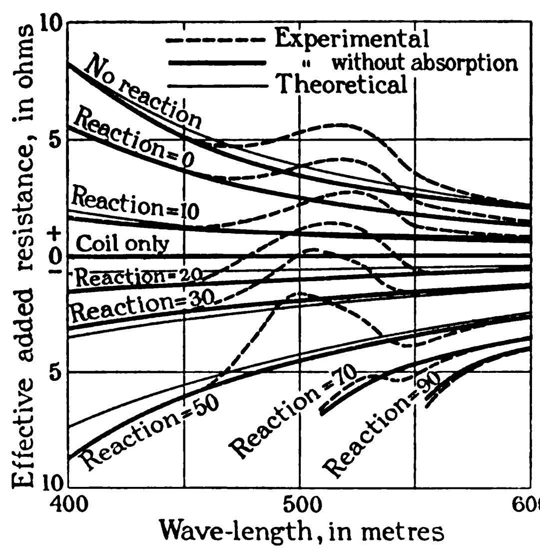

FIG. 14.—Effective added resistance due to amplifier: stud 2.

slightly disturbs the amplifier conditions. The proximity of an operator also seriously modifies the injecting field.

For these reasons, therefore, it was thought preferable to keep the test-circuit constant and to vary the input frequency. As the resonance curve is obtained with changes of less than 1 per cent in frequency, great accuracy of oscillator constancy and calibration is required.

An oscillator was therefore built with a standard condenser and a special 40 $\mu\mu$F condenser in parallel. This condenser was controlled at a distance of several feet and was calibrated to $0 \cdot 1$ $\mu\mu$F. The self-capacity of leads and coils was measured and thus the value of C_r was accurately known. The rectifier was found to follow a square-law curve to within $\frac{1}{2}$ of 1 per cent and therefore the vibration galvanometer scale was modified to a square law, thus saving much labour in calculation.

It was found possible to plot resonance curves with this apparatus quickly and with a remarkable accuracy.

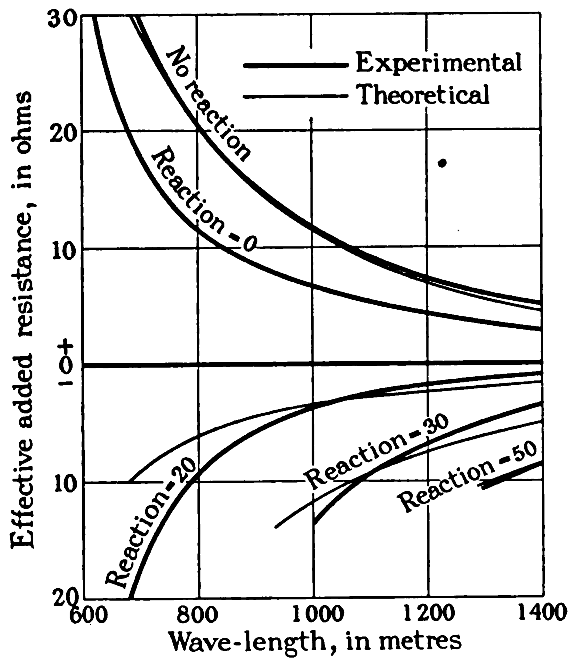

FIG. 15.—Effective added resistance due to amplifier: stud 3.

Of a total of about 300 such curves, the average error between several determinations of decrement from one curve was not greater than 1 per cent and the individual error was never greater than 5 per cent. Many interesting and important points would have been missed if a more approximate method had been adopted.

(c) *The effective load on the resonant circuit due to the amplifier.*—Decrement curves obtained for three inductance ranges are shown in Figs. 8, 9 and 10. These curves do not diverge by more than $\frac{1}{2}$ of 1 per cent from the actual points taken. In Fig. 8 a peculiar absorption is noted at a wave-length of 505 m, which occurs at all settings of reaction. This is due to the natural wave-length of a very loosely coupled aerial tuning coil which forms part of the tuning panel.

The decrement of the tuned circuit without an amplifier is also shown, this being determined by plotting resonance curves as before with a vacuo-junction in series as a recording instrument, the source being a powerful calibrated oscillator.

From these curves the resistance of the circuit was plotted, since $\delta = R/(2fL)$, where R = resistance, f = frequency, and L = inductance of tuned circuit, in henrys. These curves are shown in Figs. 11, 12 and 13. By taking the resistance of the circuit (without the amplifier) as datum and plotting the change in effective resistance with various reaction settings, the curves shown in Figs. 14, 15 and 16 are obtained. They represent the effective added positive or negative resistance produced by the amplifier for different settings of the reaction coil and at different frequencies.

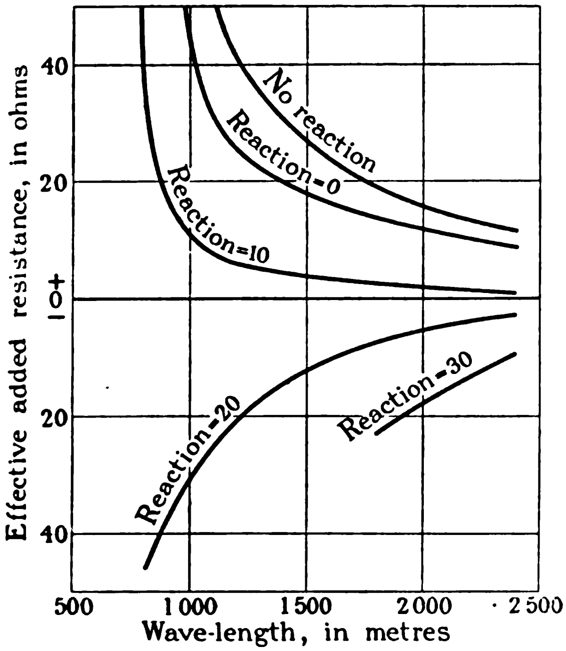

FIG. 16.—Effective added resistance due to amplifier: stud 4.

The following points are at once noticed :—

(1) The effective resistance load cannot change sign at varying frequencies.

(2) All curves appear to bear a definite mathematical relationship to each other.

(3) The departures from the mean form of the curves occurs only near to oscillation, when instability occurs.

In most of the cases given, oscillation may be obtained when the tuning condenser is very small, i.e. the curve may suddenly bend back and give a negative resistance. As this period was always unstable, it was deemed unwise to consider these conditions in the curves.

(*d*) *Theoretical treatment.*—Miller's analysis * of the effect of an amplifier on an outside circuit cannot conveniently be adapted to frequency variations. The theory has therefore been attacked from first principles, and practical expressions have been obtained for the particular cases under consideration.

The amplifier may be considered as a resistance and capacity in series acting as a load across the tuned circuit. Since the effect of this load is always positive without reaction, the resistance must also be positive. Let R_1 and C_1 be the effective resistance and capacity respectively of the amplifier input circuit. We have to find R_1 and C_1 in terms of the effective increase of resistance, ΔR, in the tuned circuit, the initial high-frequency resistance of which is R. In the vector diagram shown in Fig. 17, E_c and I_1 represent the E.M.F. and current in the branch circuit, the leading angle being ϕ_1. The main current I will equal the vectorial sum of I_1 and $I_c = E_c\omega C$. The increased E.M.F. due to the load is $I\Delta R = E_c \sin\theta$, and the resonant condition is fulfilled when $\omega LI = E_c \cos\theta$, the effect of the load thus being to alter the value of C to tune to any definite frequency.

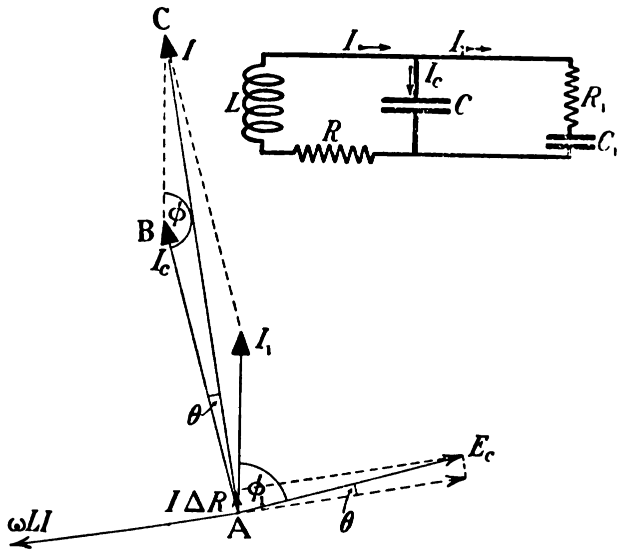

FIG. 17.

From the triangle A B C we have

$$\frac{I_1}{I} = \frac{\sin\theta}{\sin\phi} = \frac{\sin\theta}{\cos\phi_1} \text{ (since } \phi_1 = \phi - \tfrac{1}{2}\pi)$$

$$I_c = E_c\omega C = I_1 Z\omega C$$

where $Z = \sqrt{[R_1^2 + (1/\omega C_1)^2]}$ and $E_c \cos\theta = \omega LI$ at resonance,

$$E_c = \frac{\omega LI}{\cos\theta} = I_1 Z$$

$$\therefore \frac{I_1}{I} = \frac{\omega L}{Z\cos\theta} = \frac{\sin\theta}{\cos\phi_1}$$

Now $$\sin\theta = \frac{\Delta R}{\sqrt{[\Delta R^2 + (\omega L)^2]}}$$

$$\cos\theta = \frac{\omega L}{\sqrt{[\Delta R^2 + (\omega L)^2]}}$$

and $$\cos\phi_1 = \frac{R_1}{\sqrt{[R_1^2 + (1/\omega C_1)^2]}} = \frac{R_1}{Z}$$

$$\therefore \frac{\omega L}{Z} = \frac{\sin\theta\cos\theta}{\cos\phi_1} = \frac{\Delta R\omega LZ}{\{\Delta R^2 + (\omega L)^2\}R_1}$$

$$\therefore R_1\{\Delta R^2 + (\omega L)^2\} = \Delta RZ^2$$

$$\therefore \Delta R^2 R_1 - \Delta RZ^2 + R_1(\omega L)^2 = 0$$

* "Dependence of the Input Impedance of a Three-Electrode Vacuum Tube upon the Load in the Plate Circuit," *Scientific Papers of the Bureau of Standards*, No. 351.

Solving this quadratic, we get

$$\Delta R = \frac{Z^2 \pm \sqrt{[Z^4 - 4(R_1\omega L)^2]}}{2R_1}$$

$$= \frac{Z^2}{2R_1}\left[1 \pm \left\{1 - 4\left(\frac{R_1\omega L}{Z^2}\right)^2\right\}^{\frac{1}{2}}\right]$$

and, since $\left(\frac{R_1\omega L}{Z^2}\right)^2$ is small compared with unity

$$\Delta R = \frac{Z^2}{2R_1}\left[1 \pm \left\{1 - 2\left(\frac{R_1\omega L}{Z^2}\right)^2\right\}\right]$$

$$= \frac{Z^2}{2R_1} \times \frac{2(R_1\omega L)^2}{Z^4}$$

$$= \frac{R_1(\omega L)^2}{Z^2}$$

if the plus sign $\left(\text{which gives } \Delta R = \frac{Z^2}{R_1} \doteqdot 10^9\right)$ is neglected,

$$\therefore\ \Delta R = \frac{R_1(\omega L)^2}{R_1^2 + [1/(\omega C_1)]^2}$$

To find R_1 and C_1 for given values of ΔR, L and ω, we solve the two simultaneous equations given by

$$R_1^2\Delta R - R_1(\omega L)^2 + \Delta R/(\omega C_1)^2 = 0$$

In Fig. 14, taking the curve of no reaction, we find that $\Delta R = +8\cdot25$ ohms at 400 m and $+2\cdot15$ ohms at 600 m. From these values we get $R_1 = 20\ 800$ ohms, and $C_1 = 9\cdot9\ \mu\mu$F.

Substituting these values in the general expression we obtain a theoretical curve, the correlation with the experimental being within 10 per cent.

A few of the values obtained are given in Table 1.

TABLE 1.

Wave-length	ΔR (theoretical)	ΔR (experimental)
m		
400	8·25	8·25
450	5·50	5·20
500	3·90	3·50
550	2·87	2·60
600	2·15	2·15

TABLE 2.

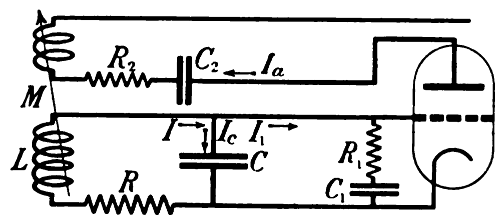
Wave-length	ΔR (theoretical)	ΔR (experimental)
m		
700	28·95	29·0
800	20·8	20·4
900	15·03	15·4
1 000	11·92	11·8
1 100	9·26	9·2
1 200	7·28	7·3
1 300	5·82	6·0
1 400	4·67	5·2

In Fig. 15 we get $R_1 = 87\ 600$ ohms and $C_1 = 9\cdot0\ \mu\mu$F. The values obtained from them and the theoretical curve are given in Table 2.

The positive load introduced by the amplifier can therefore be expressed in terms of a definite resistance and capacity, this capacity appearing to remain constant at all frequencies and values of the inductance in the resonant circuit. However, the resistance values obtained were found to differ for various values of L as follows:—

L	R_1
$\mu\mu$H	ohms
126	20 800
654	87 600
1 930	249 000

The value of R_1 increases with L and approximately follows the law $R_1 \propto L^{0\cdot8}$.



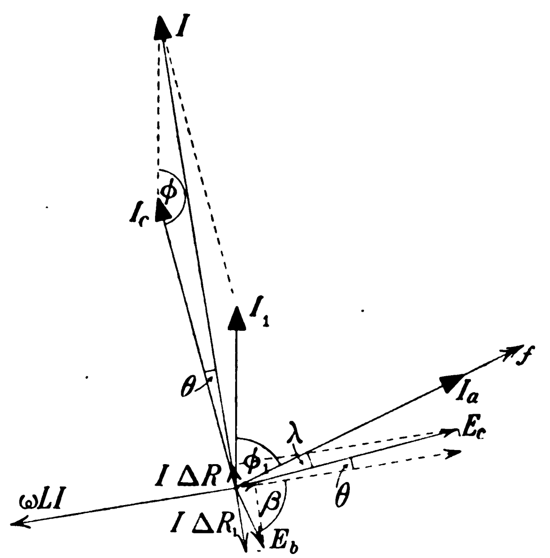


FIG. 18.

C_1 can be determined with an accuracy of about 5 per cent, but it is impossible to obtain a greater accuracy than 10 per cent for the value of R_1 with the limits of 1 per cent imposed by experimental error.

(*e*) *The theory of retroaction.*—The load imposed on the tuned circuit may be positive or negative when reaction is employed. These reaction curves possess properties similar to those of the curves of a pure load on the oscillatory system, and could be expressed in terms of a constant series capacity and resistance shunt. However, the results obtained would serve no more useful purpose than the diagrams themselves. It was thought preferable to express the reduction in the

effective load due to reaction in terms of the actual electrical constants of the anode circuit, in order to show whether the fundamental theory would explain the experimental results.

In Fig. 18 the plate-circuit impedance is represented by a capacity and resistance in series, the resistance consisting of the anode-filament resistance of the triode and the capacity (the self-capacity of the iron-cored intervalve transformer), which will probably form a lower reactance at these frequencies than the inductance.

A fourth E.M.F. vector E_b' is thus inserted into the resonant circuit which has two components, the one in phase with I producing a reduction of the effective resistance, and the other quadrature component altering the resonant conditions slightly.

The phase angle in the anode circuit is denoted by the angle λ, and the reduction of circuit resistance is given by $\Delta R_1 = (E_b/I) \sin \beta$.

The resonant condition gives from the vector diagram

$$\omega LI = \Delta RI \cot\theta + \Delta R_1 I \cot\beta$$
$$\therefore \omega L = \Delta R \cot\theta + \Delta R_1 \cot\beta$$
$$\therefore \Delta R_1 = \frac{\omega L - \Delta R \cot\theta}{\cot\beta}$$

Now $\cot\beta = \tan(\theta + \lambda)$.

Assuming $R_2 >> 1/(\omega C_2)$, and knowing from experiment that $\tan\theta \doteq \Delta R/(\omega L) << 1$, we have

$$\tan\theta = \theta \propto \Delta R/\omega = (p/\omega)\Delta R$$

and $$\tan\lambda = \lambda \propto (1/\omega) = q/\omega$$

$$\therefore \tan(\theta + \lambda) = \theta + \lambda = (p\Delta R + q)/\omega = \cot\beta$$
$$\therefore \Delta R_1 = \frac{\omega L - \Delta R\omega/(p\Delta R)}{(p\Delta R + q)/\omega}$$
$$\therefore \Delta R_1 = \frac{\omega^2[L - (1/p)]}{p\Delta R + q}$$

where p and q are constants for any given curve.

From Fig. 14 (reaction = 0) we get

$$p = 7\,930, \text{ and } q = -0{\cdot}117 \times 10^6$$

and the equation of the curve is given by

$$\Delta R_1 = \frac{0{\cdot}00607 Y^2}{0{\cdot}117 - 0{\cdot}00793\Delta R}$$

where $Y = \omega/10^6$.

This curve, when plotted against the experimental values, gives very close agreement, as shown in the figure, and demonstrates that the results can be expressed theoretically. Similarly, in Fig. 15 (reaction = 0) we get

$$p = 1\,530 \text{ and } q = -0{\cdot}1733 \times 10^6$$

and the equation of the curve is given by

$$\Delta R_1 = \frac{0{\cdot}1957 Y^2}{0{\cdot}1733 - 0{\cdot}00153}$$

where $Y = \omega/10^6$.

Since $$\tan\lambda = X_a/R_a = q/\omega$$

X_a is small compared with R_a. The anode circuit thus consists virtually of a small inductance in series with R_a, and the impedance of this circuit will now be considered to be sensibly that of R_a.

(*f*) *The determination of the mutual inductance between the reaction and primary.*—It is now necessary to determine the value of the mutual inductance at various settings of the reaction coil. A known high-frequency current at a frequency of 300 000 p.p.s. was passed through the reaction coil, and the open-circuit E.M.F. of the untuned primary was determined by means of a calibrated amplifier. The values of M and the coefficient of coupling so obtained are shown in Fig. 19. The relationship between M and the angular position of the coils is very nearly a sine relationship, as would be expected, but the law varies with different primary coils. The maximum coupling is only 32 per cent.

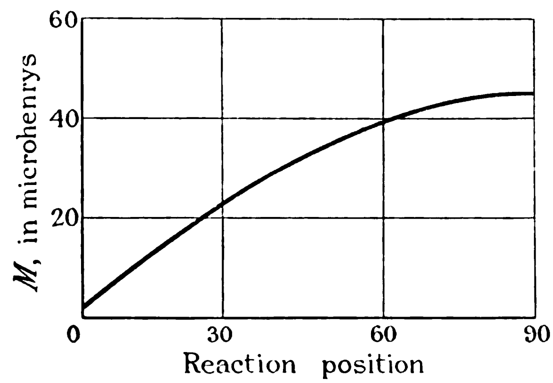

FIG. 19.—Experimental determination of M: stud 2.

From Fig. 18 we obtain the following relationships

$$E_b = \omega M I_a$$
$$I_a = uE_c/Z_a$$

where u is the voltage factor of the tube, and

$$Z_a = \sqrt{[R_2^2 + (1/\omega C_2)]^2}$$
$$\Delta R_1 I = E_b \sin\beta$$
$$= \omega M I_a \cos(\theta + \lambda)$$
$$= \frac{\omega M u E_c}{Z_a} \cos(\theta + \lambda)$$
$$= \frac{\omega M u I_1 Z}{Z_a} \cos(\theta + \lambda)$$
$$\therefore \Delta R_1 = \omega M u \frac{I_1}{I} \frac{Z}{Z_a} \cos(\theta + \lambda)$$

Now $$\frac{\sin\theta}{I_1} = \frac{\sin\phi}{I} = \frac{\cos\phi_1}{I}$$

$$\therefore \frac{I_1}{I} = \frac{\sin\theta}{\cos\phi_1}$$
$$\therefore \Delta R_1 = \frac{\omega M u Z}{Z_a} \frac{\sin\theta}{\cos\phi_1} \cos(\theta + \lambda)$$

Now $\cos(\theta + \lambda) \doteq 1$, $\cos\phi_1 = \dfrac{R_1}{Z}$ and $\tan\theta \doteq \sin\theta$

$$\therefore \Delta R_1 = \frac{\omega M u Z}{Z_a} \cdot \frac{\tan\theta}{R_1} Z$$

and
$$\tan\theta \doteqdot \frac{\Delta R}{\omega L}$$
$$\therefore \Delta R_1 = \frac{\omega M u Z \Delta R Z}{Z_a R_1 \omega L} = \frac{M u Z^2 \Delta R}{Z_a R_1 L}$$

From Fig. 14 (reaction = 10) we get $M = 6 \cdot 12\ \mu$H, where

$Z_a = 13\ 000$ ohms (determined experimentally)
$u = 4 \cdot 92$ (determined experimentally)
$Z = R_1 + j/(\omega C_1)$

where $R_1 = 20\ 800$ ohms and $C_1 = 9 \cdot 9\ \mu\mu$F
$$L = 126\ \mu\text{H}$$

The experimental determination gave 10 μH.

Assuming the ratio of changes in M given by experiment, theoretical curves for each reaction position were obtained and are shown for two values of L in Figs. 14 and 15. The agreement shows how nearly the experimental results agree with the theoretical treatment. The tailing-off of each curve when near oscillation is due to unstable amplifier conditions. The reason for the 40 per cent error between the measured and calculated values of M can be roughly explained, since in the measuring case the field is due only to the current in the mutual coil, whereas when the actual measurements were taken the mutual inductance formed part of a complex field generated at a considerable distance from the coils, and in addition the primary current would seriously modify the field form. The amplifier used consisted of a simple rectifier followed by two audio stages. The valves used were dull-emitters.

(*g*) *Summary of results.*—The amplifier may be considered as a resistance and capacity in series forming a load across the resonant system. The value of this capacity appears to be sensibly constant under all conditions, whereas the value of the resistance is dependent upon the value of the tuning inductance. The effects due to reaction can be expressed in terms of the known theoretical conditions.

Section 3. Distortion in Audio-Frequency Amplifiers.

(*a*) *Errors in measurements due to distorted waves.*—It has been shown that the output wave-form given by a 2-stage amplifier is nearly sinusoidal with very weak outputs, but if these amplification figures are extended to signals of about ½ mA (R.M.S. value) as in loud-speaker work, the voltage ratios have little value, for the wave is no longer sinusoidal.

It is generally assumed that if the valve is operated with no grid current and upon a linear part of its v_g/i_a characteristic, the output wave-form is sinusoidal. However, R.M.S. determinations of output have shown severe discrepancies, for the vibration galvanometer measures the amplification of the fundamental only, whereas the R.M.S. instrument gives a power determination including the energy in the harmonics that may be present.

It was soon noticed that the audible strength of a signal did not appear to be proportional to the R.M.S. value of current through the instrument. If harmonics were present, the same apparent sound intensity could be obtained with R.M.S. values of current but one-sixth of the current required if the wave was sinusoidal. Since the ultimate object of amplification tests is to indicate the relative strengths of the output *sound* intensity, it is necessary to establish the type of wave given by an amplifier under various conditions with a sinusoidal input.

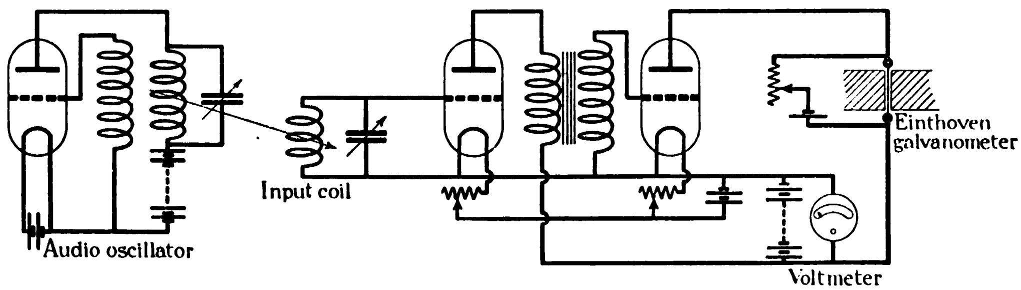

Fig. 20.

Great amplification can be obtained if reaction is pushed near its limit, but the distortion may be so great that the output signal may be of little value. For telegraphic signal reception the presence of the harmonics may be no disadvantage, but for telephonic reception it seems necessary to postulate a definite maximum departure from the sinusoidal form and to obtain the amplification under these conditions.

The 2-stage audio amplifier shown in Fig. 7 was used for the following investigations. The distortion was soon found to be so large that one transformer only was used. It may be stated that these transformers were known to be well above the average in performance.

(*b*) *Low-frequency determination of wave-form.*—At frequencies below 300 p.p.s. an Einthoven galvanometer was used as shown in Fig. 20. This galvanometer had a 14 μ copper string and the main d.c. anode current component was balanced out. Photographic results were obtained on a high-speed paper camera which ran at 6 m/sec. Records were obtained at low frequencies lying between 130 and 300 p.p.s. The output was about $0 \cdot 6$ mA (peak value) and showed a great departure from the sinusoidal form. The input was obtained from a filter circuit and when

photographed was found to be sinusoidal. The distortion is a minimum with large negative grid bias, but is still very appreciable. The decrement of the string was about 0·3 and its natural frequency about 800 p.p.s. Although it did not seriously affect the wave-forms obtained, the method could not be extended to the higher-frequency cases.

(*c*) *Higher-frequency determinations of wave-form.*—Since the amplification measurements were all performed at a frequency of 1 000 p.p.s., it was necessary to obtain a more complete series of results at that frequency. A cathode-ray oscillograph was used as the recording instrument and was connected as shown in Fig. 21. The difficulty when using this oscillograph is to obtain a large enough undistorted voltage replica of the weak anode-current changes. This, however, was effected by introducing a non-inductive resistance of 20 000 ohms into the anode circuit and suitably raising the high-

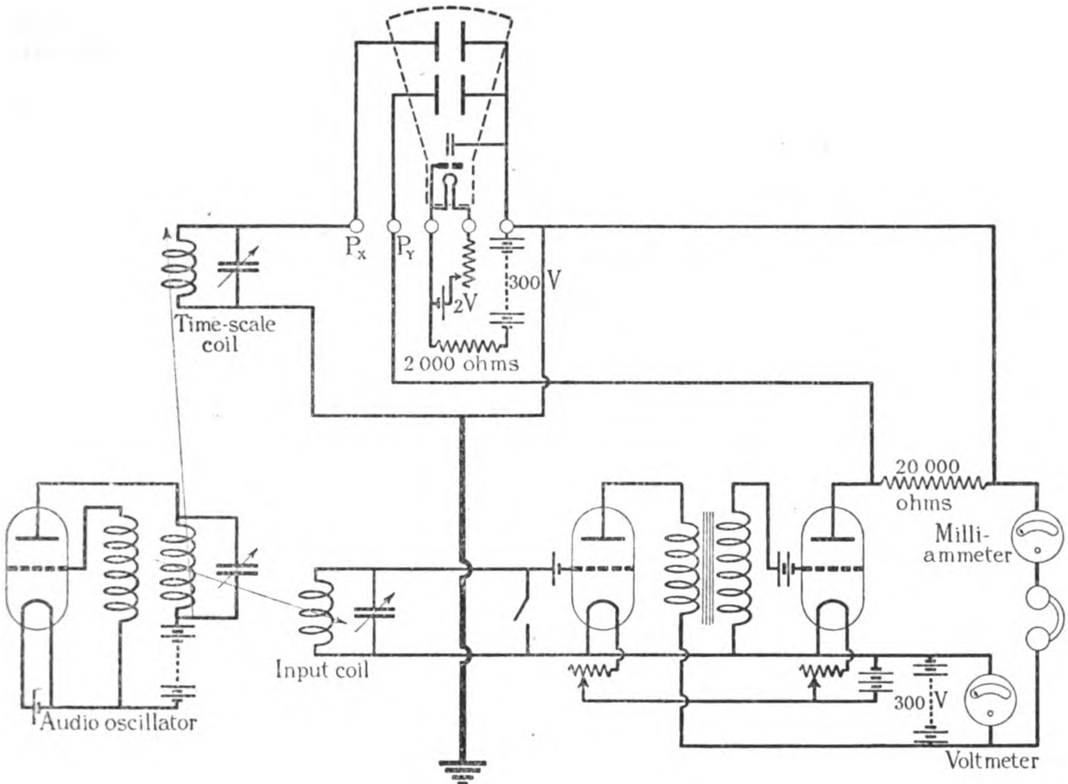

Fig. 21.

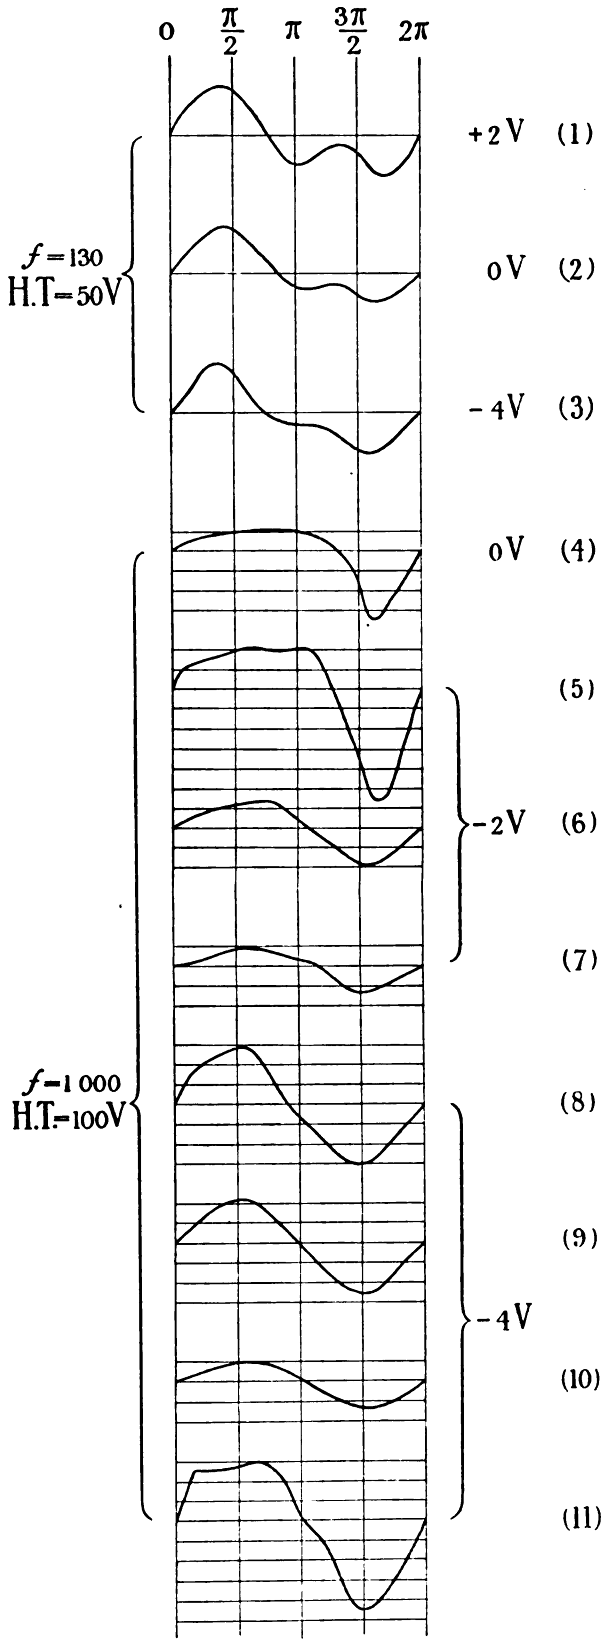

FIG. 22.

tension battery voltage until the plate voltage measured electrostatically was the same as before the insertion of the resistance. In this way a voltage of 10–15 was obtained for the overall changes, and the normal drop across the resistance was balanced out.

The input to the amplifier was the voltage across a tuned circuit very loosely coupled to the audio oscillator. The wave-form was found to be sinusoidal. The output across the anode resistance was taken to one pair of the cathode-ray tube plates, the other pair being connected across another tuned circuit loosely coupled to the same audio source. The magnitude of the input E.M.F. could be varied by adjusting the coupling of the input coil, and any convenient width of time scale can be obtained by adjusting the coupling of the time-scale coil. The sensitivity with 250 volts on the anode of the tube was about 1 mm scale deflection per volt.

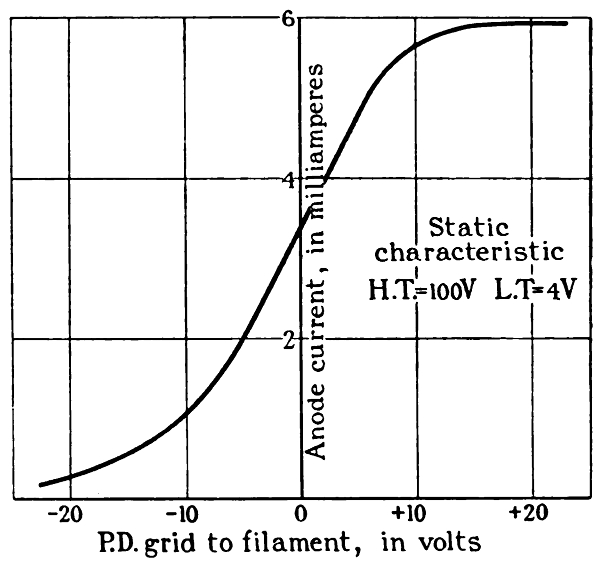

FIG. 23.

Photographic results were obtained by exposing bromide paper held against the screen. The Lissajous figures so obtained were analysed and the most important of the curves of wave-form deduced from them are shown in Fig. 22. The details of the Fourier analysis are given in Table 3.

(*d*) *Discussion of some observed cases.*—From a study of these curves it will be seen that the number and magnitude of the harmonics is considerable, and that the actual peak value may be as much as 75 per cent greater than the assumed peak value obtained from the R.M.S. value.

The grid-voltage variation is therefore in all these cases greater than would be given by a R.M.S. determination.

The output was never great enough to give a grid current in the cases with 2 or 4 volts negative bias on the grid, as seen from the static characteristic in Fig. 23. The following conclusions can be drawn from these results, remembering, however, that they must be considered only as provisional, considerably more

experimental work being necessary to confirm the general conclusions so far obtained.

(i) The effect of *increasing output* is to modify the wave-form seriously. In general, the harmonics increase in magnitude far more rapidly than the fundamental.

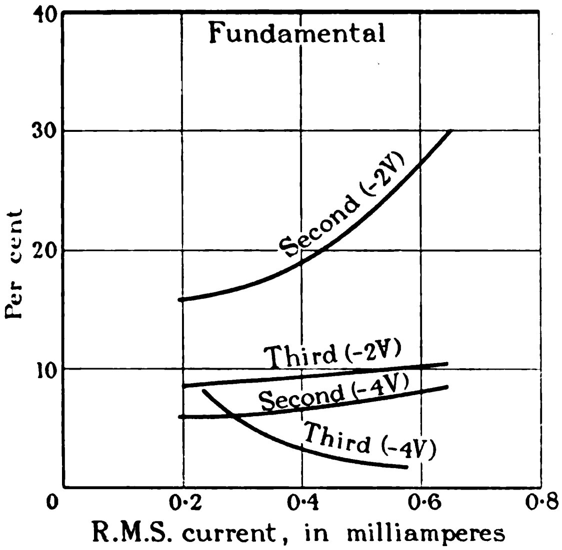

FIG. 24.—Percentage harmonics, with different grid potentials.

(ii) As the *frequency* is lowered, the distortion becomes much more serious. It is safe to say that at 150 p.p.s., the fundamental may be almost completely eclipsed by the harmonics with outputs of about 1 mA.

(iii) The effect of *negative grid bias* is to reduce the

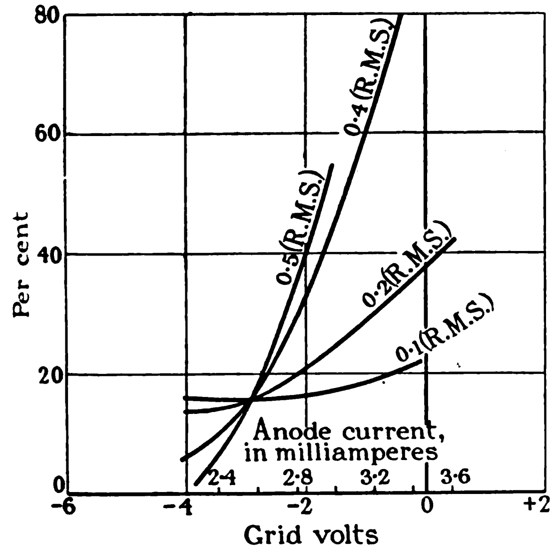

FIG. 25.—Ratio (Peak/Fundamental peak) expressed as a percentage greater than 1.

magnitude of the second and third harmonics and to introduce small harmonics of a higher order.

(iv) The *form factor* remains sensibly constant under most conditions.

(v) In curve 11 (Table 3), it will be seen that the rapid growth of the higher harmonics, the fourth, the fifth and the sixth, produces a critical distortion. This was noticed in many cases. The shape of the Lissajous figure quite appreciably changes with a very small increment of current beyond a given critical value.

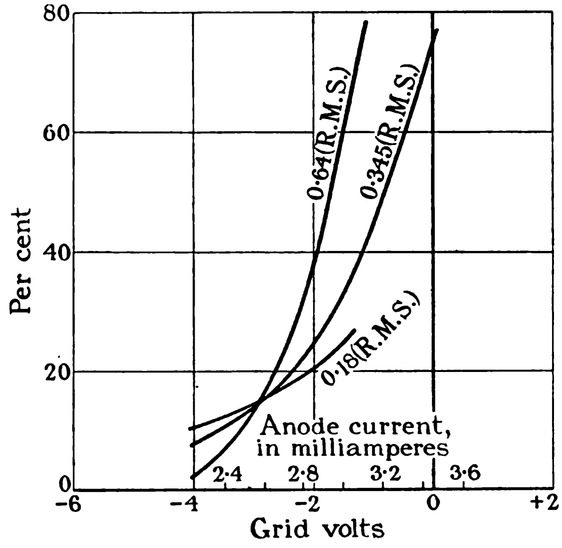

FIG. 26.—Ratio (Peak/R.M.S. peak) expressed as a percentage greater than 1.

The form factor and other ratios are seriously upset in this case, and do not fall into the final inferences with smaller outputs.

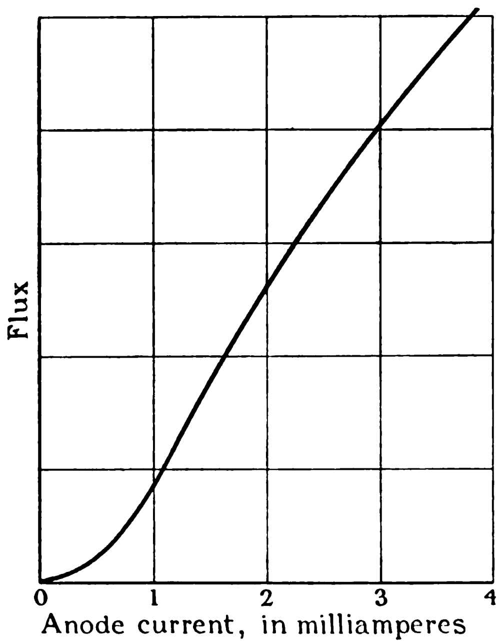

FIG. 27.

(vi) In Fig. 24 the percentages of the second and third harmonics are given for various outputs with different grid potentials. It will be seen that the rate of growth of the harmonics is much greater than that of the fundamental, thus demonstrating the rapid wave-

form change as the amplitude of the sinusoidal input is increased.

(vii) In Fig. 25 the ratio of the actual peak to the fundamental component peak is plotted for various output currents and mean grid potentials and is expressed as a percentage greater than unity. These curves all intersect at a point corresponding to a mean negative grid potential of 2·9 volts. This means that the wave-form is *not altered* by increasing the magnitude of the output, and this condition is valid only at this point.

Further, there is a *definite distortion* leading to an error of 18 per cent *which apparently cannot be removed by reducing the signal amplitude.*

(viii) The ratio of the actual peak value to the peak of a sine wave of the same R.M.S. value is plotted in Fig. 26, from which a precisely similar result is obtained at the same mean grid-voltage condition. It seems probable that this condition is one defined by the normal d.c. anode-current component in the primary of the transformer rather than any loading effect on the secondary, due to grid-filament impedance, which will be very large in all the cases we have considered.

This grid voltage corresponds to 2·6 mA primary current. In Section 1 it has been shown that the transformer voltage ratio is materially affected by the normal d.c. anode current, thus supporting this opinion. The shape of the *B–H* curve for the transformer is shown in Fig. 27, from which it will be seen that the polarizing flux brings the normal working point just at the beginning of the saturation bend. It is not easy, however, to observe any definite properties at this point.

(*e*) *Summary of results.*—It is apparent that the error between an R.M.S. determination of output and a fundamental wave determination as given by a resonant instrument may be often as much as 20 per cent. Further, the grid variation is much in excess of the theoretical as given by an R.M.S. measurement.

The general observations point to peak values giving the chief measure of output sound effect upon the human ear, and if this can be established it is clear that much modification will be necessary in our measurements of signal intensity.

These investigations were carried out for the Radio Research Board under the Department of Scientific and Industrial Research, and the author wishes to acknowledge his indebtedness to Sub-Committee D1 of the Board for their useful advice throughout the experiments.

He also wishes to acknowledge his indebtedness to Mr. J. Hollingworth, M.A., B.Sc., for his valuable co-operation in the early part of the work, to Dr. R. L. Smith-Rose, M.Sc., for much useful advice and assistance, and to his assistant, Mr. G. Warren, for his valuable aid in all the latter portion of the work.

Discussion before the Wireless Section, 2 December, 1925.

Prof. C. L. Fortescue: The use of the vibration galvanometer in the measurements described in Section 1 of the paper suggests that the amplitude of the output is much greater than that required for reception by telephone. A method of measurement more nearly equivalent to the ordinary telephone receiver will be necessary if the properties of the amplifier are to be investigated down to outputs as small as that of a just-audible signal. The observed increase of magnification with decrease of output amplitude is no doubt due, as suggested by the author, to change of wave-form, and this confirms the view that the amplitudes at which the measurements have been made are rather high. For loud-speaker amplitudes the vibration galvanometer is no doubt quite suitable if its indications are properly interpreted. The author points out in Section 2 the difficulties arising from the disturbance of the amplifier by changes of the geometric form of the input circuit, but in Section 1 he appears to have taken no precautions to avoid inserting switches in the "high tension" side of the apparatus used for applying the small voltage to the amplifier input terminals. It seems likely that capacity effects may have been appreciable and that they may explain the differences in the behaviour of amplifiers of apparently identical construction. The screening arrangements, also, appear to have been inadequate and the re-designed testing apparatus mentioned by the author in reading the paper will be a great improvement though even now it is doubtful whether they are sufficiently complete. With regard to the three conclusions on page 261, the author should make quite clear under what conditions the first of them is applicable, as there is a general belief that with many forms of amplifier the reaction on the input circuit may change sign. The theoretical treatment given by the author assumes that the valve may be regarded as equivalent to a resistance in series with a capacity—both at the grid and the anode. This assumption neglects cross-capacity effects which are almost always of fundamental importance, and the observed fact that the resistance R_1 is found to vary from 20 000 to about 290 000 ohms for different values of the inductance in the input circuit seems to be directly attributable to this omission. For the same reason the author's vector treatment of the subject cannot be regarded as even approximately complete. Unfortunately the data given in the paper are not sufficient to enable the effects of cross-capacity to be computed for the apparatus in use but it would, no doubt, be possible for the author to investigate the effects. The wave-forms of output in Section 3 bear out the results obtained by other observers when the amplitudes are as great as the 10–15 volts given in the paper. Up to 5 volts and with frequencies of 1 000 there should be no serious distortion if the valves are suitable and suitably adjusted. It would appear that a great deal more work is required in connection with this part of the paper.

Mr. L. B. Turner: The behaviour of amplifiers is a subject which calls emphatically for exact measurements. Amplifiers of various types are in very common use and give very varied overall performances; confident but nevertheless meaningless or obscure statements about amplification and distortion are met on all sides;

and it is far from easy for even serious experimentalists to analyse quantitatively the phenomena they observe qualitatively. Consequently the report of an orderly and painstaking research such as that of the present paper should be given an eager welcome. The author has elected to make output measurements throughout at an acoustic frequency and employs a vibration galvanometer registering sensibly only the amplitude of the component of fundamental frequency. His method of acoustic 100 per cent modulation of the high-frequency input is ingenious. He states on page 256 that the modulation is readily adjusted to 100 per cent by the ear's recognition of the second harmonic of the modulating frequency when 100 per cent is exceeded. I should be glad if he would give an account of the method and observations by which he was able to establish the accuracy of this easy way of adjusting to 100 per cent modulation. The modulation method is inspired presumably by the desire to make as much as possible of his plant serve for both high-frequency and low-frequency amplifiers. Whilst I appreciate the value of the vibration galvanometer for the low-frequency amplifiers, it does not appeal to me as the best method for high-frequency amplifiers. It does not in any way discriminate between the fundamental and harmonics of the high-frequency output of the amplifier, since the 1 000-cycle current passed to the galvanometer is proportional to the square of the *virtual* value of the P.D. on the rectifier.* It is said on page 257 that "the discrepancies" (in high-frequency voltage amplification) "arising due to a neglect of the harmonics present may be, as shown later, very serious"; but this method cannot investigate these discrepancies. If virtual voltage, and not the fundamental component only, is to be dealt with, a Moullin thermionic voltmeter or its equivalent, without acoustic modulator or vibration galvanometer, seems to have everything to recommend it on the score of simplicity. The author is mistaken, I think, when he says (see page 254) that the valve rectifier is objectionable on account of large earth capacities. It is precisely as unobjectionable in this respect as his own "measuring valve" (Figs. 1 and 3), whose place it would take. If it is desired to take cognizance of the fundamental alone of the high-frequency input, a possible method would be to produce the acoustic frequency for the vibration galvanometer, not by the author's acoustic oscillator, but by a high-frequency oscillator used as a heterodyne. A few practical details in the apparatus call for comment. Fig. 2 is very puzzling to me. First, it is surely a very poorly designed current transformer whose ratio is so sensitive to change in the magnetic condition of the core; and in this connection I should like to ask why (as stated on page 255) the secondary of the transformer was given a resistance equal to the total resistance of the galvanometer. Secondly, how is it that the curve relating transformation ratio with the polarizing current in the primary is not symmetrical about zero current? In Fig. 3, the high-frequency potentiometer F is shown with two sliders, the right one of which is connected to earth. Motion of this slider thus changes the earthed point in the high-frequency transformer secondary circuit. This seems to invite errors, particularly as the transformer primaries are, surprisingly, connected in the non-earthed side of the radio oscillator A. Fig. 6 shows a rapid fall of amplification with increasing input. No details of this amplifier are given; and I venture to suggest that perhaps here, as elsewhere, not enough account has been taken of grid damping. Were all the grids of this amplifier adequately negative in potential? If not, there need be no mystery as to the cause of the inconstancy of amplification. The series of curves in Figs. 8–16 are very interesting, but it is not clear to what amplifier they refer. Was it the six-stage amplifier mentioned at the end of page 258 or some simpler arrangement, as seems rather to be implied in the paragraph on the theory of retroaction? Whatever it was, one would like to have full details of the amplifier under examination. The later portions of the paper deal with distortion in low-frequency amplifiers, and are full of interest. I venture to think the sources of distortion are not so hard to find as the author seems to suggest. He says (see page 264): "It is generally assumed that if the valve is operated with no grid current and upon a linear part of its v_g/i_a characteristic, the output wave-form is sinusoidal." I hope to be able to continue to assume this, except, of course, in the presence of unsuitably designed iron-cored chokes and transformers. I think that in some at least of tests 1 to 11 of Fig. 22 there *were* grid currents, and the straight-line region of the triode characteristics was *not* adhered to. In tests 1 to 3 the output current was 0·6 mA through a negligible impedance, so that (judging from Fig. 23) the grid amplitude was some 2 V to 3 V. This would produce asymmetric grid damping in tests 1 and 2, but not in 3. But the large magnetizing current in any ordinary amplifier transformer, when used at a frequency as low as the present 130 cycles per sec., may well be credited with the distortion here. In tests 4–11, which were at 1 000 cycles per sec., the iron effect was doubtless much less. But here a resistance of 20 000 ohms was inserted in the anode circuit, across which a P.D. of 10–15 V amplitude was produced. Fig. 23, unfortunately, does not show the amplification constant of the triode; but taking it as 5, I calculate that the grid amplitude would be 6 V when that of the anode was 15 V. This would produce severe grid current in all the tests, and in some would reduce the anode current to values dangerously near the curvilinear region. In conclusion, I think we often ask too much of the last triode on our low-frequency amplifiers. The anode joined to an ordinary room loud-speaker may easily suffer an amplitude of some 50 V, and its grid (say) 8 V: it should be fed with grid and anode voltages accordingly. If the author had been more generous with his grid and anode voltages—say − 8 V and + 150 V—we should, I think, have had more shapely curves in Fig. 22.

Mr. P. W. Willans: The author in Section 1 of the paper gives under heading (*a*) a summary of the practical difficulties of measuring voltage amplification, and outlines a few general methods of making this measurement. In the course of this summary he

* See E. B. Moullin and L. B. Turner: *Journal I.E.E.*, 1922, vol. 60, p. 706.

remarks that the output of the amplifier must be either determined or kept constant, and whatever method be adopted the output must be measured in some way. I am venturing to bring forward a general method which does not depend upon such a determination of output or upon its constancy, but only on a comparison between the output and input voltages of the amplifier. The basis is a null observation, and not only is a comparison between the scalar values of the input and output voltages obtained but also the phase angle between these voltages. The method of making the observation may conveniently be considered in relation to Fig. A.

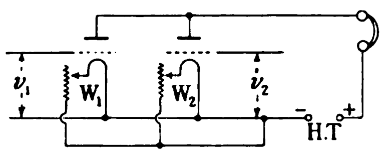

FIG. A.

Here W_1 and W_2 are two valves the filaments of which are controlled by separate rheostats. The anodes of these valves are connected in parallel through a pair of telephones and a source of high-tension current, and to the grids of the valves are applied alternating voltages v_1 and v_2, of the same frequency, from any source whatever. Then it is clear that if the valves have linear characteristics and identical mutual conductances, and if v_1 and v_2 are equal and in opposition of phase, then no sound will be heard in the telephones. In practice the valves can be so

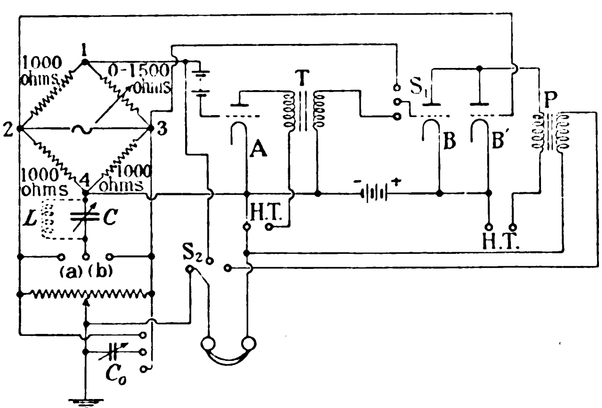

FIG. B.

adjusted that their mutual conductances are equal, by first arranging that the applied voltages are exactly equal and in opposition of phase and then adjusting the filament resistance of either W_1 or W_2 until no sound is heard in the telephones. If, then, one of these voltages, say v_1, be replaced by a voltage which varies in conformity with the adjustments of any measuring apparatus, we can bring this voltage into equality and opposition of phase with v_2 by effecting an extinction of sound in the telephones. It is worth noting that such an extinction will, in practice, only be attainable with the fundamental frequency of the applied voltages if their wave-forms are not identical. This is an advantage, since it helps to separate the effects of amplification on different frequencies. To apply a detecting device of this type to the measurement of voltage amplification it is convenient to use a bridge arrangement as illustrated in Fig. B. This shows the measurement of a single-stage transformer amplifier consisting of a valve A followed by an intervalve transformer T, and has been used mainly in the development and testing of audio-frequency intervalve transformers. The valves B and B′ correspond to the two valves shown in Fig. A, the anodes being connected in parallel and to the primary winding of a telephone transformer P. To the grid of the first valve is applied a fraction of the input voltage to a bridge which consists essentially of four arms, three of 1 000 ohms resistance and one, in general, slightly different from that value. Further, either of the ratio arms of the bridge can be shunted by a variable condenser. Referring to Fig. B, it will be seen that the condenser marked C can be connected either across the arm 2, 4, or across 3, 4; simultaneously we can throw the bridge out of balance in respect of resistance by adjustment of the arm 1, 3, which is variable from 0 to 1 500 ohms. The grid of the valve B′ is permanently connected to point 2 on the bridge, and the grid of B can be connected either to the output of the voltage amplifier or to the point 3 on the bridge, a switch S_1 being provided for this purpose. In order to effect the measurement we must first ensure that the mutual conductances of the valves B and B′ are the same. For this purpose we connect the grid of valve B to the point 3 on the bridge, balance the latter exactly, thus making the applied voltages equal and opposite, and by means of the filament resistances of these valves reduce the sound heard in the telephones to zero. Having made this adjustment we throw over the switch S_1 to the output of the voltage amplifier, and then displace the balance of the bridge until the output voltage is such that no sound is heard in the telephones. We then know that the output voltage of the transformer is equal and opposite to the voltage across the arm 2, 4 of the bridge and the input voltage to the amplifier is equal to the voltage across the diagonal 1, 4. Consequently the amplification ratio is equal and opposite to the ratio of the voltages across 2, 4, and 1, 4, respectively. These voltages can very readily be calculated. The resistance R_0 and the condenser C_0 constitute a Wagner earth connection, the arrangements being such that we can reduce to zero the voltage between the point 4 of the bridge and earth under all conditions of measurement. The resistance R_0 is of a total value of about 10 000 ohms, and the condenser C_0 consequently requires to be roughly one-tenth of the value of the capacity across the ratio arms, though it will deviate slightly from this value due to the stray capacities of batteries, etc., for which it is required to compensate. The switch S_2 enables the telephones to be connected to the bridge terminals direct, to the earth bridge, or to the output of the valves B and B′. In Fig. B an inductance L is shown as a dotted line across the condenser C. This may be used for the purposes of frequency measurement, the resonant circuit LC being shunted across either ratio arm and the condenser and variable resistance arm

being adjusted for exact balance of the bridge. It is important to note the conditions of measurement, namely, that there is, practically speaking, no impedance either in the input grid circuit or in the output anode circuit. In the first case the total impedance of the bridge is of the order of 1 000 ohms, which is negligible in comparison with the grid filament impedance of the valve at even fairly high frequencies. In the second case, since the adjustment is made in such a way that there is zero alternating current flowing through the telephone transformer windings, there is no alternating voltage on the plates of these valves and, in consequence, no retroactive effect on the amplifier. This reduces the conditions of operation to the simplest possible terms, and if it is required to observe the effect of input or output impedances these can be deliberately introduced in such a manner as not to interfere with the measuring apparatus. The calculation of the amplification ratio differs according to the position of the condenser C. Referring to Fig. C, which is a simplified diagram of the

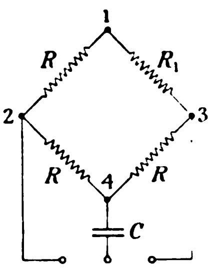

FIG. C.

bridge itself, if we denote the two positions of the switch as (a) and (b) and the voltages across 2, 4; 1, 4, etc., by v_{24}, v_{14}, etc., the formulæ can readily be established. Thus, for the switch in position (a)

$$\frac{v_{24}}{v_{14}} = \frac{R' + R}{R' - R - j\omega R^2C}.$$

And for the switch in position (b)

$$\frac{v_{24}}{v_{14}} = \frac{R' + R}{R' - \dfrac{R(1 - \omega^2R^2C^2)}{1 - \omega^4R^4C^4} + j\dfrac{\omega R^2C}{1 + \omega^2R^2C^2}}$$

ω being of course the angular frequency of the applied alternating voltage. In by far the greater number of practical cases the second formula can be simplified by neglecting $\omega^4R^4C^4$ in comparison with unity in the real term, and $\omega^2R^2C^2$ in comparison with unity in the imaginary term. We then have, as an approximate formula with the switch in position (b)

$$\frac{v_{24}}{v_{14}} = \frac{R' + R}{R' - R + \omega^2R^3C^2 + j\omega R^2C}$$

This method of measurement has been employed mainly on the investigation of audio-frequency intervalve transformers, where it has given results in excellent agreement with theory. I believe that work on multistage amplifiers has also been carried out on the same lines by other investigators, but I am not in possession of any results obtained. The advantages which I suggest are obtainable from the use of a general method of this type in measuring voltage amplification are threefold. First, in a number of cases it is possible to obtain more information regarding the performance of the amplifier under test if the vector ratio of output to input voltage is measured. This has certainly proved to be the case in respect of intervalve transformer work. Secondly, we are enabled to carry out measurements at very small output voltages, as, for example, ¼ volt or less at any frequency, without the use of calibrated apparatus. Lastly, the use by this method of a phase-splitting device as input makes it possible for a correction to be applied for the stray E.M.F. picked up by the amplifier, and this reduces the necessity for an elaborately screened source. In this last connection, referring again to Fig. B, we may disconnect the valve B′ in any manner and then reduce the output of the amplifier to zero by adjusting the bridge (with valve B connected to the amplifier) until no sound is heard in the telephones. If there is no stray E.M.F. picked up by the amplifier, the bridge will be exactly balanced under these conditions; if such an E.M.F. exists, a counter E.M.F. will be required at the input end of the amplifier and the bridge will then be unbalanced. We may then make a measurement of amplification as previously described and the input E.M.F. is reckoned as the vector difference of the *apparent* input E.M.F.'s in the two cases (the phase of the bridge E.M.F. v_{23} being counted as the same for both observations). The amplification ratio will then be corrected for the stray pick-up of the amplifier. The only condition for the success of this method is that v_{23} must be the same for the two observations, and this is substantially true in the case of measurements on powerful amplifiers, inasmuch as the bridge impedance varies only slightly for a small displacement of the balance.

Mr. J. Hollingworth: Having been associated with this work since its inception I do not propose to put forward any criticism of it, but rather to state briefly some of the early history of the investigation which occurred before, or very soon after, the author came to the laboratory. In this way, I think, the perspective of the whole can be more clearly seen. The matter arose out of a discussion in committee on two points. The first was that, whilst a great deal of mathematical work had been done on the subject of amplifiers, it had not in general been followed up by a consistent quantitative examination of any actual piece of apparatus in order to see whether the assumptions necessarily made during the mathematical work were justified in actual fact, and what values should be given to the actual constants which arose. Secondly, it was hoped to see what prospects there were for devising anything in the nature of routine tests for amplifiers in general, which would satisfy the usual conditions for such tests; namely that they should be capable of reasonably accurate repetition and at the same time should give a result really representing the behaviour of the amplifier under working conditions. The present paper is the commencement of an answer to these questions. With regard to the technical aspect, the vibration galvanometer was decided upon after considerable discussion in committee as offering

on the whole, in spite of its obvious limitations, the best method of attack. The other principal feature, the separation of the test into two parts, first the amplification of the instrument alone, and then the consideration of the effect upon its associated circuits, was derived from the work then being done upon signal-strength measuring apparatus, which had brought home very strongly the vital importance of the latter factor. This separation has been described as somewhat artificial, and doubts have been expressed as to its validity when applied to the complete apparatus; but both the results in this paper and those obtained by using the same principle in the signal-measuring apparatus during the past two years, seem to have answered this question satisfactorily. It can also be defended on theoretical grounds, but space does not permit of that. The only reservation is that there must be no stray inductive effects from the outside circuits to the intermediate circuits of the amplifier; if this occurs no real test is of course possible, as all results would be dependent on the chance arrangement of the outside circuits. Actually this has involved extremely elaborate screening, especially when an amplifier of five or six stages is under test, in spite of the fact that with this method it is no longer necessary to induce an accurately known E.M.F. into an oscillating circuit, for which the precautions would be even more severe. Considering the results obtained, the author has shown definitely, I think, that, if sufficient precautions are taken, results can be repeated to a degree of accuracy not often reached previously in this type of work; but that the precautions involved are very severe, and such small practical factors as a change of valves may have a considerable effect. He has also shown that the amplifying power, subject to these precautions, can be stated mathematically; but that it invariably involves reference to the associated circuits right back to the receiving aerial or coil. Again the results can only be expressed in the form of a vector impedance if they are to give numerical results in any way consistent with actual performance, so that it seems to follow that the results of any tests on an amplifier involving radio frequency can only be expressed in an elaborate mathematical form; and that any simplification of the mathematics would inevitably lead to results so different from those actually obtainable by experiment as to have very little value for purposes of classification. The use of the crystal circuit referred to in the paper for the determination of 100 per cent modulation is based on the following idea. Tests on the radio-frequency oscillator used showed that the curve between the high-tension voltage and radio-frequency current was, within the limits employed, a straight line which did not pass through the origin but cut off almost abruptly at a critical positive value of high-tension voltage. Consequently, if an audio-frequency E.M.F. were superimposed on the direct-current and so adjusted that the d.c. voltage exceeded the peak value of the audio-frequency voltage by this critical value, complete modulation should be obtained. At first all these voltages were measured directly in every case, but as this became very laborious when varying intensities were required, the crystal method was tried and was found successful. It is based on the idea that if the audio-frequency E.M.F. is too great, so that during part of the cycle the resultant E.M.F. becomes less than the critical value referred to above, the radio-frequency current ceases abruptly, and consequently the rectified wave-form will at once contain a second harmonic. Tests as described above and also with a cathode-ray oscillograph have shown that the accuracy is about 5 per cent, but it should be noted that the E.M.F.'s should be adjusted to the correct order before the crystal is used, as extreme forcing may bring in this harmonic again due to entirely different causes.

Major A. G. Lee: The chief point upon which I propose to touch is the measurement of the decrement of the input circuit when retroaction is present in the amplifier, the results of which are described in Figs. 8 to 16. The method adopted by the author was to use an input of constant amplitude, the frequency of which could be varied, and to plot the response in the input circuit of the amplifier in the form of a resonance curve. The response at the peak is assumed to be inversely proportional to the effective resistance of the circuit, and the response at any other portion of the curve is dependent upon the effective impedance of the circuit at the frequency of the point of the curve. From these details Equation (2), giving the decrement, is derived. Now, in a simple circuit without retroaction, the variation of impedance with frequency is given accurately by the expression $Z = \sqrt{\{R^2 + [\omega L - (1/\omega C)]^2\}}$. When retroaction is present, however, the effect of retroaction is to make both the resistance and reactance of the circuit a less simple function of the frequency. For example, the author mentions at the commencement of Section (2) that the effect of an amplifier upon the input circuit is to alter the tuning of the circuit. The subject has been dealt with in great detail by Bennett and Peters,* who show for a case somewhat similar to that of the author that both the resistance and reactance of a retroacted circuit are somewhat complicated functions of the frequency. It would seem, therefore, that the simple expression for the decrement in Equation (2) would not give the decrement accurately. A further point in connection with these measurements is that a strong input oscillator was used in order to get thermocouple readings in the input circuit. A question which arises in this case is whether the retroaction conditions of the amplifier were disturbed by this strong input, and whether the retroaction would have been the same with weak inputs. With strong inputs, for example, there is a danger of grid currents being produced at various points in the amplifier chain, and this would result in a reduction of the retroaction. The following are some minor points in the paper to which I should like to call attention. In Section 3 (*a*), paragraph 3, the statement is made that "the same apparent sound intensity could be obtained with R.M.S. values of current." I do not find this clear, and perhaps the author could amplify the statement. In the same Section, which deals with *audio*-frequency amplifiers, paragraph 4 refers to reaction being pushed near its limit, but, so far as I am aware, retroaction is not intentionally used in audio-frequency amplifiers.

* "Resistance Neutralization," *Journal of the American Institute of Electrical Engineers*, 1922, vol. 41, p. 234.

Lieut.-Col. K. E. Edgeworth: The point in the paper that particularly interested me was the question of distortion in audio-frequency amplifiers. Some time ago I was trying to compare the input and output of a 2-stage amplifier, and I found that the musical note was so altered in character that a reasonably accurate comparison was out of the question. I formed the opinion that the distortion due to the production of harmonics was at least as important as the distortion due to unequal amplification. Only small currents were used and valve distortion was probably absent. When a valve is worked in such a manner that the grid is positive during a portion of the oscillation, there is a large variation in the input impedance of the valve, and the consequences of this change of impedance are increased by the use of transformers with a high transformer ratio. This effect has already been referred to by Mr. Turner. I believe that it is fairly well understood, and that it is generally accepted that the correct remedy is to employ a valve with large emission worked under suitable conditions. On the other hand there appears to be very little definite knowledge as to the distortion produced by the iron core of the transformer, and the best method of dealing with the trouble is by no means obvious. It would appear that several of the curves in Fig. 22 were taken under conditions which must involve distortion due to the valve as well as distortion due to the transformer, and it is difficult to separate the two effects. I suggest that research in the immediate future should be devoted to the investigation of the distortion produced by the transformer, this being the problem about which least is known. Experiments might be carried out with valves of high emission worked under such conditions that valve distortion is inappreciable. Such an arrangement would not only reduce the complexity of the effects to be interpreted but would enable larger currents to be used and would facilitate the question of measurement. There appears to be a tendency to assume that uniformity of amplification is the only condition which a transformer has to fulfil, whereas in fact transformers which give very uniform amplification may cause excessive distortion owing to a large production of harmonics. The best transformer is probably one which provides a compromise between the two conflicting sets of requirements. I feel very strongly that further knowledge in regard to transformer distortion would lead to a definite improvement in the reproduction of speech by audio-frequency amplifiers.

Mr. P. K. Turner: According to the paper very inconsistent results were obtained with the ordinary resistance-variation method of trying to find the input impedance of a valve, and these inconsistent results were ascribed largely to the fact that this method altered the geometry of the circuit; but I do not quite understand why it is that the substitution, say, of an inch or two of 47 S.W.G. Eureka wire in the exact location of an inch or two of 40 S.W.G. copper wire, should make a sufficiently important alteration in the circuit. It is standard practice, of course, to use exactly similar links, merely substituting Eureka wire for copper wire. Another difficulty is the fact that obviously the amplification of all high-frequency amplifiers is so greatly governed by retroaction effects. Twice in the paper the author brings out the point that the amplification on the high-frequency side appears to diminish as the input increases. A tendency towards a constant output has been found by an American writer. The statement on page 261 as to the effective resistance load not changing its sign with varying frequencies has already been mentioned. I take it that that refers purely and simply to a resistance-coupled amplifier. Of course it is generally recognized now that in all cases where some sort of tuned coupling is being used between valves that theory no longer holds good at all, and that whenever the anode circuit becomes reactive in the positive sense there is a tendency towards regeneration which may eventually lead to oscillation. Another point which has already been admirably dealt with is that, with the large distortion shown in experiments on audio-frequency amplification, the author has hardly been fair to his own circuit. Noting the characteristics shown in Fig. 23 at 100 volts, and comparing them with the grid inputs and R.M.S. currents produced in Fig. 22 (though the grid characteristic of that valve is on rather a small scale), it appeared to me obvious that the larger input could not be dealt with even by working the valve down on the lower portion of its curve by increasing the grid bias. The saturation current of this valve is of the order of 6 mA, and for swings of the amount given, as far as I can make out from rough measurements from the curves and Table 3, one would need a saturation current of 12 mA and a considerably lengthened curve before one could hope to get distortionless amplification.

(*Communicated*): Since the date of the meeting I have looked further into the matter of measuring input impedance and find some interesting points: (1) If the effect of reaction can be represented as simply a change in the input resistance of the first valve, without the introduction of a reaction E.M.F. into the tuned input circuit, then there is no difficulty. (2) If the effect of reaction can be represented by an E.M.F. (a function of the input voltage), then *if* this E.M.F. is in phase with the input E.M.F. the resistance-variation method may be modified to function, but the reaction variation method will not be satisfactory. If, in addition, the reaction E.M.F. is proportional to the input E.M.F., the ordinary resistance-variation method will suffice. (3) If the reaction E.M.F. is *not* in phase with the input E.M.F., then all the usual methods fail. The analysis on which these rather sweeping statements are made is quite simple and is merely omitted to save space.

Dr. R. L. Smith-Rose: I should like to take this opportunity of justifying the attitude which the National Physical Laboratory has had to adopt in regard to the testing of commercial wireless receiving sets. From time to time we are asked to carry out tests not only of amplifiers of high or low frequency, but also of complete receiving sets. We are requested to give some sort of certificate of merit of performance of the instrument. I think that the present paper, and also the discussion thereon, has emphasized the great difficulties there are in the way of obtaining consistent results in dealing with the amplifier alone, without adding receiving circuits to the front end of it, as would be the case in the complete receiving set.

The National Physical Laboratory has a reputation to maintain, and in the absence of any consistent method of measuring the various factors which it is necessary to measure in the receiver, we have had to confess that we do not know how to test these receivers so as to give some satisfactory certificate of merit of performance of the instrument. The paper shows, however, that an investigation has been commenced with a view partly, at any rate, to arriving at some satisfactory method of testing a receiving set. In view of Prof. Fortescue's remarks I feel that some explanation is necessary in regard to the screening that has been adopted recently, more particularly since I have been partly responsible for the screening methods adopted. I showed some time ago that in order to get complete screening of a radio-frequency field it was necessary to use tin-plate, and to solder up all joints round about the lid of the box in which the instrument to be screened was located. As that was, of course, very impracticable, methods of partial screening have been adopted, and a way has been discovered of fitting on lids to make adequate contact round the side. In continuing this work Mr. Barfield showed that wire netting gives moderately good screening for many purposes, provided care is taken to use netting of a fairly small mesh, and also to bond over all the joints. He also showed that the field inside a 1 in. mesh wire netting screen could be reduced to something like 4 per cent of what it is outside at wave-lengths of from 500 to 7 000 metres. In discussing what we should do in regard to putting these amplifiers in screens, we considered first of all the question of making big tin boxes, i.e. boxes large enough to crawl about inside. But in view of the fact that the radio oscillator and all leads therefrom are already screened with tin-plate, it was considered that if the stray field were reduced to about 4 per cent of its original value, that would eliminate any error due to direct induction from the oscillator. I believe that the author's recent measurements on that particular point have justified the adoption of a whole-room screen of wire netting in place of a small-space screen of tin-plate. I was very interested in Mr. Willans's method of testing low-frequency amplifiers and hope to study that in more detail later. The ideal method of testing low-frequency amplifiers should, I think, be one in which telephone receivers could be dispensed with. It is very difficult to make good telephone measurements at and below 250 cycles per second, yet, as we all know, the characteristics of the amplifier are required at frequencies down to something like 50 cycles per second.

Mr. R. C. Clinker (*communicated*): In connection with the paper, and also with Mr. Willans's contribution to the discussion, it may be of interest to describe a method of measurement due to Mr. C. G. Garton and used in the laboratory of the British Thomson-Houston Co., Ltd. This method can be applied to the determination of the amplification ratio of a low-frequency amplifier of any usual number of stages. It is used regularly for obtaining the frequency/ratio curves of low-frequency transformers, and has proved simple and accurate. In Fig. D (from which some items are omitted for clearness), T is the transformer under test. Its characteristic is to be determined when working with valves V_1 and V_2. The principle employed is to balance the voltage output from the secondary S against the drop across a known resistance R_2 which is placed in series with R_1 and carries a current measured by A. As the secondary voltage is out of phase with the drop across R_2, a mutual inductance M is inserted to provide a quadrature component and give a balance. Valve V_2 has its grid negatively biased, and serves as amplifier for headphones, H. A known audio-frequency voltage from source G is applied to the grid of V_1 by the drop across R_1. When a balance is obtained, the total amplification of one stage, consisting of valve V_1 and transformer T, is equal to $[(R_1 + R_2)^2 + M^2]/R_1$, and the tangent of the phase angle is $pM/(R_1 + R_2)$, where $p = 2\pi f$. For low frequencies a vibration galvanometer may be substituted for H, and a condenser shunted across R_1 for M. Section 3 of the paper shows some distortion effects obtained with the particular valve

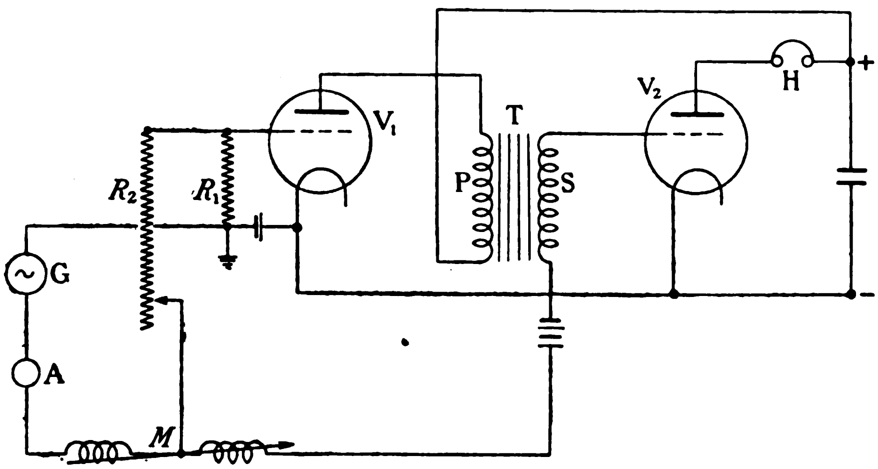

FIG. D.—Method of measurement of low-frequency amplification.

and transformer used, but although a curve is plotted in Fig. 23 no indication of the value of anode impedance of the valve is given. It would seem, however, that as distortion increased rapidly with the lowering of the frequency, the impedance of the valve must have been high in comparison with that of the transformer primary.

Mr. K. Sreenivasan (*communicated*): After everything is taken into consideration, the galvanometer method of measurement is decidedly superior to the telephone method from considerations of accuracy and sensitivity. Perhaps some simplification in the circuit and the apparatus used could be secured by either of the two following modifications: (*a*) Instead of using an audio oscillator for modulation purposes, a rotating contact breaker (or commutator) inserted in the oscillating circuit of the radio-frequency oscillator and driven at any required speed by a motor would do away with any necessity for the crystal circuit in order to detect the presence of harmonics. In this case an ordinary d.c. microammeter or galvanometer of the required sensitiveness will replace the vibration galvanometer. As the author remarks, a d.c. instrument keeps its calibration far steadier than a vibration galvanometer. (*b*) If an audio oscillator is indispensable, it would be a good plan to adopt a tuning-fork generator with the necessary arrangements in the output circuit. In this case a small 6-volt battery is all that is necessary. A tuning-fork generator not only works far more steadily than a tube oscillator, but is also remarkably free from harmonics, which are generally sources of trouble. The output will then be of constant frequency of great steadiness. The curve for the voltage amplification of a six-stage capacity-resistance amplifier is obviously obtained without any reaction introduced in the circuit. The average maximum amplification per stage comes to about 3·2, which is rather low. In view of the difficulties in working a resistance-capacity amplifier of more than four stages without self-oscillation, it appears to me that any steadying arrangements in this connection will reduce, more or less seriously, the individual, and so the overall, voltage amplification. It would be of some interest to know the amplification of a 2-, 3- and 4-stage resistance-capacity amplifier in order to have some idea of the fall in amplification per stage with an increase in the number of stages. Another aspect of resistance-capacity amplifiers about which one wishes to have more information is their behaviour with capacity reaction, say, between the grid of the first tube and the anode of the second, third or fourth tube. In a case like this it will naturally be difficult to reconcile experimental results with theoretically obtained values. The author's remarks in Section 2 regarding the resistance-variation method are very interesting. Experiments conducted in the Radio Laboratory at the Indian Institute of Science, Bangalore, with this method have given reasonably consistent results, variations from 5 per cent to 20 per cent being common, and 100 per cent extremely rare. These extreme variations were attributed to errors in reading the instruments. The resonance method, though very accurate, seems to be cumbersome and rather elaborate. I do not understand what "Reaction = 20," "Reaction = 30," etc., mean. Do these stand for any definite quantities or do they merely indicate the dial readings of the reaction coil? I should like to know if it was found necessary to adopt any system of shielding in order to avoid interference due to other radio or audio sources in the neighbourhood. This question arises because the author has used inputs of the order of those generally met with in reception. The adoption of the tuning-fork generator in the distortion experiments would have been of great advantage with regard to purity of wave-form. As a result of this investigation, I would ask the author if he can suggest any further remedies in minimizing the effects due to distortion. In the case of an amplification system consisting of a high-frequency amplifier, a detector and a low-frequency amplifier, how are the distorting effects due to the three individual portions related to the overall distortion? It is to be hoped that the author will give us later, comparative figures of the best performances of amplifiers of all the three types for a good range of frequencies. These would be extremely valuable to all interested in the design and building up of efficient and reliable amplifiers.

Mr. H. A. Thomas (*in reply*): With reference to the remarks of Prof. Fortescue, I would point out that the vibration galvanometer is capable of measuring an output of 6 μA, which is the current value for a medium telephone signal. The sensitivity range of this instrument is in fact that of weak telephone signals, and the galvanometer cannot be used for strong signals unless it is heavily shunted. I know of no other instrument which could be used for current measurement below 1 μA under the existing conditions.

In Section 2 I refer to the detrimental effect produced by inserting switching arrangements in the tuned input circuit, but in Section 1 there is no input circuit and the switches are permissible, as we are merely applying a small, known voltage to the amplifier input directly. Capacity effects have been calculated for this case and have been found negligible, as all leads are most carefully spaced. The screening methods adopted have been adequately defended by Dr. Smith-Rose, whose remarks answer the points raised.

The conclusions arrived at on page 261 are only meant to apply to the special case under investigation. In the absence of further comparative information it is not possible to extend these conclusions to other cases. In this particular case the observed results can be expressed mathematically if the amplifier input circuit is considered as a condenser and resistance in series, the chief merit of this conception of the input impedance being that the capacity component appears to remain sensibly constant under all conditions.

Mr. L. B. Turner asks for a more detailed account of the method of determining audibly the completely modulated condition for radio injection. I would refer him to Mr. Hollingworth, who has already given a statement of the method.

The minimum high-frequency output which can be measured by the use of the rectifier, audio amplifier and vibration galvanometer is 5 mV, taking the maximum sensitivity of the vibration galvanometer as 10 μA. If a thermionic tube voltmeter were used, the maximum

sensitivity would need to be 5 mV, and this could be obtained with a balanced pointer instrument in the anode circuit. However, I do not see how this method has any advantages, since it will only give R.M.S. values, and will not help in the determination of the amplification of the fundamental alone. A high-frequency resonance instrument or cathode-ray oscillograph is necessary for this purpose.

I think that the measurement of coupling values and currents would be so indirect that a heterodyne method of obtaining an audio output would give little accuracy. The frequency of both the injecting radio source and the heterodyne would have to be perfectly constant to give a constant-frequency beat note, thus requiring fork-driven circuits. However, since the resonant frequency of the vibration galvanometer is constantly changing, and is difficult to keep in adjustment, the audio source is very slightly variable to allow the galvanometer resonance condition to be tuned to. With constant oscillator and heterodyne the output beat note is inflexible in frequency, and thus the galvanometer would require adjustment for every reading.

I admit that the current transformer used is not a particularly good one, although the reason is not easy to find, as the iron section is large. The curve shown in Fig. 2 is merely given as the ratio calibration of the particular transformer used.

I wish to thank Mr. Turner for his helpful suggestion concerning the potentiometer and the current transformers. Small errors have been observable in this transformer, and the removal of the primary winding from the high-potential end of the oscillator has given greater accuracy. As the screening methods are improved it is found unnecessary to earth any point, in which case the whole system is effectively screened.

The amplifier used to obtain the curve shown in Fig. 6 was of the 3-stage tuned-transformer type, using bright R valves and 100 volts high tension, and, as is usual with such an amplifier, the grids were connected to the negative end of the filament. Negative bias causes oscillation when several stages are coupled in cascade and tuned.

I wish to thank Mr. Hollingworth for his remarks, which materially help to give a clearer concept of the purpose of the work. He has also effectively given the reasons why the audible 100 per cent modulation determination is comparatively accurate.

I am glad the experience of Col. Edgeworth tallies so well with my own. I am pleased to say that I hope in the near future to progress along lines such as he suggests. Large valves will be used and special transformers of known constants adopted for the purpose of determining the production of harmonics by the iron core.

With reference to the remarks of Major Lee, the case given in the paper before the American Institute of Electrical Engineers by Bennett and Peters is not a parallel case to the one I have cited. In my case the grid is directly connected to the tuned circuit, and retroaction takes place from the anode circuit into this tuned circuit. Surely, however, the best reply I can give is that, since the resonance curves obtained gave the same value of decrement for all cases taken on the curve, these curves *do* represent the condition of a circuit which has a constant apparent resistance for small changes of frequency. If rapid changes in resistance and reactance values had occurred over a small change in frequency, the resonance curves could not have given one value only for the effective high-frequency resistance.

I would point out that the input voltage applied to the amplifier for these tests was of the order of 10 μV, the oscillator used being 15 ft. away from the tuned receiving circuit. A powerful oscillator was used only for the determination of the normal high-frequency resistance of the circuit without an amplifier, and thus the suggestion that grid currents existed can only apply to the case of the weak input. In this case there was a 3-volt negative bias on each valve and the last valve had an input of only 200 μV upon its grid.

In the advance copies of the paper there was a slight error in the text in Section 3 (*a*), paragraph 3. I have now altered this to read: "If harmonics were present, the same apparent sound intensity could be obtained with R.M.S. values of current but one-sixth of the current required if the wave was sinusoidal." In paragraph 4 of the same Section I mean to infer that with an amplification system consisting of a rectifier followed by audio stages, great amplification due to high-frequency retroaction can be obtained, but the distortion due to the overloading of the audio amplifier may be so great that the output signal is of little readable value.

Dr. Smith-Rose has adequately stated the position that the National Physical Laboratory must adopt regarding the testing of commercial radio goods. Until we can interpret the behaviour of an amplifier in terms that will be of immediate practical utility to the manufacturer, we do not feel justified in testing apparatus of this kind. He has also answered the questions raised by Prof. Fortescue in connection with the screening methods adopted. As a result of some recent tests it has been found that 96 per cent of the external field is eliminated at a wave-length of 350 m and 94 per cent at a wave-length of 10 000 m. When one considers that the main oscillator is efficiently screened in a completely lined metal box, reducing the field to about 10^{-4} or 10^{-5} of the original, I think it must be admitted that the screening, although not perfect, is quite sufficient for most purposes.

The reasons for abandoning the inserted-resistance method raised by Mr. P. K. Turner are dealt with in the paper. The effect of this inserted resistance is to modify the amplifier conditions. It would, of course, be possible to duplicate the mechanical shape in copper and then in resistance wire, if that were the only difficulty. However, since I know of no one who claims high accuracy for this method when applied to the measurement of the high-frequency resistance of a tuned circuit the resistance of which is partly neutralized by the retroaction of an amplifier, I felt justified in obtaining more accurate results by the resonance method which, although complicated, yielded very excellent and consistent results. The curves given for the load introduced by the amplifier apply only to the case of

a rectifier followed by audio stages. The question of the effect of high-frequency stages has not yet been dealt with. It is apparent from a perusal of Fig. 18 that the grid voltage vector E_c is *not* in phase with the retroacting E.M.F. E_b.

The remarks of Mr. Willans are more of the nature of a separate statement of a method of measuring stage amplification than a criticism of the paper. However, the method which he has given is not without interest.

I cannot see why screening the oscillator is deemed unnecessary. Surely induction effects between the two valves used cannot be separated from the actual amplification of the system. The output valve is not working under normal conditions. The secondary of the transformer has certainly the load due to the grid-filament impedance of a triode, but this triode has no output impedance and, as Miller has shown, the input impedance will be modified seriously by this departure from actual conditions.

The method is essentially limited by the sensitivity of the human ear to pick out zeros of the fundamental in the presence of harmonics. At low acoustic frequencies, e.g. those below 200, this is very difficult, as pointed out by Dr. Smith-Rose. I cannot see that the apparatus is simple. A bridge of the type shown is essentially a complex piece of apparatus. I feel that more care should be taken over the many leads with their capacity and inductive effects. He speaks of a $\frac{1}{4}$ volt as being a small output voltage. I personally consider this to be very large, my measurements rarely exceeding 5 mV on the output valve.

Mr. Clinker's remarks, like those of Mr. Willans, do not bear very definitely upon the main subject of the paper. He describes a method of measuring the stage amplification of one audio valve and transformer, and adds yet another method to the many already in use. I would point out first what is surely a mathematical error. The amplification of the stage must be

$$\{(R_1 + R_2)^2 + (\omega M)^2\}/R_1$$

and not $\{(R_1 + R_2)^2 + M^2\}/R_1$ as he gives it.

This method requires the calibration of a mutual inductance and two variable resistances and appears to be unduly complicated. The calibration of the mutual inductance over a wide range of frequencies is by no means a simple matter and the final result is dependent upon a zero telephone balance which at low frequencies gives a rather poor sensitivity. Finally, the last valve is not working under normal conditions, since there is no oscillating current in the anode circuit. If the amplifier is modified by the insertion of the suggested apparatus, the amplification figure will be sensibly different from the normal case of a loaded output and an absence of the measuring gear. It has been my experience that any insertion of measuring apparatus intermediate to the input and output terminals may completely modify the performance of any amplification system.

Whilst I appreciate the suggestions made by Mr. Sreenivasan, I feel that the modification suggested would lead to an unnecessary complication of the apparatus rather than a simplification. If the radio oscillations were chopped in the manner suggested, the resultant envelope wave-form of the modulated continuous-wave output would seriously depart from the original rectangular wave-form, and the d.c. instrument in the last stage of the amplifier would of course give the R.M.S. value of this wave. It would consequently be difficult to interpret the amplification, as the output wave-form would depend upon the number of stages used in the amplifier. Charging effects, time-lags, and transient starting and stopping conditions of the high-frequency oscillations would all tend to distort the original rectangular wave-form. I think that a tuning-fork arrangement for providing the audio modulation would not give the output required, especially in those cases where the audio oscillator is used to supply the input to a pure audio amplifier. A master control of the main oscillator could be arranged, operated by a self-maintained fork, but this constancy in frequency is not required for this class of work, as the vibration galvanometer itself does not preserve its resonant frequency accurately and the audio oscillator has to be slightly varied in frequency to tune to the galvanometer for every reading.

It must be remembered that the one oscillator is used for a dual purpose :—

(*a*) As a modulator for high-frequency injection.
(*b*) As the direct injecting agent for low-frequency injection.

I agree that the maximum permissible stage amplification before oscillation occurs falls as the number of high-frequency stages is increased. Unfortunately I have no comparative figures to give definitely, but I have not noticed that the first stages give a greater factor than the last. All seem to be equally affected.

The problem of intervalve coupling and its effect upon overall amplification is an exceedingly difficult one, which is to be more fully investigated in the near future.

The resonance method is admittedly more complicated than the inserted-resistance method, but is justified on the score of accuracy. It is possible to obtain an accuracy of 1 per cent with this method, and this is, as the speaker states, greater than the experimental accuracy of other methods.

"Reaction = 20," "Reaction = 30," etc., are meant to signify the settings of the reaction coil in terms of the particular scale used. The amplifier is completely screened in a special room, the radio oscillator is screened with metal plate, all leads are well spaced and screened in metal-lined trunks, and finally the measuring control panel itself is shortly to be enclosed in a large metal-gauze screen, thus forming the final link in a completely screened piece of apparatus.

It is early to consider remedies to minimize distortion in low-frequency amplifiers, the causes of such distortion being as yet an unsolved problem. When the causes are understood, methods of elimination will be considered. The distortion so far considered is entirely that occurring in the audio side of the amplifier.

A special cathode-ray oscillograph equipment, nearly completed, will examine the high-frequency distortion

produced. It has also been demonstrated recently that distortion takes place in the rectifier due to the modulated nature of the applied input.

I would point out in conclusion that the many combinations that require examination are such that the final statement of the observed results cannot be given until much more work has been done. Only by a careful examination of each case can a thorough understanding be obtained, and the results must of necessity be slow in appearing.

INSTITUTION NOTES.

Faraday Medal.

The Council have made the fifth award of the Faraday Medal to Colonel R. E. B. Crompton, C.B., Honorary Member and Past-President of the Institution.

North Midland Centre.

Mr. H. Cecil Fraser has been appointed Hon. Secretary of the North Midland Centre, to fill the vacancy caused by the death of Mr. J. D. Bailie.

The following Informal Meetings have been held :—

71st Informal Meeting (26th October, 1925).

Chairman : Mr. R. A. Chattock (President).

Subject of Discussion : "How can the Cost of Distribution be cheapened" (introduced by Mr. R. A. Chattock).

Speakers : Messrs. P. Rosling, W. Brown, A. F. Harmer, T. Rich, W. E. Rogers, G. H. Stevens, W. P. Fanghanel, H. Richardson, N. W. Prangnell, D. G. Hurlbatt, W. F. Andrews, E. S. Ritter, J. S. Rann, C. D. King, J. Coxon.

72nd Informal Meeting (9th November, 1925).

Chairman : Mr. A. H. Allen.

Subject of Discussion : "Modern Developments of Telephone Cables" (introduced by Mr. E. S. Ritter).

Speakers : Messrs. W. E. Twells, T. W. Riley, A. C. Rosen, W. Day, G. C. Marris, S. M. Catterson, J. Coxon, A. F. Harmer, F. Tremain, M. D. Hart, J. W. Wheeler, H. T. Werren, Major A. G. Lee, Mr. A. H. Allen.

73rd Informal Meeting (23rd November, 1925).

Chairman : Mr. J. Coxon.

Subject of Discussion : "The Testing of Large Electric Plant" (introduced by Mr. E. E. Tasker).

Speakers : Messrs. F. Creedy, M. D. Hart, W. E. Highfield, J. F. Shipley, W. E. Rogers, J. Coxon, J. R. Bedford, W. A. Erlebach, R. Samphier, A. Barraclough, W. J. Minton, R. D. Gifford, D.Sc., C. L. Lipman, D. G. Hurlbatt.

74th Informal Meeting (7th December, 1925).

Chairman : Mr. P. Dunsheath, O.B.E., M.A.

Subject of Discussion : "Design and Performance of Protective Relays" (introduced by Mr. C. L. Lipman).

Speakers : Messrs. R. D. Gifford, D.Sc., A. G. Hilling, F. E. Ockenden, J. F. Shipley, E. S. Ritter, G. N. Wright, F. H. Nalder, — Laws, H. S. Petch, H. Lloyd Williams, F. Pooley, P. Dunsheath, O.B.E., M.A., Col. K. Edgcumbe.

75th Informal Meeting (11th January, 1926).

Chairman : Mr. A. G. Hilling.

Subject of Discussion : "The Electrical Installation in the Rockefeller Building, University College" (introduced by Mr. W. C. Clinton, B.Sc.).

Speakers : Messrs. H. T. Young, J. R. Bedford, W. E. Rogers, G. C. Allingham, E. H. Freeman, C. L. Lipman.

76th Informal Meeting (25th January, 1926).

Chairman : Mr. C. L. Lipman.

Subject of Discussion : "Impressions of my Visit to America, mainly about Switchgear" (introduced by Mr. H. W. Clothier).

Speakers : Messrs. H. Trencham, M. D. Hart, A. F. Harmer, R. C. Andersen, — Ferguson, G. M. Davies, Col. K. Edgcumbe, Messrs. D. Kingsbury, C. L. Lipman.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 December, 1925–25 January, 1926 :—

	£	s.	d.

AN ALL-ELECTRIC HOUSE.

By Professor S. PARKER SMITH, D.Sc., Member.

(*Paper first received 25th August, and in final form 7th October,* 1925; *read before* THE INSTITUTION *3rd December, before the* SOUTH MIDLAND CENTRE *2nd December, before the* NORTH MIDLAND CENTRE *8th December, and before the* NORTH-WESTERN CENTRE *15th December,* 1925, *also before the* NORTH-EASTERN CENTRE *8th February, before the* SCOTTISH CENTRE *9th February and 9th March, and before the* IRISH CENTRE (DUBLIN) *25th February,* 1926.)

SUMMARY.

The scarcity of precise and detailed information on the several domestic applications of electricity encouraged the author to write a succinct account of the arrangements adopted in a 10-roomed house designed and built in Glasgow for all-electric working. In this house neither coal nor gas is used. The sections dealt with are :—

(1) Layout of house.
(2) Distribution board.
(3) Wiring.
(4) Bells.
(5) Lighting.
(6) Clothes-washing and drying.
(7) Cooking.
(8) Hot water.
(9) Ventilation.
(10) Heating.
(11) Running costs.
(12) Conclusions.

The total cost of 16 584 units used in one year's working was £43 8s. The consumption and costs are analysed for the several services.

In an Appendix, the results of a 4-roomed all-electric flat are given. The consumption for one year was 4 656 units and the total cost of energy was £14 18s.

INTRODUCTION.

In 1923, the author, being in need of a house in Glasgow, where the Corporation actively encourages the domestic use of electricity, seized the opportunity offered to build himself an all-electric house. The most noteworthy feature connected with this proposal, apart from details, was the adverse criticism which it elicited from the majority of electrical engineers with whom the scheme was discussed; so much so, that the carrying out of such an unpopular idea must be largely attributed to the obstinacy of one who thought that the time had arrived when a professor of electrical engineering ought to have enough faith in his convictions and calculations to put them to the test. Apart from doubts of critics as to cost, due in most cases to ignorance of the cost associated with the use of gas and coal, a coal fire for the sitting-room was almost universally advocated. The drudgery associated with the burning of coal in open fireplaces—such as removal of ashes and blackleading of grates—the pollution of the atmosphere, needless labour and waste, etc., in the eyes of many engineers seemed to be negligible compared with the romance of the coal fire. The layman, and particularly the laywoman, however, proved to be easier converts, especially where the domestic-servant problem was acute or where young children had to be considered. To the lay mind, the disposal of refuse—particularly garbage—seemed to be the main argument for retaining a coal fire. It was soon discovered, therefore, that the main objections to an all-electric house would be :—

(1) Excessive running cost.
(2) Absence of coal fire in sitting-room.
(3) Difficulty of disposing of refuse, mainly garbage, in the house.

It is hoped that this paper will show that none of these objections proved serious.

It is not intended here to do more than give a description of the layout of the house in question and a summary of one year's working. The calculations are all based on the tariffs of the Glasgow Corporation (which, by the way, also arranges for the hire of electric cookers and fires). Whilst thus limiting the scope of the paper to the author's own experience, it has to be remembered that there is nothing novel in the general problem of the use of electric appliances for domestic purposes, or in tariffs suitable for the domestic load.

In Glasgow the domestic consumer is offered the choice of two alternatives :—

(1) Energy at 4½d. per unit for *M* units and ¾d. per unit thereafter, where *M* is the estimated annual consumption for lighting and includes the consumer's share of capital and fixed charges.
(2) A two-part tariff consisting of a fixed charge to cover the consumer's share of capital and fixed charges, and ½d. per unit for all energy taken. The fixed charge appears to be about one-eighth of the rent, and in the author's case works out at £12 10s. per annum.

A simple calculation shows that domestic users will usually choose the latter alternative where heating and cooking loads predominate. For the author's house $M = 582$, and the two-part tariff led to a saving of £7 6s. 5d. in the first year's working. Compare also Figs. 10 (*a*) and 10 (*b*).

In passing, it may be pointed out that, even with favourable rates, the cost of an abundant supply of hot water might be considered unduly high, but it will be shown in the section on "Hot Water" how a satisfactory solution has been found.

Before considering the main points, such as heating, cooking, lighting, hot water, etc., a word may be said about capital cost. The house was built to be a home and not a showroom. This is an important point in determining the capital cost of an all-electric house, for in addition to the increased convenience obtainable with essential apparatus such as electric cookers, fires, etc., there are many available and possibly desirable appliances such as cleaners, warming pads, etc., which cannot be legitimately included under capital

cost. Even apart from appliances it is a difficult matter to determine accurately the effect of "electrifying" a house on the cost of construction, for it is not easy to analyse the installation costs. Suppose, for example, the house were wired and gas and coal were also to be used, a certain number of sockets for plugs would properly be included in a modern layout, and up to this point the cost of the installation of the all-electric house would be the same as for any other modern house of the same size. Unless, therefore, electricity be used for lighting only, any estimate of the effect of electrification on the cost must be necessarily rough.

After careful consideration, and taking into account that many appliances can be hired, the author is of the opinion that the cost of the house was 3 to 4 per cent higher than it would have been with coal (or coke), gas appliances and electric lighting. Whether there has been undue extravagance, the reader can judge for himself. It must, however, be remembered that the architect can effect many savings; for example, neither coal-house nor scullery is needed, nor is restriction placed on the design by the position of the flues, etc.

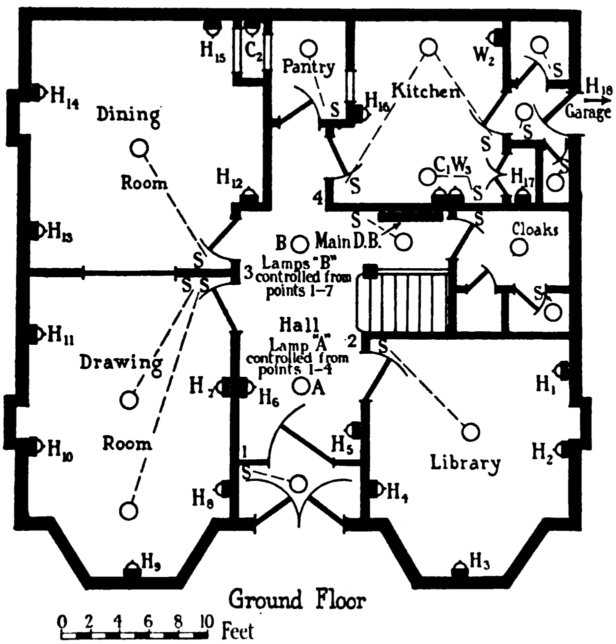

Fig. 1.

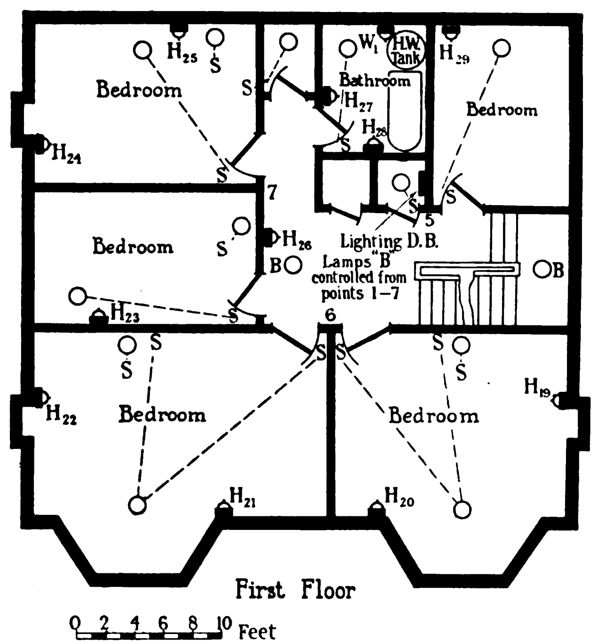

Fig. 2.

(1) Layout of House.

An idea of the layout can be obtained from the plans in Figs. 1, 2 and 3. The architect, Mr. J. Austen Laird of Glasgow, designed the house to meet the requirements of all-electric working, whilst the author was responsible for the electric layout. In passing, it may be mentioned that an all-electric house is essentially a case for co-operation between architect and engineer, for to obtain the best results the peculiar nature of electricity (just as in the case of gas or coal) must be consulted.

In all, there are 10 rooms—three reception-rooms and kitchen on the ground floor, five bedrooms on the first floor, and a large attic nursery. Below the ground floor there is a sloping space like a shallow cellar, 3 to 4 ft. high, which is accessible and is used for much of the ground-floor wiring. The floor dimensions of the rooms can be obtained from the figures; on the ground floor the rooms are 9 ft. 6 in. high, and on the first floor 9 ft. high.

From the enlarged plan of the kitchen in Fig. 3 it will be seen that there is no scullery or wash-house. No provision is made for coal storage, the only out-house being a garage.

It will be noted that there are three external chimney breasts; these are used for ventilation. By fitting grates and replacing the ventilators by chimney-pots, coal fires could be used—a feature which calls forth the approval of many critics of the all-electric idea. There are no mantelpieces or overmantels, but the fireplace recesses have been retained owing to the common practice of sitting round a fire. Since the only dirt, generally speaking, comes from outside (through the windows), the architect had a fairly free hand in determining fixings and decorations. The floors (on the ground flat) are polished and of hard wood, whilst the remaining woodwork is polished cedar.

(2) Distribution Board.

From Fig. 4 it will be seen that separate meters were installed for registering the respective consumptions for heating, hot water, cooking and lighting. These meters can be regarded as experimental and would not be needed for the ordinary consumer. The main meter is of the two-rate type and is actuated by a 40-day clock, so that the day and the night consumptions can be recorded separately; the purpose of this will be explained later. There are 31 heating circuits, and 5 circuits for cooking and hot water. Each of these circuits has its own fuses and goes to one point only, as indicated in

Figs. 1, 2 and 3, by H_1 to H_{17}, H_{19} to H_{29}, C_1, C_2, W_1, W_2 and W_3. (H_{18} is in the garage; H_{30} and H_{31} are in the attic nursery.) These points are 15-ampere wall sockets, with the exception of the cooker and the hot-water tank which are wired for 30 amperes. The lighting distribution board is fixed in the housemaid's closet on the first floor (Fig. 2) and feeds four circuits.

The main distribution board is placed in an accessible position between the hall and cloak-room, and the teak board and boxes accord well with the neighbouring woodwork, which is polished cedar.

(3) Wiring.

In general, the Wiring Regulations of the Institution were adhered to. Though screwed conduit appears to be favoured in Glasgow, the author decided that tough rubber sheathing (C.T.S.) was better for his purpose. With the large number of circuits throughout the house it is probable that C.T.S. was the simplest solution, and nothing has yet occurred to make the author believe that it was not also the cheapest and the best solution.

The supply is direct current at 250 volts, the positive and neutral being brought to the house.

The sizes of wire used are as follows :—

Cooker circuit (C_1)	7/·044 C.T.S. twin.
Hot-water circuit (W_1)	7/·044 C.T.S. twin.
Heating circuits (H_1 to H_{31}) ..	3/·036 C.T.S. twin.
Hot-water circuits (W_2 and W_3)	3/·036 C.T.S. twin.
Cooking circuit (C_2)	3/·036 C.T.S. twin.
Fan circuit	3/·036 C.T.S. twin.
Lighting circuits	3/·036 C.T.S. single.
Bell circuits	1/·044 C.T.S. single.

A 7/·036 bare stranded copper cable connects all sockets, etc., to earth.

Switch-sockets are used throughout. These are of the 15-ampere, 3-pin, flush pattern with a mechanical interlock to prevent the plug being removed with the switch on, or switching on before inserting the plug. With few exceptions all switch-sockets are inserted in the skirting board and the switches are arranged to be put on or off by the foot. The object in employing sockets all of the same size is to enable all fires and other appliances—kettle, iron, vacuum cleaner, etc.—to be used wherever desired. Against the objection to using, for example, a lamp standard on a circuit fused for 15 amperes, there is the advantage of convenience. Moreover, wherever there are several points per circuit, lamps and other appliances have often to work with liberally rated fuses.

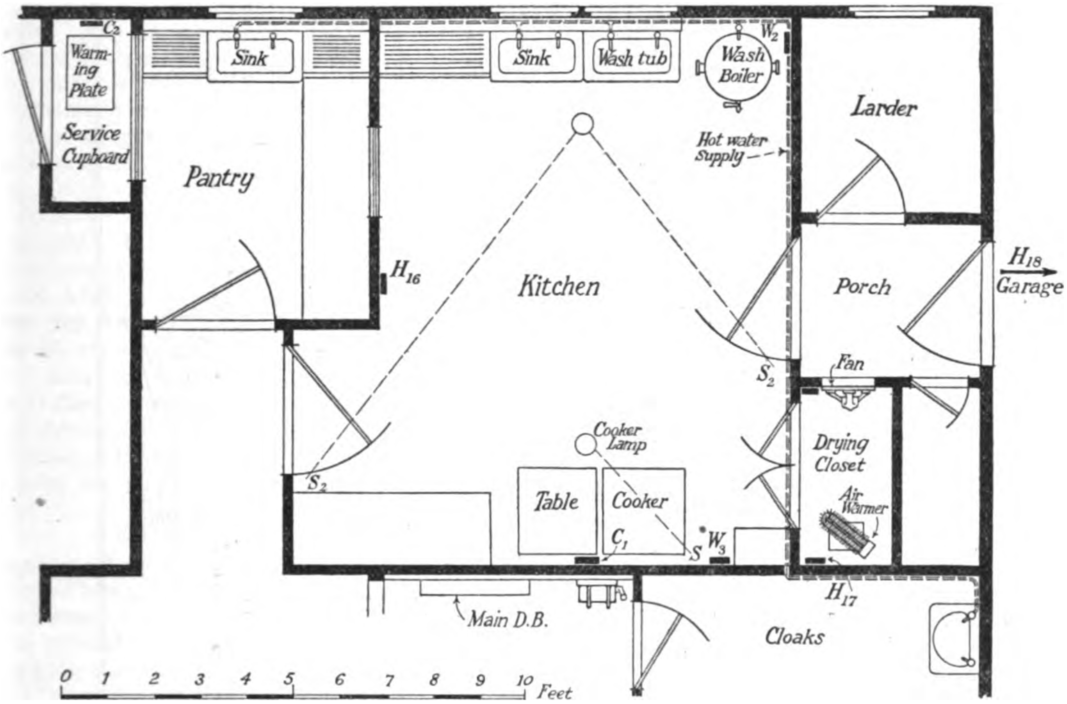

Fig. 3.—Enlarged plan of kitchen and services.

The number of points per room needs careful consideration. The author's experience has shown that in the living rooms 4 to 5 points per room are desirable. It is not unusual to have such a combination as the following in service in one room at the same time :—two fires, a desk lamp and a tea kettle; or a fire, a toaster, a coffee percolator and an egg boiler. In certain places it has been found convenient to duplicate some of the points by using a 15-ampere plug with a 5-ampere adapter.

(4) Bells.

In order to have the bell circuits as sound as the lighting and heating circuits, C.T.S. wire was also used. This may appear to be extravagant; but it is an advantage to have reliable bell circuits in an electrical engineer's house. In addition to an indicator, there are three bells—a deep-toned bell for the front door, a shrill-toned one for the side door, and a gong for the indoor pushes.

In important rooms there are bell-pushes near the door and near the fireplace.

(5) LIGHTING.

It will be seen from the costs in Table 3 that the charge for lighting works out at about nine shillings per quarter —consequently abundant lighting everywhere is permissible. Relatively, therefore, the cost of lamps is an important factor, and indeed this may be a case where under-running lamps (i.e. running lamps at less than the rated voltage) may be sound policy for the user.

Wherever it is desirable to operate a light from more than one point, suitable switching is provided. The hall light A can be operated from 4 points—vestibule door, kitchen and pantry, dining-room and drawing-room, library and foot of stairs. A second light B at the foot of the stairs is in the same circuit as the lights B on the half-landing and landing. In addition to controlling these 3 lights from the 4 points just mentioned for the hall light, they can also be controlled at 3 points on the first-floor landing. The convenience of being able to control the stair lights from 7 points can scarcely be

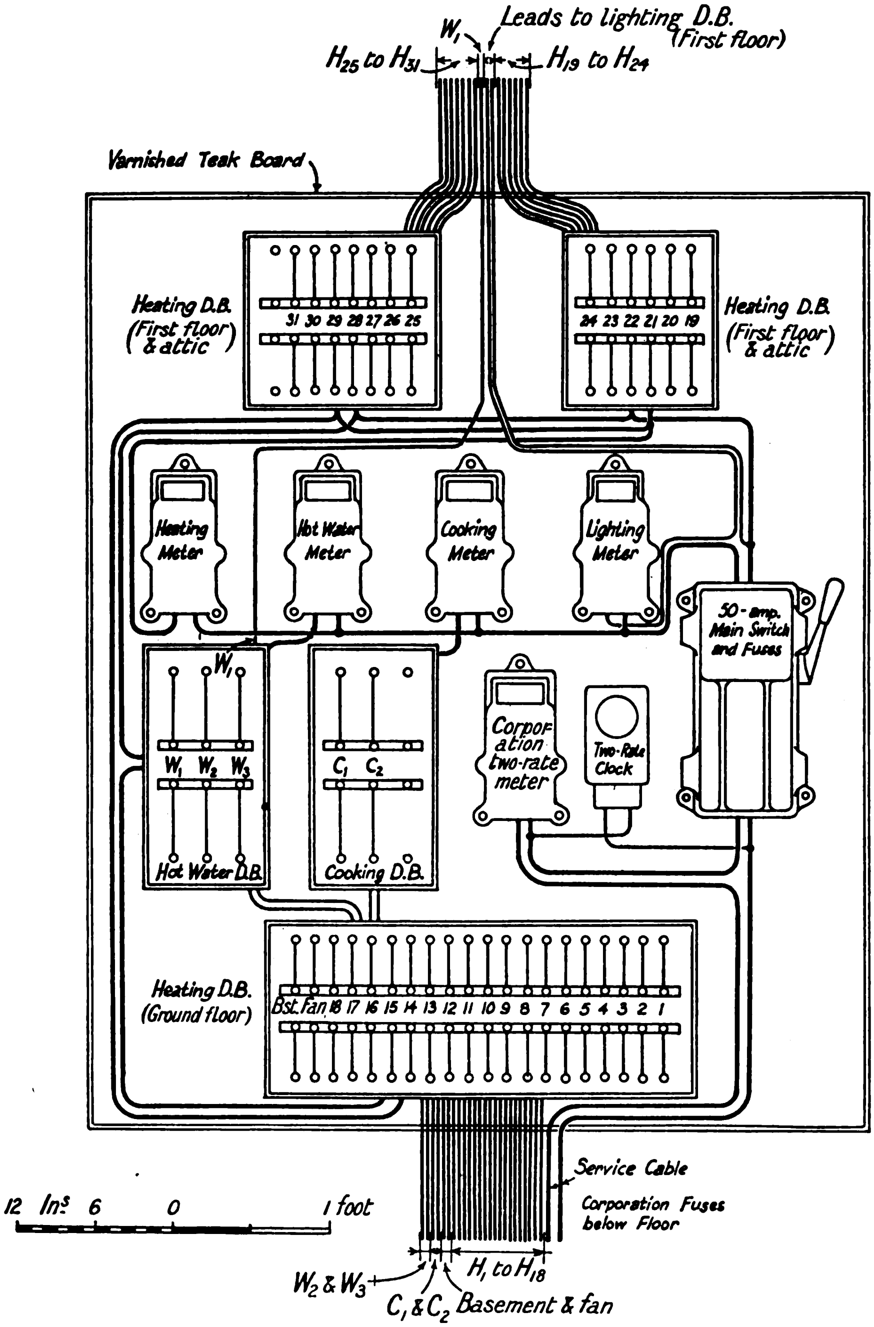

FIG. 4.—Main distribution board with experimental meters.

exaggerated. These control points are indicated in Figs. 1 and 2.

In the principal bedrooms, the dressing-table lights can be controlled from either the door or the bed, whilst an additional independent reading-lamp is placed over the bed.

In the kitchen an additional strong light is placed over the cooker and is controlled from a convenient point. All the switches are of the flush pattern, and exposed or unshaded filaments are avoided throughout the house.

(6) Clothes-washing and Drying.

In Glasgow a wash-tub is often fitted alongside the sink, and a small wringer with rubber rollers can be readily attached. Alongside the enamelled tub a wash-boiler of the percolator pattern has been placed (see Fig. 3). The loadings are 2 kW, 1 kW and ½ kW. Articles, after being soaped, are placed in this boiler, no preliminary scrubbing being necessary, as the washing is done by the continuous circulation of the boiling water. Unpleasant steaming is avoided by controlling the heat; and after bringing the water to the boil the process is usually completed in half an hour with the rotary switch on "low."

Drying facilities become essential in a wet climate. For this purpose, the drying-closet shown in Fig. 3 has been provided. The clothes are hung over 10 wooden rods, while an exhaust fan draws air from the space below the floor. On entering this closet the air passes over an air warmer of the convector type, rated at 1¼ kW. After an hour the dried clothes come out as fresh as if they had been hung out in sunshine. Not only is this drying closet a convenience at all times for sundry articles, but it is a vast improvement on the unsightly poles and pulleys often seen in kitchens.

(7) Cooking.

Electric cooking well merits the success it has gained. The absence of smell, smoke, dirt and fumes shows that many objectionable odours commonly associated with cooking are avoidable. Indeed it is probable that with electric cooking much less will be heard of the "nasty smell of cooking throughout the house." Smell there may be, but not the nasty smell which is so repugnant. Other merits of electric cooking rapidly discovered are simplicity in working and ease in obtaining good results. The thermometer on the oven door and the clock enable results to be obtained which will be particularly appreciated by the large and growing number of educated and refined women who have to do their own cooking—indeed it may not be an exaggeration to say that the splendid results obtainable may make cooking attractive to many intelligent people.

The cooker installed is of the table type; that is, the oven is alongside the boiling-table. This avoids stooping or kneeling when attending to the oven—the low oven seems to be designed to cause irritation. The oven and the griller can be given unstinted praise.

The boiling-plates—two in number—are rated at 1½ kW and 2 kW respectively and are of the open type. Though satisfactory, when properly maintained, manufacturers must try to do better with their boiling-plates. Safety and speed are the ideals at which to aim. The efficiency of the open-type boiling-plate may be 20 to 25 per cent when starting from cold—or little better than that of a coal fire. Numerous experiments made by the author have shown that substantial improvements are possible—see "cooking" load curve in Fig. 7 showing the fall in consumption—and no one will be better pleased than supply undertakings when makers can improve the efficiency and reduce the upkeep charges of boiling-plates. In this connection it may be noted that investigations are being made with various types of boiling-plates and cooking utensils.

Probably in some households it would be better to provide three boiling-plates on the boiling-table, while a large and a small oven might be an advantage. It has been found that rustless steel makes excellent baking shelves for ovens.

In passing, a thought may be given to the question of development. Are we proceeding along correct lines? Is not an electric range an imitation of a coal or gas range, and are we certain thereby to utilize to the best advantage the unique merits of electricity? Instead of the present inefficient boiling-plates, may it not be better to use a number of economical cooking utensils each with its own heating element, like a kettle, and fitted with watertight plugs? The idea, though old, is at least worth consideration.

(8) Hot Water.*

It has long been recognized that the provision of an abundant supply of hot water in an all-electric house presented a tough problem, owing to the large amount of energy required for this purpose. Here, above all, a low tariff is essential. True, it is possible to use small tanks or geysers in different parts of the house and so avoid all pipe losses; but an adverse critic, or one accustomed to an ample supply of hot water at all times, might regard such methods as a makeshift.

The solution adopted in this case was made possible by Mr. R. B. Mitchell, the City Electrical Engineer at Glasgow. When first discussing the author's proposals for an all-electric house and the effect of domestic load on load factor, Mr. Mitchell produced load curves similar to those shown in Figs. 5 and 6, and emphasized the desirability of developing new forms of night load. No better occasion offers itself for this purpose than heat storage in water. Not only is the load large, but it is constant throughout the year, while it can be taken only during the hours when the supply undertaking is best able to give it. It was therefore decided to take energy for heating water between the hours of 11 p.m. and 7 a.m. As regards a tariff, it is obvious that such energy must be cheap enough to make the proposition feasible. But here, again, the situation proved to be favourable. Since the consumer's share of the capital charges is included in the two-part tariff already referred to, it follows that running charges will form practically the entire cost. The average running charges at Dalmarnock station, in which coal, of course, is the chief item, are of the order of 0·25d. per unit; and the charge of 0·375d. per unit proposed by Mr. Mitchell for current

* S. Parker Smith and N. M. MacElwee: "The Heating of Water by Electricity for Domestic Purposes," *World Power*, 1926, vol. 5, p. 7.

for domestic hot-water storage during night hours therefore appears to be reasonable, and should become popular. In order to make the experiment successful, however, it was necessary to obtain a well-lagged tank. This proved to be a difficult task, but the author was fortunate in obtaining the co-operation of Mr. Duncan Low of Messrs. Arch. Low and Sons of Glasgow.

For several weeks tests were made with different forms of lagging until at last it was found that with a suitable application of cork the fall in temperature of the water was less than 1 degree F. per hour. Further, it

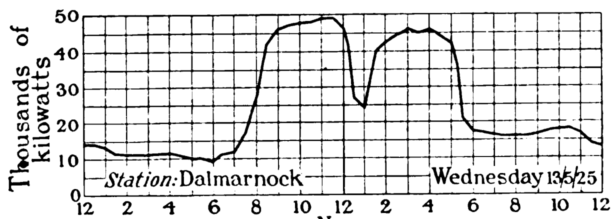

FIG. 5.

was found that by proper design the amount of mixing of the incoming cold water with the hot water in the tank could be made negligible. The tank installed is fed from the cistern and has a cubical capacity of 87 gallons. It supplies the bath and hand-basin in the bathroom, the maid's room, pantry, cloak-room and three points in the kitchen. Near the bottom of the tank there are immersion heaters rated for 4 kW, 2 kW and 1 kW. Near the top of the tank there is an emergency immersion heater rated at 2 kW. This

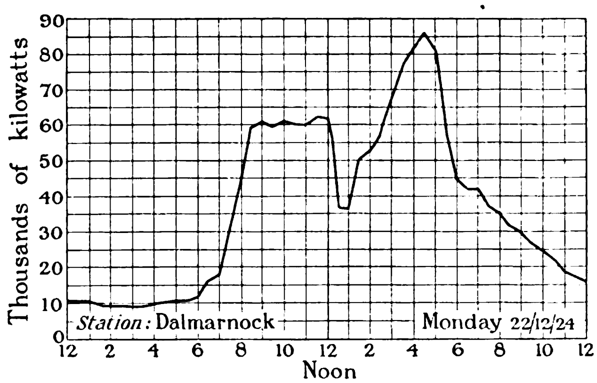

FIG. 6.

auxiliary heater has proved to be very serviceable when the demand for hot water has been exceptional and the temperature has fallen too low for domestic purposes. For instance, it will heat up sufficient water for a 35- to 40-gallon warm bath in 30 to 60 minutes, according to the water temperature when switching on.

The tank is fitted with a thermometer which is calibrated " high," " medium " and " low," to indicate in which position the switch has to be placed in the evening. Experience has shown that in winter it is mostly necessary to place the switch at night in the " medium " position: in summer it is occasionally possible to switch on to " low." As a rule the tank is switched on about 10.30 p.m. and off at 7.30 a.m.—which partly accounts for the " hot-water " load curve being higher than the night load curve in Fig. 7. Under the above conditions, the temperature of the water on switching off is usually in the neighbourhood of 140° F. —it is seldom as low as 120° F. or higher than 160° F. In addition to the house service throughout the day, there is sufficient water for two hot baths per day. The tank is placed in the bathroom, so that any heat loss is useful in warming this room. As a result, the temperature of the bathroom is always comfortable, and it is seldom necessary to close the window or use a fire.

The question may well be asked—why not heat the water to, say, 180° F. and so install a smaller tank? This would certainly be feasible and cheapen the first cost, but there are advantages in having the larger tank and using water between 120° and 140° F. The losses from the tank and the pipes are much less at the lower temperature. Experience shows that it is more economical to supply water to the kitchen at the lower than at the higher temperature. Moreover, the possibility of working at the higher temperature in case of need gives the tank a good overload capacity.

Since the tank was installed no trouble whatsoever has been experienced and there has at all times been an ample supply of hot water—equal to some 12 to 15 gallons per person per day. Without asserting that the above method is the cheapest for obtaining hot water, Table 3 will show that the cost is reasonable. The value of such a night load to the station and the convenience of the method will scarcely be disputed. By means of a thermostat it is a simple matter to arrange automatic heat control for such a tank.

As far as the author knows, this method has been widely adopted only in places served from hydro-electric stations, but it is encouraging to find that supply authorities in this country are beginning to give attention to the matter. For example, the Clyde Valley Power Company are prepared to sell energy at ½d. per unit for domestic water-heating during night hours. It is possible that this charge may be reduced to ⅜d. per unit. The Corporation of Greenock are offering energy for the same service at ½d. per unit to all classes of domestic consumers. Supply authorities might also consider the desirability of hiring out storage tanks to consumers.

(9) VENTILATION.

The scheme of ventilation adopted is simple and effective, and its only drawback is the dirtiness of the ventilating medium—a drawback associated with all houses built in or near large towns. Fresh air is drawn into the rooms through air bricks behind the fires in the recesses, and the amount of air can be regulated in a simple manner. The outlet for the vitiated air is a wooden grid let into the frieze and communicating with the flue in the external chimney breast. This arrangement has proved to be satisfactory, and the rooms do not get stuffy when the windows are closed.

The imperfection in the system is not peculiar to this house. In all houses in or near towns, roads, etc., work is caused on account of the dirty or dusty air which surrounds them. To supply rooms with filtered air would

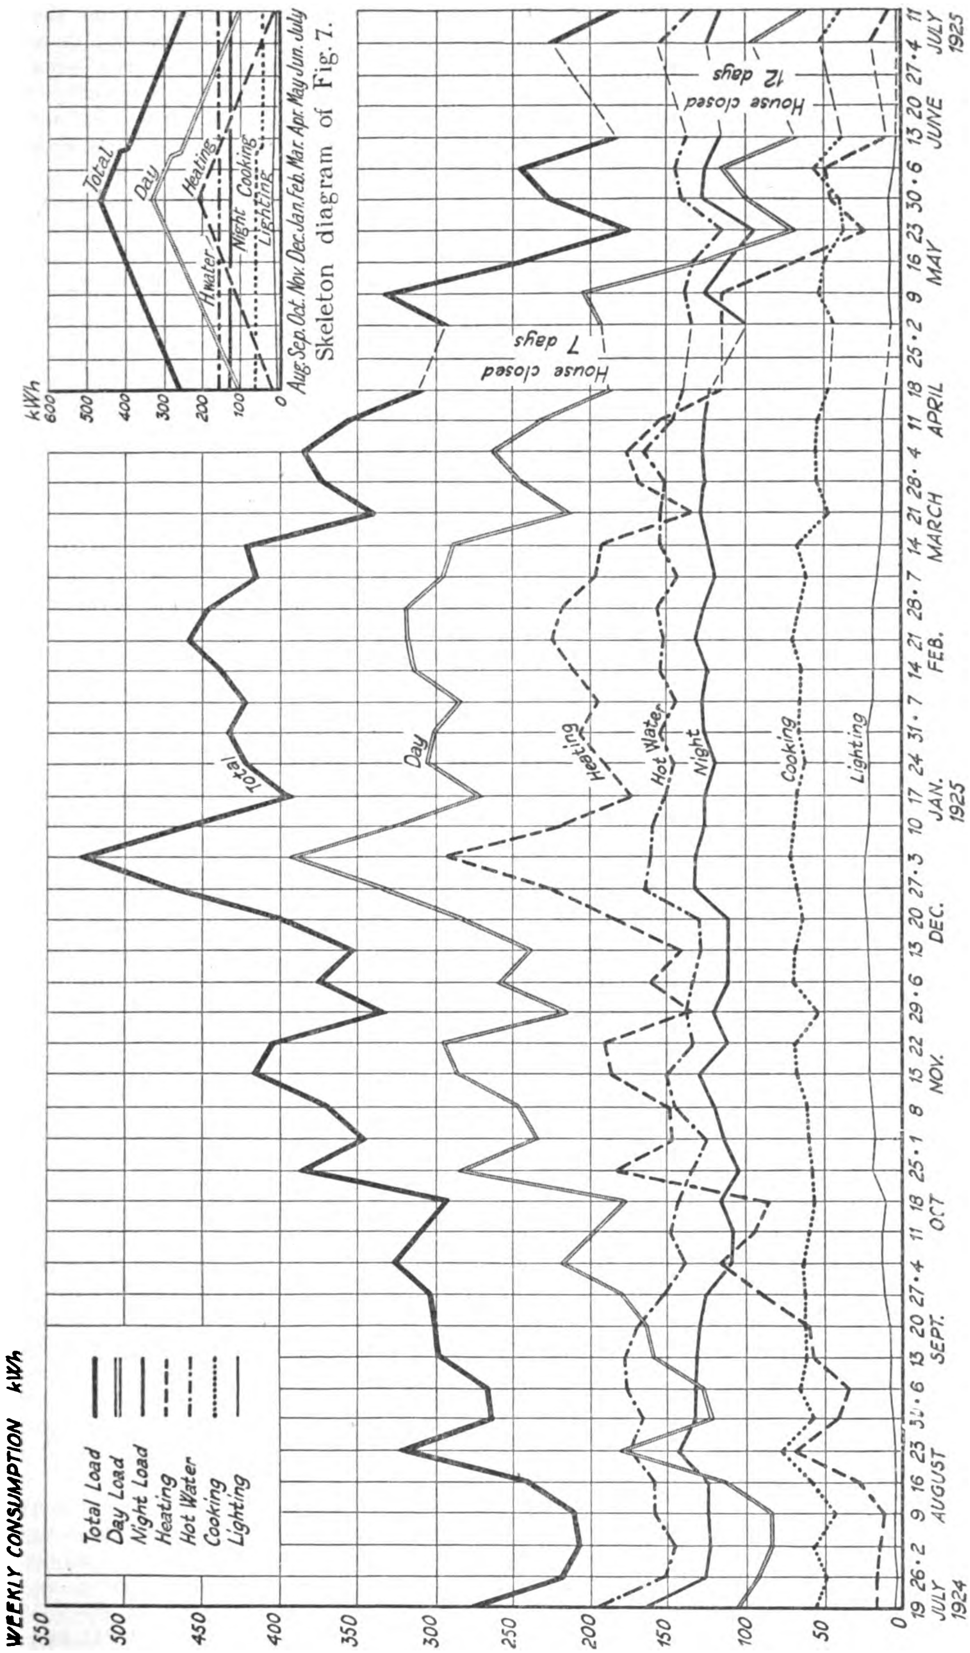

FIG. 7.—Weekly consumption in all-electric 10-roomed house for year 12 July, 1924, to 11 July, 1925.

entail forced ventilation; namely, a small fan, filter and ducts to lead clean air into the several rooms. If this method were adopted the air could, if necessary, be slightly warmed by passing it through a convector before it leaves the outlet channel. Provision has been made for the possibility of forced ventilation (e.g. circuit marked "Bst" in Fig. 4), but the full details have not yet been worked out, as the need has not arisen. It might be necessary to place the fan in the garage to prevent noise in the house.

If country areas were supplied with electricity at reasonable rates and local lines were electrified, this problem might not arise: at present the effects of our backwardness in air purification are keenly felt.

(10) Heating.

The question of heating by means of electricity is a fruitful subject for debate. Doubtless individual predilections have an important bearing on the decision arrived at. Broadly speaking, there are two alternative ways of heating to be considered, convection and radiation. In the former case the air is first warmed by means of air warmers (e.g. hot-water convectors, anthracite stoves, etc.). In the latter case persons are warmed by means of radiant heat (glowing fires—whether coal, gas, or electric).

The author discarded the former method of living in heated air as being inferior to the latter for the home. As is well known, the human body appreciates heat rays whether from the sun or from a glowing fire. Moreover, radiant heat is more pleasant in a cool than in a warm atmosphere, as is often experienced on a sunny day in winter, or in the morning and evening of a summer's day. The value of a coal, gas, or electric fire is determined mainly by the amount of heat radiated, and to a much less extent by the amount of convected heat (warmed air).

The electric fire renders it possible to obtain radiant heat in rooms with cool air, while owing to the portability of such fires the heat can be directed just where it is needed. Naturally, after a time the air becomes heated by the warmed objects in the room, etc., but the room can be kept cool by adequate ventilation. Experience shows that with ample radiant heat an air temperature of 50° to 55° F. is very comfortable; whereas with warmed air, 62° to 65° F. is desirable.

To obtain the best results from electric fires care must be used to have the heat where it is needed. In cold weather it is often much better to have two or three small fires suitably distributed in a room than even one large fire.

The fires for occasional heating—as in bedrooms, etc.—should be portable and, when in use, placed where they are needed, e.g. near the dressing-table, bed, etc.

As regards comfort, it has only to be mentioned that no difficulty or inconvenience of any kind has been experienced. The coal fire is not missed, while the ease with which the heat can be distributed and controlled is an advantage that would not be readily sacrificed when once enjoyed. The large number of attractive designs available render it possible to choose a fire that will harmonize with any style of decoration.

It is possible, of course, to make use of heat-storage stoves which can be switched on during the night hours. In the author's opinion, however, the disadvantages of such Dutch stoves—great bulk, weight and cost, and heating by convection—act decisively against them. Moreover, the radiator load in the home, though large, reaches its maximum in the evening, and thus occurs after the afternoon peaks during the winter; consequently the domestic heating load is not troublesome to the power station.

(11) Running Costs.

There are many features in an all-electric house, the value of which it is hard to appraise. Thus, saving in domestic labour, cleanliness, health, freedom from smoke or fumes, etc., may all have an actual money value, but on what is this value to be reckoned?

Then, again, what may be called the higher standard of living rendered possible by the many additional and genuine comforts and conveniences of electrical appliances has a real value. Nor would it be correct to put these down as mere luxuries—they become necessities in the same way as a water service.

Ignoring, however, for the sake of argument all these advantages, it is valuable to study the actual running costs of an all-electric house.

The figures in Tables 1, 2 and 3 set forth the consumption and costs for the above 10-roomed house for one complete year. It will be seen that heating, cooking, hot water and lighting have been separately metered. The small discrepancies between Tables 1 and 3 are to be accounted for by meter inaccuracies. The analysis in Table 3 is based on a total day consumption cost of £33 19s. 2d. divided in proportion to the day meter readings in Table 2. The curves in Fig. 7 represent the weekly consumptions of these items.

In order to compare the costs for a smaller all-electric house, the figures obtained by Mr. B. Hague for a four-roomed flat are given in an Appendix. Mr. Hague's charges are based on the same two-part tariff as the author's.

(12) Conclusions.

Costs.—The figures in the tables are of interest both to the supply engineer and to the consumer. For the consumer, the first question will probably be that of relative costs, apart from merits and demerits. Now, a true and fair comparison can scarcely be made unless corresponding costs are available for similar services obtained from coal, gas and electricity in some combination or other. Unfortunately, not many householders keep sufficient data to check their annual expenditure on coal, coke, anthracite, gas, oil, candles, firewood, matches, etc. A fair estimate can, however, be made when some of the smaller items are omitted, though there are doubtless many cases where it would be irksome to keep accurate accounts, e.g. where coal is purchased in small quantities. Nevertheless, such information is needful wherever fair comparisons are to be made. In the author's case, the all-electric house in Glasgow cost practically the same as a somewhat smaller house in Wimbledon in which coal, gas and electricity together cost £42 and £45 in two successive years. Here, however, much less hot water was obtained.

TABLE 1.

All-electric House (10 *Rooms*).

Lighting	1 16 7	8½	1	¼
Total ..	43 8 0	16 8	2 4½	4¾

In a slightly larger house in Helensburgh, using coal and gas, the costs were somewhat higher—varying from £58 to £44.

As a comparison with Mr. Hague's figure in the Appendix, it may be mentioned that a Glasgow bungalow with three persons using coal, gas and electricity cost £15 15s. per annum. In these cases the smaller items, such as firewood and matches, have been ignored.

Roughly speaking, the author would say that with energy at about one penny per unit and a low tariff for

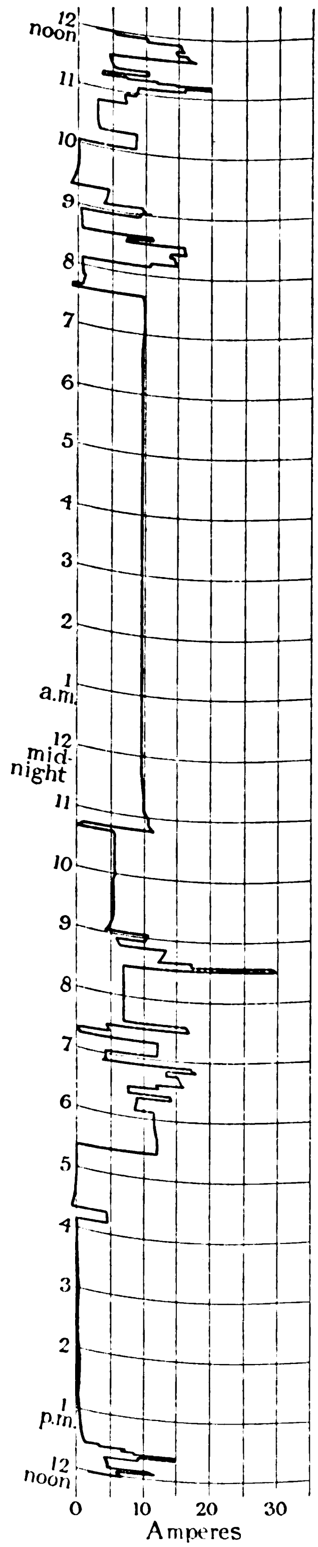

FIG. 8.—Load curve for Monday, 25th August, 1924.

Average height = 6·74 amps.

water heating there would seem to be very little difference between the cost of an all-electric house and the same house using coal, gas and electricity. Consequently, on the score of running cost, even when the manifold advantages of electricity are entirely ignored, the objection to the all-electric house herein described cannot be sustained.

The author would suggest that interested consumers should collect data to enable comparisons to be made with the figures in the tables.

Load factor.—The supply engineer fortunately can see at a glance how valuable is the load of an all-electric house. The hot-water and cooking loads are practically constant throughout the year and together form some 60 per cent of the total energy consumption. Moreover, a part of the constant load representing 36 per cent of the total load is taken at night-time. It is also interesting to see how unimportant lighting becomes both as a load and as a source of revenue when all services are worked electrically. Thus the all-electric house in question has an aggregate consumption of about 30 times the lighting consumption, and this practically without increase of station plant. An example of the daily load curve is shown in Fig. 8. This was taken by the Glasgow Corporation Electricity Department and represents the demand on a day when room-heating was practically restricted to the evening hours.

Reliability.—As regards reliability, it need only be said that as yet the service has not once failed.

Maintenance.—Upkeep should not be a serious item when cookers and fires can be hired and are kept in order by the supply undertaking. Actually, however, very few repairs or renewals are needful. Minor faults causing varying degrees of annoyance occur in electrical appliances, owing to faulty design or inspection in manufacture. Probably the weakest part of the installation is the flexible cord between the plug and the appliance. Makers might take note of these points.

Refuse disposal.—Careful observation has shown that by using a small, closed refuse-bin no nuisance of any kind whatsoever has resulted—the bin is emptied twice weekly, and refuse has never been less troublesome to the author than at present. It is difficult to see how garbage disposal can seriously affect the question, or even entail the use of an incinerator on the premises.

Boiler coal versus house coal.—An interesting point arises in connection with coal consumption. Dalmarnock generating station uses about 1·8 lb. of coal per unit generated. Assuming then, for the sake of argument, that a unit delivered at the house needs 2·24 lb. of coal, then 1 000 units require one ton. Consequently, between 16 and 17 tons of coal would be needed at Dalmarnock annually to supply the services of the above all-electric house. This amount of house coal—assuming that all services could be obtained from raw coal on the premises—would cost, let us say, £33, while the coal used at the station would cost less than half this amount. For the coal industry it is probably better to increase the demand for station coal rather than for house coal; while as regards convenience, etc., the householder will readily forgo the handling. That this mode of working a house entails a relatively large amount of coal is, apart from enhanced conveniences, essentially due to the inefficient method adopted for obtaining electrical energy.

Cooking.—The drop in cooking consumption seen in Fig. 7 is mainly due to lighter grids, raised elements, and blackening the bottoms of utensils. Increased efficiency means reduced cost—an important matter in the development of electric cooking. At the same time, indestructible elements are no less important. Speed and indestructibility are the ideals to aim at in the design of boiling-plates. The merits of separate utensils with built-in elements are receiving closer study.

Development.—Though domestic apparatus has now reached the stage when reliability can be guaranteed, much remains to be done. Manufacturers should aim at improving designs, avoiding inferior workmanship and careless assembly, and, above all, reducing the cost of domestic appliances. Backward supply undertakings throughout the country should mend their ways by reducing their charges for the domestic load and hiring out appliances on a commercial basis. Electrical contractors should encourage consumers as energetically to install appliances as to adopt electric lighting, and ensure that all wiring work is carried out in a conscientious and sound manner. Technical men should undertake researches relating to household appliances.

Advantages of an all-electric house.—The manifold advantages of the all-electric house will probably appeal chiefly to people whose habits are not inflexible and to innumerable small households where coal merely means drudgery. As regards cost, with electrical energy not exceeding 1d. or even 1½d. per unit overall, it would seem to be feasible, particularly where no maid is kept, to work large, medium or small houses electrically, though the cost of installation may remain a difficulty. Fortunately, this matter seems now to be receiving the sympathetic attention of supply undertakings, and it may therefore be not too presumptuous to look forward to a time in the near future when the full advantages of electricity in the home will be available to all. Among the advantages associated with electricity, cleanliness and health may well be emphasized. The absence of coal fires in a house like the one here described may make it possible to dispense with one domestic servant and thereby not only more than repay the total cost of the electrical energy, but also lighten the domestic labour problem. Equally, the improved health of the household and of the community, by eliminating smoke, is an inestimable benefit. Again, the rational mode of distributing and controlling heat is a great boon, Internal decorations seldom need renewal: cut flowers may last a month or even longer. Numerous minor luxuries become normal comforts and conveniences.

APPENDIX.

Results of an All-electric Flat.

(*Communicated by Mr. B. Hague, M.Sc., Associate Member.*)

The particulars and figures given in this Appendix refer to the past year's electric working of a tenement flat with three rooms and a kitchen in

the west end of Glasgow. These may be of interest since they demonstrate the possibility of utilizing the "all-electric" principle in a quite different type of dwelling from that described in the paper. Tenement flats are so common in Glasgow and the domestic smoke nuisance is so acute that the application of electric operation at economical rates to such property is a matter of considerable social importance.

The flat is situated at the top of the building, so that the bringing up of coal and the removal of ash present real problems. The household consisted of two persons and was run without a maid, but with the aid of occasional labour. In order to reduce to the absolute minimum all causes of domestic drudgery, it was decided to install electric appliances for lighting, heating, cooking, hot water, and auxiliary services.

One of the regular criticisms levelled at the abolition of the coal fire and the adoption of electric heating is

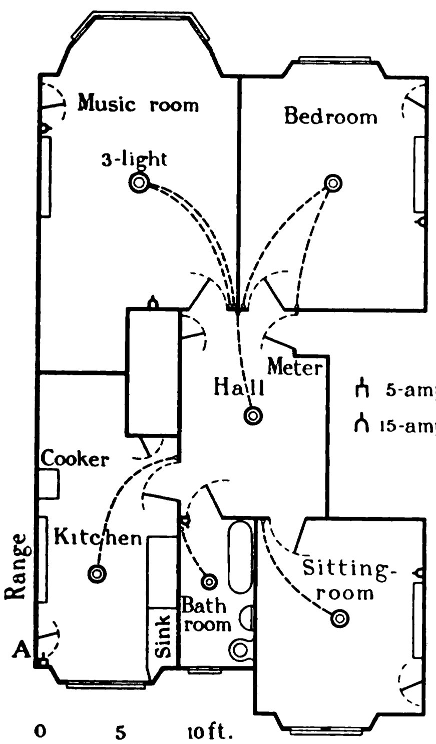

FIG. 9.—Plan of all-electric four-roomed flat.

that there is no place in which to incinerate household refuse. A little forethought and care have, however, overcome any difficulty in this connection.

Wiring.—The building in which the flat was situated is about 15 years old, and had not previously been wired for electric supply, and thus represents a case of conversion. Advantage was taken of the scheme of the Glasgow Corporation Electricity Department for the wiring of old property on the following basis: (1) The landlord bears the cost of installing the rising main from the street to all floors of the building. (2) The tenant pays for the installation in the particular flat occupied by him.

The charges are exceedingly moderate; in the case of the present installation £10 was charged for the wiring. Since the provisions of the scheme were inadequate for all-electric working, additional points and circuits were added to suit requirements; these were charged for as extras.

Fig. 9 shows a plan of the flat with the various circuits. The wiring is of lead-covered bonded cable throughout, the conductor being 7/·052 copper. The allocation of the circuits is as follows:—

Room	Supplied under scheme	Additional
Hall	Light pendant and switch	——
Bedroom ..	Single light and switch	Two-way switches for light. 15-amp. socket for fire
Music-room	3-light pendant with two switches. 15-amp. socket for fire	15-amp. socket for fire
Kitchen ..	Light pendant with switch. 5-amp. socket for iron	Wiring for cooker and immersion heater
Bathroom..	Light pendant and switch	15-amp. socket for fire
Sitting-room	Light pendant and switch	15-amp. socket for fire

Sockets throughout are B.E.S.A. Standard and, with the exception of the 5-amp. socket for the iron, are not provided with switches.

Supply.—Current is taken from the 250-volt d.c. supply of the Corporation Electricity Department. Since the economical use of electricity in houses depends so entirely on the fixing of a rate of charge sufficiently low to attract the domestic consumer, the question of tariffs may here again be considered. The choice of the correct rate is a matter determined by the annual demands of the consumer. The two schemes are as follows:—

(*a*) *Ordinary tariff.*—In this system, by which a certain number of units M are charged at $4\frac{1}{2}$d. per unit, and any excess number of units at $\frac{3}{4}$d. per unit, the cost for an annual consumption of X units will be $4{\cdot}5M + 0{\cdot}75\ (X - M)$ pence. For the flat in question M is fixed at 120 units, making

Annual cost in pence $= 450 + 0{\cdot}75X$, or

$$\text{Annual cost in £} = 1{\cdot}875 + \frac{X}{320} \quad . \quad . \quad (1)$$

The cost per unit in pence under this scheme will be:—

$$\left.\begin{aligned}\text{Cost per unit} &= \frac{450}{X} + 0{\cdot}75, \text{ when } X > 120 \text{ units}\\ &= 4\tfrac{1}{2}, \text{ when } X \lessgtr 120 \text{ units}\end{aligned}\right\} (2)$$

(*b*) *Two-part tariff.*—Under this system, a capital sum $£F$ is charged, approximately one-eighth of the annual rateable value, plus the cost of the entire consumption reckoned at $\frac{1}{2}$d. per unit. In the present house $F = £5{\cdot}2$, so that—

Annual cost, in pence = 1 248 + 0·5X, or

$$\text{Annual cost, in £} = 5{\cdot}2 + \frac{X}{480} \quad . \quad . \quad . \quad (3)$$

and

$$\text{Cost per unit, in pence} = \frac{1\,248}{X} + 0{\cdot}5. \quad (4)$$

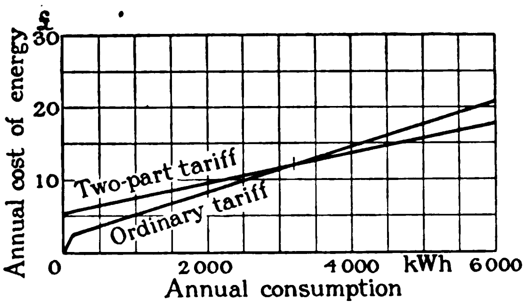

FIG. 10 (*a*).—Annual cost of energy at Glasgow rates.

Ordinary tariff:—4½d. per unit for 120 units and ¾d. per unit thereafter.
Two-part tariff:—Fixed charge of £5 4s. All energy at ½d. per unit.

In the present instance, the two methods of charging give identical annual costs for a consumption of 3 192 units. Fig. 10 (*a*) shows the graphs of Equations (1) and (3), from which it is seen that for a large domestic supply the two-part tariff is the cheaper of the two methods. This was accordingly adopted. Fig. 10 (*b*) shows the cost per unit in the two schemes, from Equations (2) and (4).

The following apparatus has been installed :—

Cooking.—Cooking is done on a 7-kW cooker hired from the Corporation at a charge of £1 for the first year and 10s. for subsequent years. The cooker is maintained in working order by the Corporation and is wired gratis. This appliance is of the customary type with a 2-kW oven surmounted by two boiling-plates, one of 2-kW and one of 1·5-kW loading, and a 1·5-kW griller. The oven and boiling-plates are provided with 3-heat switches.

The cooker has proved in every way satisfactory: the oven and griller are excellent; the boiling-plates, a little slow, are also satisfactory. It was found that

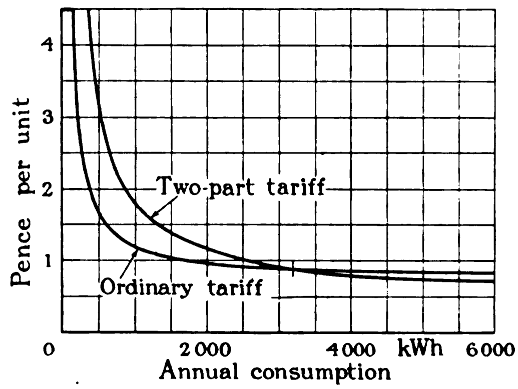

FIG. 10 (*b*).—Cost per unit at Glasgow rates.

there was no operation of cooking previously done on a gas cooker that could not be done equally well on the electric cooker, though sometimes a slight modification in culinary technique was necessary to enable the maximum of success to be attained. The certainty of results to be obtained by the use of the cooker has proved an invaluable asset to the housewife.

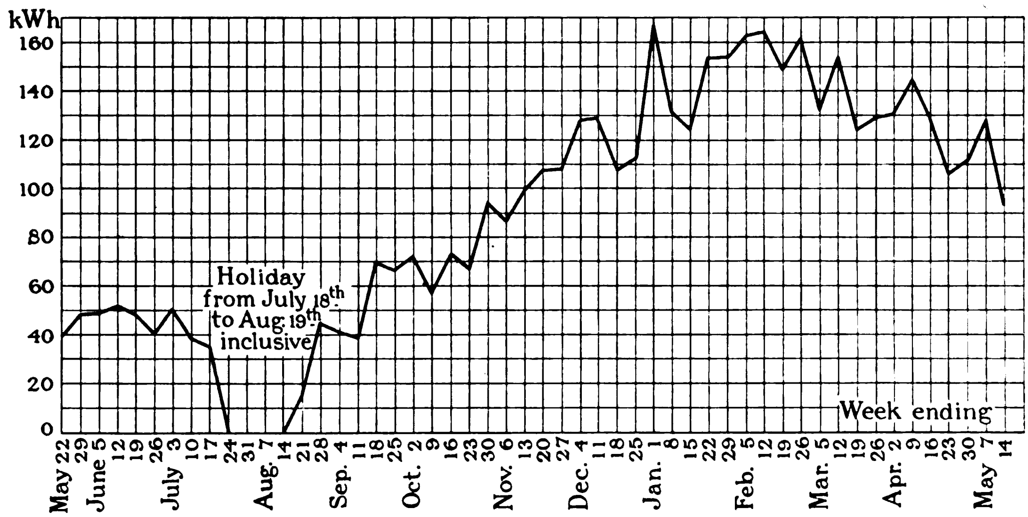

FIG. 11.—Weekly consumption in all-electric four-roomed flat, 22nd May, 1924, to 14th May, 1925.

Hot water.—Hot water for ordinary domestic purposes, cooking, washing-up, etc., has been satisfactorily supplied by a 3-pint kettle rated at 825 watts and hired with the cooker. This has been supplemented by a 2-pint, 575-watt kettle for additional purposes.

The provision of hot water on a larger scale for baths, and for such washing as is done at home, extra cleaning, etc., is made by the installation of a "High-low" 1–2–3-kW immersion heater. This heater is fitted in the hot-water tank of the household hot-water system, necessitating no more than the cutting of a

hole in the tank and the fitting of the flange for the reception of the element. The tank is situated above the cupboard in the kitchen at the place marked A in Fig. 9; the service pipes pass overhead directly to the sink and bathroom. The tank was specially lagged with a thick layer of hair felt; this and the shortness of the pipe-line make the thermal losses extremely low.

The heater has proved very satisfactory. The tank contains 22 gallons of water, which can be brought to a temperature of about 110° F. by the application of 3 kW for 1¼ to 1½ hour, according to the temperature of the cold feed.

Heating.—When the flat was first occupied, heating was done by one 2-kW and one 3-kW fire hired from the Corporation at 8s. and 12s. per annum respectively. A little experience, however, soon showed that it is best to use not one large heating unit but several small ones distributed about the room, and the 3-kW fire was therefore, later on, replaced by two 2-kW units. It has been found that the most satisfactory way of heating is to apply for a short time, say ½ hour, a high power, and then to reduce the power to the required amount. It is found that satisfactory ventilation can be obtained from the now unused fireplaces, combined with the judicious use of opened windows. It should be noted that the fires are *not* placed in the fire recesses, but are set out in the room where most required. For heating in bathroom, etc., a 750-watt bowl fire is used.

Results.—In presenting these results of a year's working, it is essential first to realize what the costs represent. They provided for a household of two persons (not counting guests and occasional labour), lighting, cooking of meals, hot water for domestic services and baths, heating of rooms (inclusive of occasional heating of bathroom and bedroom) and small auxiliary services. Only a single meter was provided, and this was read daily. No attempt has been made to allocate the consumption among the various items, but an analysis of the daily readings serves to verify the general conclusions given in the paper, viz.:—(1) Lighting is a small factor; (2) cooking is a fairly steady load; (3) heating is the cause of the greatest consumption and fluctuates greatly in response to seasonal variations of temperature.

The variation of weekly consumption throughout the year is shown in Fig. 11, and the energy costs are given in Table 4.

Conclusion.—It will be observed that the cost is reasonable, especially when it is remembered that no further charges for gas, coal, or any other heating or lighting material are involved. Beyond ordinary care to avoid waste, such as would be undertaken by any reasonably economical householder, no special care has been exercised.

One figure, often quoted in statistics of this nature, requires comment, namely the cost of energy per person per day. This figure in itself is a misleading criterion of the working of any scheme unless it is accompanied by a statement to show what services are rendered for the price. If the present household were increased to 3, in none of the services would the consumption increase in proportion to the larger number of persons. Hence the cost per head per day would fall roughly to perhaps three-quarters of the preceding figure for the same domestic facilities. Thus it will be seen that the cost per day is a truer criterion than the cost per day per person. This is also borne out by comparison between Tables 1 and 4, which show the cost per day per person to be practically the same, whereas the services in the larger house were greater than in the smaller house.

Finally, it remains to be mentioned that the supply was maintained by the Corporation with perfect continuity throughout the year. Maintenance has only been a slight item. In the year two boiling elements have been replaced in the cooker, and one lamp has burnt out—speaking well for the reliability of the apparatus installed.

TABLE 4.

All-electric Flat (4 Rooms).

Energy Costs for year ended 14th May, 1925.

Total consumption for year, 4 656 units.

Cost of energy at ⅛d. per unit			2 328d.
Fixed charge of £5·2			1 248d.
			3 576d.
	£	s.	d.
Total cost of energy	14	18	0
Average cost per week		5	9
Average cost per day			10
Average cost per day per person			5
Average cost of energy per unit			0·768d.

The cost of hiring the cooker and two fires was £2.

DISCUSSION BEFORE THE INSTITUTION, 3 DECEMBER, 1925.

Colonel R. E. Crompton: During the last 30 years of the period which has elapsed since we began to use electricity for lighting purposes, at first in detached installations and in or about 1889 by putting down central stations for supply, I have had before me the immense advantages of trying to persuade users to adopt electricity for heating, cooking and as a domestic source of power, so as to raise the load factor of a purely residential district from that due to lighting—which used to be as low as 10—to a hoped-for figure of 25. We in London have already taken a substantial step forward; the load factor has, even in the purely residential districts, already risen, due to its use for heating and cooking, to about 20 or thereabouts, and this has had a material effect in reducing the average price to the public. I therefore welcome the paper as a practical addition to our knowledge of what can be done, if and when electricity can be supplied as cheaply as has apparently been the case in Glasgow. I think that the Glasgow Corporation were quite right in quoting the author specially low prices, but I am afraid that in London at any rate there is little chance of reaching

such figures. It is fortunate that the author was able to show considerable designing power as an engineer, and he is to be congratulated on the excellent results which he has obtained. He refers to the undoubted fact that in the past there has been far too much imitation; the gas fire has imitated the coal fire, and the electric fire has imitated the gas fire, and even the author has, as the lantern slides show, been impressed by the tradition that he must show a fireplace as a means of heating a room by radiation. I personally have for many years been trying to find out how electricity can be used to the best advantage for heating, in order that I might have reasonable arguments to put before our customers to induce them to adopt electrical heating and cooking. A very strong case can be made out for heating by radiation from electric radiators placed close to the person who has to be warmed. A very small radiator placed near a person working in an office will enable him to work in comfort in a room otherwise far too cold for his health or comfort. In the bedroom this is even more the case. Although I am an old man and require artificial heat much more than younger persons do, I found that in the recent cold snap when the air of my bedroom was at 40° F. or thereabouts I could obtain absolute comfort by a radiator which was placed conveniently near to my bedside and could be moved close to the dressing-table when I got up to dress. As this radiator is only on for very few half-hours the cost, even at the London price of 1¼d. per unit, is ridiculously low and is actually far less than the cost of warming the same bedroom by central heating or by a gas fire. But at the present time we *must* take advantage of the convenience and portability of our radiating units. In London we should be able to show little or no advantage if we retained the traditional fireplace, but with a portable heater the case is very different. In the case of electric cooking we can show great advantages over gas cookers; all roasting and similar processes done in the oven by gas are carried out by radiation from gas flames, the oven must therefore be thoroughly ventilated and a calorific loss follows thereon, whereas with an electric oven there need be no ventilation, and the flavour of the meat is retained so that meat and game cooked electrically are distinctly superior, as regards flavour and economy of the meat juices, to anything possible in the best-designed gas cookers. The author has put very valuable facts and data before us, which will be of great use to all who are trying to forward the cause of electric heating and cooking.

Dr. S. Z. de Ferranti: The outstanding feature of the paper is the faith which the author has had. Faith in this case has enabled him to produce an installation which is of very great value. It has also enabled him to equip his home in such a way that he will live with a much greater degree of material comfort than he could possibly have done if he had not carried out the work so thoroughly. My experience is that the greatest disadvantage of an all-electric house is that there is nowhere to throw those odds and ends that would ordinarily be thrown on the fire. In my case we have had to install a refuse destructor at some distance from the house. To come to a most important feature, the author has explained the desirability of heating by radiation. Heating plays a very big part in any system of satisfactory house equipment, and it is all-essential to heat by radiation; every process which heats up the air in a room is unsatisfactory. What we want to do is to live in a comparatively cold atmosphere and to be kept warm by radiant heat. In Switzerland one lives all day out in the open in winter time in an atmosphere many degrees below freezing point, and yet one is perfectly warm so long as one keeps in the sun. Living in hot air has an enervating effect, and I understand from doctors that the lungs require a fair amount of comparatively cold air to keep them in good condition. Electricity gives us radiant heat in the best form. As may be gathered from the paper, the heating in the author's house is provided by radiant electric fires which do not appreciably heat the atmosphere but which heat the occupants of the rooms. The author says that it is not his business whether the Glasgow Corporation makes a profit or not, but I think it is a matter of national importance. Nothing should be run at a loss. My opinion is that there is no question that the Glasgow Corporation is making a profit on this business. The chief engineer is a business man and knows perfectly well what he is doing in encouraging the author to make his home an all-electric house. Unfortunately, electricity is very dear in many places. There are various reasons for this, the principal being the small extent of the business. Again, there is the poor load factor—i.e. the short hours during which the capital is utilized—and, especially in London, the excessive rating of supply undertakings. All these difficulties could be very largely overcome if electricity were used for the whole of the 24 hours. That is the commercial solution: let better advantage be taken of the present capital. Our great handicap in electrical work is that we have no efficient means of storing electricity. Batteries store it perfectly well by chemical action, but the capital cost is heavy and the maintenance cost is also heavy, and it would not pay, I think, for every house to have a battery to take electricity for the whole 24 hours and to use it at the times that it is required. Fortunately, however, a large amount of the heat we require in a house is low-grade heat, and that we can store in the form of hot water. Hot water is a very cheap form of energy storage and, as pointed out in the paper, the provision of a large water tank enables electricity to be taken at a time when it has practically no value—when the capital invested is practically lying dead—and turned to good account by storing energy in the form of hot water which is used at any time during the rest of the 24 hours. I think that further development along these lines will do much in the way of solving our electrical difficulties. The particular house described in the paper cost £43 a year for current, and at that rate, as I have said before, I think it pays the Glasgow Corporation very well. This £43, in my opinion, is not nearly the value of the service which the author gets from the supply. If he were to try to run his house without electricity, by other means, he would not spend much—if anything—less on the direct services that he has described, but all sorts of other expenses would be involved which, I think, would mount up to several

times what his electricity bill comes to to-day. I should like to add a few words with regard to my own experience of an electric house. I live 13 miles from the nearest source of supply, Sheffield, and some years ago I put an electric installation into the house. This installation has been modified from time to time, and is at present not complete, although now, and in fact for the past 6 months, we have had no fires in or near the house for any purpose. We burn no coal or coke, and use no gas. We burn crude oil in a 25 h.p. engine. Our maximum load up to the present has been 18 kW. This is at a time when the battery is assisting the engine. The whole or a very large portion of the heat of the jacket water and of the exhaust is used to supply the hot-water storage in the house. In a case of this kind probably about 25 per cent of the fuel energy is obtained in the form of electricity, and the jacket water and the exhaust would probably add another 50 per cent. I have a storage battery containing, I think, about 2 tons of lead, and the hot-water storage is a tank in the basement 6 ft. in diameter and 6 ft. 6 in. long, with about 6 in. of insulation. This tank holds about 6 tons of hot water. We therefore store our energy in about 2 tons of lead—the electrical part—and 6 tons of water—the low-grade heat storage. The capital cost of hot-water storage is of course much less than that of direct electrical storage. We find that with this particular plant we get all the hot water that we require for baths and washing and house-heating. The system of heating the house is in accordance with what I have already said on that subject, i.e. it is true heating by radiation. All the principal rooms have invisible panels in the ceiling, consisting of pipes bedded in the plaster below the surface. The general heating is therefore taken care of by radiation at low temperature from the ceilings of all the principal rooms, and not by heating the air by convectors, which are wrongly called radiators. The reason for placing the panels in the ceiling is that they shall not heat up the air; the idea is to have in the top of every room a layer of stagnant hot air which keeps the surface of the ceiling reasonably warm, i.e. which does not take away by convection from the heat in the ceilings. The heating is produced by radiation at low temperature from the warm surfaces. The temperature at the surface of the ceiling, where one wants the heating, is 110°–120° F. The high-grade radiant heat is produced by electric radiators. Every room has one or more electric radiators of various kinds in it. The heat efficiency of the whole installation is extremely high; I think that something over 75 per cent of the heat in the oil is usefully employed in one form or another in the house from the high-temperature form of light to the low-temperature form of low-grade heat radiation. It is interesting also because of its bearing on the true all-electric house such as that described in the paper. I feel that by one process or another we must find means to enable the population of the country to do all its work electrically. The advantages of a clear atmosphere are enormous. At present we have done everything we can to shut the sun out from our lives, and notwithstanding our electrical developments we are still making much more smoke than is justified.

Miss C. Haslett: It seems to me that now the electrical engineer has done so much in bringing domestic electricity to its present stage the time has arrived when it is impossible to go very much further without taking into consideration the woman's point of view. I think also that one must not regard electricity supply simply as a trade or a profession, but as a great social service. As the author has said, it is part of the duty of the electrical engineer to see that the community benefits to the greatest possible extent from this tremendous force which we have at our disposal. In any case, I think that electricity will be used more and more, if only on account of the fact that the days of a cheap supply of domestic labour are gone. In the past we could get almost all our domestic work done extremely cheaply, but now we have to face the fact that human energy must be replaced in the home by some form of mechanical energy. Another factor which I think will materially alter the whole idea of home life so far as work is concerned is that women are being trained to run their homes much more efficiently than they were in the past. Women will no longer be content with inefficient methods and long, arduous duties. Another reason why electricity will be used more and more in the home is that people are becoming more and more impatient of the prevailing smoke nuisance. I think, however, that certain facts will have to be faced before a general use of domestic electricity is established to any large extent. The public at the moment—and especially the women—believe that electricity is very expensive. That, of course, is still true in a good many places, but women must be led to understand that although electricity does seem expensive they will reap the results in increased comfort, in better health, in greater leisure and in many other ways. Women in general also have an idea that electricity is rather difficult to manage. Unless that belief is got rid of it will be impossible to make much progress; a campaign of educational work is required to tell the public how simple and easy it is to use electricity in the home. I do not think that the author has sufficiently stressed the fact that in order that electricity may become the friend of the community a much greater maintenance service is needed than has as yet been contemplated. Not only must any fault be promptly remedied, but an inspection of the apparatus in the home should be made by someone who will take a great interest in the whole installation so that the woman will feel she has a confidant to whom she can look for advice. I do not think the problem of refuse disposal presents a really serious obstacle. It seems to me that we have become used to throwing things into the fire, and it is rather a bad habit. It is more a custom that we have to get over than a real difficulty. In my own small electric flat I have no fire at all, but I do not find any difficulty in getting rid of my refuse. The author mentioned cooking utensils with built-in elements as a thing which might develop in future. The system has certainly many advantages, but I fear that it will tend to increase the number of utensils which a woman has to buy and accommodate. In these days of small flats the best use possible must be made of all the available space, and for that reason, and also from the point of view of cost, I do not think there is a great deal in that idea. With

regard to appliances, whilst women are very grateful to the engineer for what he has done up to the present, I think that there is room for much improvement. On that question also I think that the woman's point of view will have to be studied. She is the person who uses this apparatus, and is thus in a position to find out a number of things which could be improved. A good deal has been said as to the high cost of electricity in London, but Marylebone, at any rate, is to be congratulated on its enterprise. After paying a very small yearly sum down—I am on what is called the "telephone" system—I get all my current at ⅜d. per unit, including lighting.

Prof. A. H. Barker: The particulars of this all-electric house are of great interest, but the author does not give all those which one might have wished, such as the position and sizes of the windows, the thicknesses of the walls, the experimentally determined heat-loss coefficient of the various rooms, the internal temperatures maintained, the habits of the occupants and so forth, on which the total consumption necessarily depends. I have deduced by calculations from the small-scale figures and particulars given as many of these details as possible. It is not quite clear whether this paper is intended to advocate the general use of the all-electric house. There are in it indications that other persons interested in the electrical industry have advised the author against the proposal as being uneconomical. The impression is conveyed that the author believes the all-electric idea to be generally feasible and in this case economical. If that is his view I do not agree with him at all. I have frequently expressed the opinion that if electricity could be supplied for such purposes as heating and other domestic duties at a really cheap rate, and if the manufacturers would rise to the level of their opportunities, there is no other form of heat either for house-warming, cooking or perhaps even hot-water supply which could compete with it. But, as things are, I believe that the use of electricity for all purposes in a house is in the overwhelming majority of cases an economic impossibility, except where running cost is of practically no account. The figures given here do not seem at first sight to bear out that opinion. Any figures of cost given with reference to any particularly low rate per unit or house or family must of necessity be somewhat misleading. It would certainly be most misleading to give the public the impression that they could run a 10-roomed house on electricity only for something like £40 or £50 a year. Advocacy of an all-coal house, all-gas house, or especially an all-electric house, appears to me to savour, I will not say of fanaticism, but at any rate of unrestrained enthusiasm. There are some things for which gas or solid fuel is obviously more suited than electricity—there are others for which the superiority of electricity is equally unquestionable. Why do not the electric people and the gas people get together and attack this problem in conjunction without prejudice against one another? I should like to discuss the question very briefly from the point of view of the destruction of fuel at the power station. The most efficient fuel-burning super-power station in the world is, I believe, the new Manchester station. It has a gross thermal efficiency of less than 20 per cent; in other words the electrical energy generated is only one-fifth of the energy of the coal from which it is produced. Now, even assuming that the efficiency of every electrical device in the house could be made 100 per cent—of course the actual efficiency does not nearly approach this—the general efficiency of an electric house is therefore limited to a possible 20 per cent, based on the coal consumed. The actual efficiency in any concrete case is lower than this, being in fact the product of the two efficiencies of production of energy and that of its use. Almost any form of reasonably efficient coal-burning domestic appliance has a higher efficiency than 20 per cent. For central heating and hot-water supply it is at least 50 per cent. The gas industry can put 80 per cent of the energy in the coal into the mains. The general efficiency of most gas-heating devices is rarely below 50 per cent, so that as far as fuel alone is concerned the gas industry uses half the coal which is consumed in doing the same work electrically. The fact is that until the thermal efficiency of electric stations can be made much higher than 20 per cent the general use of electricity for all purposes is and must remain uneconomic. It further appears impossible that if cost alone is considered an all-electric house can in practice generally be a really economical proposition, even at ½d. per unit, because there are other methods of heating (such as gas) which are almost as convenient as electricity and generally much cheaper but which have certain disadvantages which electricity has not. For instance, compare the cost of hot-water supply at 11d. per therm with electricity at 2d. per unit and coke at 35s. per ton, which are the prices I am now paying in Beckenham. The calculated cost of heating the author's 87-gallon tank from 60° F. to 160° F., i.e. 87 000 B.Th.U., would be roughly as follows, excluding heat losses:—With electricity at 2d.—52d.; with electricity at ½d.—13d.; with gas at 11d. per therm—13d.; and with coke at 35s. per ton—3½d. I know of no disadvantages of gas supply which would justify anybody in paying four times as much for electricity, neither do I think that the disadvantages of coke-heated supply are such as to justify any economically minded person in paying four times as much for electricity or gas as for coke. Further, with either gas or coke one could heat up such a tank in an hour, whilst with electricity the time would be more nearly 10 hours, so that the electrical heat losses would be 10 times as great. Then, again, is there anybody who has lived in a house reasonably warmed but not overheated (as many houses are) by well-designed hot-water apparatus who would for one moment compare the comfort of such a building with that of one heated by a few electric radiators switched on and off as required? If this 16 000 cub. ft. house of the author's had been heated in this way by electrical energy throughout a normal winter season he would have used not 5 954 but 26 500 units, which would have cost him £55, even at ½d. per unit. Coke to do the same duty would have cost £12, which is exactly what my house costs me, and my house is a good deal larger. I deprecate the publication of figures of cost based on any particular rate, especially such a rate as the ⅜d. or ½d. per unit. One can make the figures just what one likes by assuming

particular rates, and there are very few districts where one can get anything like such a rate. My view of all these matters is that any figures of consumption should only be given in the form not of money cost but of total B.Th.U., per annum and per person, expended in producing the various services. We can then calculate the total cost corresponding to any particular rate per unit and any particular efficiency of plant. The total consumption of electrical or any other energy is obviously a function of the size of the house, the degree to which the house is heated, the efficiency and arrangement of the various parts of the plant, the number of persons, their domestic habits and a multitude of other things. The total cost is obviously proportional to the total consumption and to the rate per unit. The variation between two different families occupying in succession the same house or of the same family occupying two different houses in different districts would be very great. It is not too much to say that the same house occupied in a different way may vary 500 per cent in respect of the amount of heat required for warming it. Similar variations exist for cooking. The hot-water supply is equally variable. In fact the habits of each person determines largely what his total consumption of heat will be. What, then, is the object in giving particulars of one case only unless one also gives elaborate details of the way the apparatus is used? I tried in a book I wrote some few years ago, called "Domestic Fuel Consumption," to give an estimate of the amount of heat required by the average man for the several purposes in a year. How variable and uncertain any such estimates must of necessity be can be judged from the fact that a human being can easily get along in reasonable comfort, even in cold weather, without any heat supply whatever. I say this with confidence because I have myself done it. It has been most interesting to compare the figures given in this paper with my own estimate based only on a knowledge of the efficiencies of the various parts of the plant and on observations of the habits of the ordinary normal person. I give in Table A that comparison. The figures in cols. 1 and 2 are taken from my book. The other figures in the table are partly the author's and partly some obtained from very prolonged and extensive experiments of my own on various classes of buildings. The various items are calculated as follows:—The figures taken from my book were an estimate the basis of which is described at length in that publication. The figures derived from my own experiments were calculated as follows. The actual number of cubic feet of gas used for the several purposes throughout a year were observed by a special gas meter. The figure multiplied by the value of the gas and by the actual efficiency of the apparatus in use as previously determined in the laboratory gives the figures shown in the table. In the figures relating to "cooking" there were some corrections to make on account of the circumstance that the meter controlling the cooking-plant was also used for other boiling and water-heating purposes. The figures were derived from Prof. Smith's figures in the same way by determining the total heat in the electricity used and multiplying by an assumed value of the efficiency based on experiments on electrical cookers, etc., in my own laboratory. It is obvious that from such figures any person can calculate exactly what should be his cost per annum for electricity, gas, coke or any other means of heating, provided he knows his personal equation and that of his house, the price per unit and what is the efficiency of his cook and of the various parts of the plant which he is going to use. These questions of efficiency and rates per unit are at the root of the whole problem of cost; without them the whole question is in the air. One might as well try to lay down the weekly cost of food for one person. It depends on what he eats and how much he eats. It must be obvious, too, that the most economical results can only be obtained by determining in detail what is the most economical method of dealing with each separate item of consumption in the house, having regard to all the pertinent conditions. As the result of tests at my house I have come to the conclusion that the best combination for practical cooking purposes is a gas hot-plate and electric oven with a gas preheater or booster for the oven. Such a

TABLE A.

Net B.Th.U. used per person per annum.

	Prof. Barker's estimate (From "Domestic Fuel Consumption")		From Prof. Barker's experiments (one person living alone)	From Prof. Smith's figures	From Mr. B. Hague's figure
	Well-to-do person	Artisan			
	B.Th.U.	B.Th.U.	B.Th.U.	B.Th.U.	B.Th.U.
Heating	3 000 000	1 000 000	4 500 000	3 400 000	—
Hot-water supply and laundry ..	8 000 000	2 000 000	2 100 000	4 150 000	—
Cooking	400 000	180 000	800 000	474 000	—
Total	11 400 000	3 180 000	7 400 000	8 024 000	6 100 000

combination is, of course, impossible in an ordinary household, nevertheless a range in which the peculiar features of gas and electricity were both utilized would be immensely more valuable than either a gas or an electric cooker. An all-electric or all-gas cooking range is in my view much inferior to a combined one. Much more is this the case in a whole house. I regularly use in my own house electricity, gas, coke and coal for heating, solid fuel and gas for hot-water supply, and electricity, gas and solid fuel for cooking. I am sure that everybody who wants the best and most economical results would do the same if he had the chance. The general plan of my experiments has been somewhat as follows. I have the control of a well-equipped laboratory especially designed for making these experiments. I have taken the whole of the plant with which I have been concerned and have put them through as thorough a test as I knew how to make in the laboratory. After the completion of these tests I have these appliances transferred to experimental cottages which have been placed at my service by the London County Council and have equipped several of these in different ways so that the amount of fuel consumed can be accurately measured. I have taken readings for many years, and I have a vast mass of data and of readings which I am now endeavouring to co-ordinate.

Major E. O. Henrici: As my house in the London area seems very comparable in size with the house described in such detail, some figures from my experience may be useful as a comparison. The house is an old one, and the number of persons in the house varies, being generally seven or eight. The only coal used is in the kitchen range, and in an anthracite stove in the drawing-room (this is convenient, though not ideal by any means). Practically all other rooms have gas fires, and there is a gas cooker. Lighting is entirely by electricity, whilst an electric iron and a vacuum cleaner are run from the lighting circuit. The appliances are not of the most modern description—the lagging of the hot-water system is anything but efficient—and I have no doubt that the running costs could be considerably reduced by installing a coke boiler and a more modern gas cooker and scrapping the kitchen range. I have not, however, felt disposed to incur the capital expenditure involved in modernizing the arrangements. I have recently completed three years in the house, and the total running expenditure on heating and lighting for the three years ended Michaelmas 1925 has been £150, or an average of £50 per annum. This includes cost of repairs, lamp renewals, kindling, matches, etc., but does not allow for purchase and fitting of gas stoves, or any capital charges. The price of gas has varied between 9·8d. and 11d. a therm, and there is also a quarterly charge of 2s. for meter, and 6s. 1d. for hire of certain fires (the other fires are my property). These charges are included in the total expenditure for gas. Electricity cost 5d. a unit for the first two quarters, and thereafter 4½d. In both cases there is a charge of 2s. 6d. a quarter for meter rent. There is an alternative tariff available of 10 per cent on the rateable value, plus 1½d. per unit. The figures in Table B give my expenditure for each of the three years.

TABLE B.

Year ending Michaelmas	Gas				Electricity				Coal	Coal and miscellaneous cost			Total cost		
	Therms	Cost			Units	Cost									
		£	s.	d.	kWh	£	s.	d.	tons	£	s.	d.	£	s.	d.
1923	310	15	13	2	386	8	6	1	—	23	15	0	47	14	3
1924	428	19	2	3	430	8	11	3	—	25	8	6	53	2	0
1925	378	17	5	7	466	9	4	9	—	23	0	9	49	11	1
Total	1 116	£52	1	0	1 282	£26	2	1	25*	£72	4	3	£150	7	4
Average	372	£17	7	0	427	£8	14	0	8	£24	1	5	£50	2	5

* Of the 25 tons of coal 3 tons were anthracite. The 25 tons is the amount purchased. Between 1 and 2 tons was in stock at the end of the period.

The figures under gas and electricity are those paid to the undertakings, and do not include lamp renewals, etc. The total electricity used was 1 282 kWh, or an average of 427 per annum. This is less than the lighting figure given in the paper, but the difference may be accounted for by the difference in latitude of London and Glasgow. It will be seen from this that my figures for a year's expenses are about £6 higher than those given in the paper, but they include lamp renewals, matches, etc., which the author's do not. It is also worth remarking that with the tariff now in force in my district (Barnes Urban District Council) the cost of the energy used by the author would have been over £100 per annum. I have not inquired whether a special rate would be charged for a night load. I have made an estimate of the coal consumed in heating the house, whether consumed in the house or gasworks, and in my case it works out at between 9 and 10 tons, whilst in

the Glasgow case it is about 17 tons. The coal used in the generating station is, of course, of a cheaper quality than that used in the gasworks or in the house. During the winter almost the whole of the gas consumed in my house is used for "heating" and very little for cooking, and from my figures for December 1924 and January 1925 (nine weeks) I get a consumption of about 10 therms a week of gas, plus 11 therms a week of anthracite for heating my house. The corresponding Glasgow figure is 200 units, or about 7 therms, showing apparently that electrical heating is about 3 times as efficient in a thermal sense (counting from the energy brought into the house) as my particular combination of gas and anthracite. Comparisons of this sort must, however, not be taken too seriously, as so many factors vary in different houses. Generally speaking, it would appear that the cost of electric cooking and heating becomes comparable with that of gas plus coal when current can be obtained at ½d. a unit or less. Water-heating would appear to compare with an ordinary kitchen boiler at about 0·3d. a unit, but even at this price I am afraid it would not compare with a modern independent coke boiler and an efficiently lagged hot-water system. It would be interesting to know more about the capital cost of the installation in the author's house, and of the various appliances for cooking, heating, etc. Whilst there would certainly be a saving of labour were I to change to "all electric," the saving would not be very great, and would not be sufficient to enable any reduction to be made in the wages bill.

Dr. Margaret Fishenden: The paper enables very valuable practical comparisons of the costs of different methods of providing for domestic heating and cooking requirements to be arrived at. I do not propose to refer to lighting, as I believe it may be taken for granted that at anything like a reasonable tariff most householders would prefer electricity to gas for this purpose. The total cost of the energy used for all purposes in the author's 10-roomed all-electric house in a year's working was £43 8s., as compared with averages of £43 10s. for a slightly smaller house using coal, gas and electricity, and £51 for a slightly larger house using coal and gas—say a mean value of about £47. Major Henrici has shown that in a house closely comparable with that of the author's, but equipped with an old-fashioned kitchen range and back-boiler, a gas cooker, gas fires and an anthracite stove, the total cost of fuel and lighting, after deducting rent for meters and fires, was about £48 per annum, of which gas accounted for £15 15s., electricity for £8 4s., and coal, etc., for £24. In my own 10-roomed house, which is again dependent upon an old-fashioned kitchener with back-boiler for hot-water supply, but which has a coke-fired boiler feeding radiators in the hall and on the first landing, one open sitting-room grate burning coal, gas fires, a gas cooker and a small gas boiler, the bill for fuel and electricity has averaged about £44 for the past 2 years. Gas has cost £8, electricity (for lighting and one iron) £9, coal £22 and coke £5 per year. There are five people in the house. Whilst the figures quoted obviously depend upon the prices paid for the various fuels used, they are, without going into further detail, sufficient to show that where such tariffs for electricity as that available in Glasgow are offered to the domestic consumer, a house of moderate size can, with care, be run on electricity alone at a cost not exceeding that of coal, gas and electricity as ordinarily used. On the other hand, it shows equally clearly that electricity at prices exceeding 1d. per unit would be quite out of the running. These comparisons are with houses using coal-fired kitcheners with back-boilers for hot-water supply, a type of installation well known to be extravagant for establishments of the class under consideration, and although the total bill for electricity which has been quoted is no heavier than that of fuel in a good many houses where electricity is not used, except perhaps for lighting, it can be shown that by the substitution of more up-to-date appliances considerable reductions might be effected, especially in the cost of water-heating. When considerable quantities of hot water are required, an independent coke-fired boiler is generally the cheapest means of producing it. The cost of potential heat units in electricity at 0·44d. per unit, which is the very low price paid by the author for water-heating, is about 7½ times those in coke at 40s. per ton. Small independent boilers, as a rule, yield a water-heating efficiency of some 45 per cent, and even if an efficiency of 100 per cent is allowed for electric appliances they remain, on the basis of equal hot-water production, about 3½ times as dear as coke. In other words, the author's bill of £13 8s. 10d. for electricity might have been replaced by one of less than £4 for coke, a saving of more than £9 per annum. Normally there would be heavy storage losses due to inadequate insulation of pipes and cylinders, which would increase the amount of coke necessary, but such losses would apply equally to water heated electrically, especially overnight, were not special steps taken to prevent them. It is, however, a drawback of the coke-fired boiler that difficulty may be experienced in maintaining combustion at the minimum rate requisite. In this case, for instance, about 12 lb. of coke per day would produce sufficient hot water, and it is doubtful whether combustion could be maintained continuously at so low a rate. The fire could, of course, be run intermittently, which would mean increased labour and lessened convenience; or, alternatively, an extra amount of coke might be burned, and hot water used more freely. Even at double the consumption, which certainly need not be exceeded, there would be a saving of nearly £5 per year in comparison with electricity, and twice as much hot water available. This might be utilized for heating a radiator. For cooking purposes, if electricity at ½d. per unit is to compete in cost with gas at 9d. per therm, it must be used with about 60 per cent higher efficiency. The Gas Standardization Committee estimated that four times as much gas was used on the hot-plate as in the oven. There seems to be no reason why the proportion should be different for an electric cooker. Many tests have shown that well-designed and properly adjusted gas-rings will give an efficiency of 50 per cent in water-heating. On the prices quoted, electricity at 80 per cent efficiency would cost no more than gas. Self-contained kettles meet this condition, but the efficiency of the best types of commercial electric hot-plates is probably nearer 60 per cent. The author speaks of

efficiencies so low as 20–25 per cent, starting from cold, but these would appear to be unusually low. Dr. Fleming, in 1911, gave corresponding values of 46–47 per cent, the Swiss Association of Electrical Engineers 40–65 per cent and the Hotpoint Company 33–61 per cent, according to the type of hot-plate and cooking utensil used. For continuous use much higher values were of course obtained. If we take 60 per cent for electrically-heated and 45 per cent for gas-heated appliances, for hot-plate work electricity would be rather dearer than gas. On the other hand, however, electric ovens are, or ought to be, far more efficient than gas ovens, and for all-round cooking purposes electricity at ½d. per unit can probably hold its own against gas at 9d. per therm. For heating requirements there is no doubt that the portability of electric appliances is often a great advantage. The low amount of energy which sufficed for the heating of the author's house appears to afford an example of this. Heating may be considered in relation to (*a*) the entire house, (*b*) a single room, or (*c*) the occupants themselves. Practically all the heat which a fire or heater emits is ultimately used in warming one part or another of the house and its contents. But an amount of heat which would be totally inadequate to warm a whole house to a comfortable temperature might yet, if generated in, or led to, the right place, suffice to warm a single room; and an amount of radiant heat too small to bring a room to a comfortable temperature throughout might yet warm occupants situated directly in its path. For the further away from a fire are the occupants of a room, the less is the intensity of the radiation falling upon them; and the fact that an electric heater can be placed where desired, and moved as convenient, results in its practical effect being magnified as compared with a heater giving similar emission at a greater distance away. No one would contend that electricity is suitable for central heating; for the individual needs of a small family, the author's experience would appear to show that at ½d. per unit it can compete successfully with other methods. In the six months of heaviest consumption an average of only about 25½ units per day were used for heating purposes, or, at 100 per cent efficiency, a utilization of 87 000 B.Th.U. per day. About the same amount of energy would be emitted into a room from a single gas fire burning 30 cub. ft. of gas per hour, or by a single coal fire burning at an average rate of 2¼ lb. per hour, over a 12-hour day. In the months of December 1924 and January 1925, the thermal consumption of gas and anthracite for heating purposes in Major Henrici's house was 3 times that of the electricity used in the author's house; and this, assuming an efficiency of 50 per cent for gas fires and anthracite stove, indicates a heat liberation in the rooms 50 per cent in excess of that in the all-electric house. Presumably the portability of the electric heaters counterbalanced their deficiency in actual heat production, but it must be assumed that the temperatures maintained in the house were relatively low. I should be interested to hear whether this caused any discomfort. I believe that it is healthy to breathe cool air, but my experience has led me to the opinion that a room with very cold walls is uncomfortable. The reason for this is not far to seek. The human body maintains itself at a temperature of about 98° F. by the oxidation of foodstuffs. Consequently, in ordinary indoor surroundings, heat is lost both by radiation and convection. The temperature of a room may be so adjusted that the resulting rate of heat loss from the occupants is not excessive; or, alternatively, the effects of reduced temperatures may be counterbalanced by the absorption of radiation from a fire or other high-temperature source. Cold air increases the rate of heat loss by convection, whilst cold surroundings increase the rate of heat loss by radiation; and to sit near a high-temperature radiator in a room with very cold air and walls gives rise to a scorched-on-one-side, chilly-on-the-other, sensation. On the other hand, I should expect the panel heating which Dr. Ferranti has described to be extremely comfortable, as its effect is so much less concentrated than that of high-temperature radiators. Freely exposed warm surfaces, other than brightly polished metals, even at temperatures of only about 100° F. emit about one-half their energy in the form of radiation; and in panel-heating convection currents are further hindered on account of the layer of warm air in contact with the ceiling being already at the highest level attainable in the room. As regards the advantages of portability, tests made by Dr. Lulofs of Amsterdam, and published last year in the *Electrical Times*, are of interest. Electric heating mats, fixed to the forms in such a manner that the feet of the children could rest on them, were used in a schoolroom, and it was claimed that by thus producing the heat exactly where it was wanted, 0·4 unit of electricity became the equivalent of 1 lb. of coke in effective heating value. On this basis, electricity at ½d. per unit would cost only about two-thirds as much as coke. On the other hand, somewhat similar tests made by Wigersma in Haarlem, in which coke, gas and electricity were compared in schoolrooms of similar size, the heating being so regulated as to provide the maximum comfort, showed electricity at ½d. per unit to be about twice as dear as coke. On the basis of equal heat production it would have been four times as dear. The difference was attributed to the improved " space factor " with electric heating.

Mr. L. J. Gooch: From my own point of view and, I believe, from that of many other would-be users of electricity, the all-electric house is at the moment impossible, because the electrical engineer has not yet produced, to my knowledge at any rate, a fire which for comfort can be compared with a coal fire. From what the author has said it would seem that even in Glasgow the all-electric house does not show any very great financial advantage over the ordinary house, and in this connection I think it behoves the sales departments of electricity supply undertakings to bring forward the other merits of electrical working, many of which the author has pointed out. One is the possibility of switching a light on and off from various points. There are, of course, many other obvious advantages which, if brought to the knowledge of the general public, should go far towards the promotion of the use of electricity for domestic purposes.

Major H. Carter (*communicated*): I believe that I am right in stating that although we have previously had papers on this subject from the supply engineer's

point of view, this is the first we have had from the consumer's viewpoint. The former are always open to criticism from sceptics, as the propaganda of people with something to sell. The statistics and opinions of the man who pays the bill are much more convincing. For the same reason, I think it appropriate that my contribution to the discussion should represent the experience of a consumer, particularly so, since during the course of the discussion it has been broadly hinted that such joys as the author describes are unattainable in London. I hope that my remarks will at any rate show that in some districts in London very considerable advantages can be gained by the use of electricity for most domestic purposes, at a reasonable cost. For more than 3 years my house in Wimbledon has been practically entirely run electrically. The rates are :— Lighting 4½d., heating, etc., 1d., water heating (continuous load) approx. ¾d. per unit. The house is smaller than the author's to the extent of two rooms, and the household consists of six persons, including two young children. A coal fire is used in the living-room from mid-November to mid-April, electricity being used for all other purposes. I must admit myself to be an unrepentant advocate of a coal fire for continuous use in winter. The apparatus in use consists of :—6·2-kW Falco cooker of 1922 pattern, two 2-kW Belling fires, 300–600 watt 20-gallon Bastian storage geyser, kettle, vacuum cleaner and small appliances. During the year ending 30th September, 1925, my consumption was approximately 9 000 units for power and 300 units for lighting, the same proportion as that mentioned by the author. The cost of this was slightly under £41, to which must be added £3 8s. 6d. for 24 cwts. of coal. It should be mentioned in passing that this must be regarded as a heavy year due to an abnormal amount of illness. I am not in a position to make such accurate subdivision of costs as the author, but knowing the way in which the apparatus is used and comparing the consumptions for summer and winter quarters, I can arrive at a fair approximation which is not without interest, and which is shown in Table C.

TABLE C.

Purpose	Units	Cost		
	kWh	£	s.	d.
Heating	2 400	10	0	0
Hot water	2 600	9	0	0
Cooking and small purposes (including kettle)	3 900	16	5	0
Lighting	296	5	10	0
Coal	24 cwts.	3	8	6

It encourages me to notice that on the rates prevailing in Glasgow my bill would be reduced by £13, and leads me to look hopefully for some reduction in the future.

I give below some details of the apparatus used.

Cooker.—The only drawback to this is the well-known slowness of the boiling-plates. I have had a happier experience than Mr. Hague as regards maintenance. In 3½ years the only fault has been a blown fuse, due to a short-circuit caused by scale falling from the reflector plates fitted to the boiling-plates. The author mentions experiments with lighter grids. I presume he means the covering plates for the elements. I find in my household an irrepressible tendency to dispense with them altogether, and to place the utensils direct on the fireclay blocks.

Water heater.—The author seems to have solved the hot-water problem very satisfactorily, and produces an adequate quantity available for distribution through service pipes, at a reasonable cost. The comparatively small capacity of the storage geyser which I am using is its only drawback; in all other respects it is the most popular appliance in the house. The author's apparatus appears to be a little more efficient, as it produces about four times as much hot water at approximately the same temperature for about three times the current consumption.

Fires.—I have found a strange tendency for the elements to fail on the back of the fireclay block, where they are secured to the terminals, and I should like to know if this is a general experience.

In conclusion, I agree with the author that with energy at 1d. per unit it is well worth while for an average household to work electrically, provided a coal fire is retained for the living-room in the winter. I will not go so far as to say that I am getting my services in the cheapest possible way, but any extra expense is amply compensated by cleanliness, convenience and extra comfort.

Mr. J. Coxon (*communicated*) : The paper contains much information of inestimable value to electrical engineers in support of the more extensive use of electricity for household requirements. This all-electric house described forms, so to speak, a distinct landmark in the progress of electrification and points the way to that desirable ideal when the smoke nuisance, at any rate from open fires, will have been abolished. It shows the advantages to be gained by co-operation with the architect and the city electrical engineer, and demonstrates clearly an excellent way of improving the load factor of our generating stations. The success of the author's scheme is dependent upon the low rates in force in Glasgow for electricity and for the hire of apparatus. I think it is the high rates for electricity and the heavy cost of apparatus which more than anything else stand in the way of the more universal adoption of electricity. We all know well the diversity of rates which exists throughout the country and even in and around London. Generally it will be found that these charges are lowest in the manufacturing centres where the population is also the densest, and thus there is the tendency to attract more and more people to these centres, making matters worse and worse from a health point of view. To overcome this it appears desirable rather to attract manufacturers and all the population that go with them, to the rural districts, and one way of aiding this is to offer cheap electricity in these districts, such as is being done by the Shropshire, Worcestershire and Staffordshire Electric Power Co. at Stourport. As a further aid in this direction, and now that we have a central authority in the Electricity Commission, could not all electricity supplies be " pooled "

and a more uniform rate applied generally so as to decentralize the manufacturing districts? It is, further, obviously unjust that in one place electricity should be less than 1d. per unit and in another as much as 1s. per unit. The author says on page 297 that with energy at about 1d. per unit and a low tariff for water-heating, the cost of an all-electric house compares with that of a similar house using coal, gas and electricity. Such low rates are at present available in very few cases and it is neither possible nor desirable that we should all settle in the few large cities where they are available. I submit that before real headway can be made in the universal use of electricity we want (1) more "linking-up" of stations; (2) a more uniform system of charging for electricity and the hire of apparatus; and (3) the elimination of the small and inefficient generating stations and of the profiteers.

Mr. J. F. Driver (*communicated*): One appreciates the statement of the author that "The time had arrived when a professor of electrical engineering ought to have enough faith in his convictions and calculations to put them to the test." Two years ago I myself, who hold the position of head of the electrical department of an engineering college, did the same. The author's experiences will, I am sure, serve as a guide to both architects and consumers, who may be doubtful as to the fate which awaits those who "cross the Rubicon." My own experience is that three or more points should be provided in every room, but I do not agree with the author in having all plugs of 15-ampere capacity. The flash from a dead short-circuit on the flexible of, say, a vacuum cleaner, might be dangerous. In my house I have one or more 5-ampere plugs in each room in addition to the 15-ampere power plugs; the 5-ampere plugs are lightly fused and are used for small appliances such as electric iron, vacuum cleaner, kettles, toaster, hair dryer, bed warmer, etc. The method described in the paper for drying clothes is most interesting and merits the careful attention of architects. I suggest that makers of electric cookers are following gas-stove design in a much too slavish manner. Why, for example, is the exterior of the oven not polished to reduce radiation? I should be very glad to have particulars as to the manner in which the author improved the hot-plates on his cooker. My first electric cooker had hot-plates with the elements sunk in grooves in fireclay supports. Six months ago the makers agreed to change the cooker for one of their latest design. On this later cooker the hot-plates consist of open "spirals" with polished aluminium reflectors underneath. These hot-plates are a great improvement on the old, partly, I suggest, due to the reflectors and partly to the fact that convection currents of hot air rise to the cooking utensils. The objections to self-contained cooking utensils are their weight and expense. Steamers having one utensil above the other overcome the difficulty to some extent. Would it be possible to produce a closed heater, the top of which consists of a recess containing a low-melting-point alloy? Saucepans and kettles would then be placed into the molten metal, thus giving intimate contact. The author's method of overcoming the hot-water difficulty is of particular interest, but I suggest that a thermostatic cut-out on the tank is desirable. I feel that in many houses two smaller tanks would be better, and I should be glad of the author's opinion as to the relative merits of his method and the use of a storage tank of low wattage continually in circuit. In spite of all that has been said about the advantage of radiant heaters over convectors, I suggest that in cold weather warm air is desirable, and that low-power wall-pattern convectors are useful to "take the chill off the atmosphere," using the radiant heaters as boosters. I suggest that electrical contractors should be prepared to act as consultants to non-technical clients. One sees large numbers of new houses being wired in a totally inadequate manner. Once a house is built, the cost of wiring extensions is high. If a contractor would point out to clients the future developments likely to take place, I feel sure that more adequate systems of wiring would often be installed.

Prof. C. L. Fortescue (*communicated*): Interesting as the paper is, it unfortunately does not deal with the aspects of domestic electric power supply which are principally of importance at the present moment. As the author remarks in the opening paragraphs of the paper, calculations of the power consumption for domestic purposes are frequently made and the basis for these calculations is tolerably well known. In this connection it may be observed that, comparing the figures given for his consumption with the other data available, it is obvious that his household has been remarkably economical. It is probable that in a normal household where there is neither the expert supervision that he has given nor the keen interest in the experiment throughout the whole household, the actual consumption for heating and for hot-water supplies is likely to be much greater than in the author's house. Some 12 months ago it was necessary for me to investigate the possibility of the complete electrification of a house of very similar size to the author's but which had a rather cold aspect and was less compactly built than his. For this house the total consumption was estimated to be about 24 000 units per annum and, being in an outlying London district, the cost for power alone would have amounted to about £220 per annum against an actual expenditure of about £60 on a central heating plant with gas cooking, gas fires and electric light. In this case it proved impossible to justify this heavy additional charge, and unless power can be provided at very much lower rates than those available in this and the majority of other residential districts it does not appear that there is any real hope for a considerable extension of the domestic load. The real problem, therefore, as it appears to me, is whether or not the development of the domestic load at a price in the neighbourhood of 0·75d. per unit is a practical possibility. There is no doubt whatever that the demand exists, but to satisfy this demand would in all probability necessitate laying new cables throughout the residential districts, and it becomes a matter of calculation on the part of the supply undertakings as to whether a charge of 0·75d. per unit is an economic proposition. If the paper leads to questions of this kind being worked out and possibly to a further paper before the Institution giving some of the results of these calculations, it will have served a very useful purpose.

Mr. R. Grierson (*communicated*): Undoubtedly the author was fortunate in selecting Glasgow as the scene of his experiments, since his records show that the average cost per unit was 0·625d. for the house and 0·74d. for the flat. If this price could be obtained, in similar circumstances, throughout the British Isles, it is obvious that it would be necessary to divert the activities of the Electrical Development Association into some other channel. In domestic electrification schemes we have two serious difficulties to contend with: (*a*) the unconverted electrical engineer who says, with a wise smile, that the proposition is both uneconomical and impossible; (*b*) the consumer who has already tried electrical cooking and heating with current in the neighbourhood of 2d. to 3d. per unit, and has been very badly bitten. In his case, once bitten, twice shy. Exactly how each of these cases is to be dealt with it is difficult to say, but the fact remains that both form serious brakes on "All-Electric" progress. I entirely agree with the author's view, that each radiator plug should be standardized at 15 amperes and wired back directly to a local fuse board, and I should like to see a recommendation to this effect included in the Wiring Regulations of the Institution. Whilst it may be safe to wire two heating plugs to a circuit so long as the present occupiers of a flat or house remain, new tenants or owners will not trouble and it is almost inevitable that at some future date two fires, each rated for 3 kW, will be connected simultaneously. True, the fuse will probably blow, but it is also true, in all probability, that the fuse will be stiffened until it holds. I was particularly interested in Section (10) on Heating because the author has practically arrived at the "panel heating" stage of electric heating by a process of logical deduction and with an entirely unbiased mind. The author states that, broadly speaking, there are two alternative ways of heating to be considered, e.g. convection and radiation, and I would agree if he would further subdivide the latter into high- and low-temperature sources. I regard the ordinary electric radiator as the equivalent of an unshaded high-power gas-filled lamp, e.g. it gives rise to glare and shadows and, to be comfortable in a living-room, the occupant has to accommodate himself to the position of the radiator. The author has realized this and proposes two or three small radiators, or the equivalent of, say, four small lamps, to minimize the undesirable effects of high intrinsic brilliancy and to avoid harsh shadows. Anyone who has used a gas fire or an electric radiator (e.g. a small, high-temperature source) knows only too well the effect of these heat shadows, which are the cause of cold chairs, carpets and other signs of discomfort, i.e. he is made to appreciate the operation of the inverse square law. When children are present, and even if they are not, two or three radiators, with their flexible conductors, straggling across the room, are without doubt excessively inconvenient, apart altogether from their effect on the decorative scheme. The logical development of electric heating, as suggested by the late Mr. Wordingham, is so to locate and spread the warming surface that all "glare" and shadows are practically eliminated. I have found that if conductors are embedded in strips of the plaster ceiling and energy is dissipated at the rate of approximately 40–50 watts per sq. ft. of surface, the temperature of the surface of the ceiling is maintained at approximately 120° F. and the radiant warmth resulting therefrom is most pleasing and ensures a condition of comfort throughout the room. Further, due to the extended surface, the inverse square law no longer holds, and walls, floors and furniture either reflect the heat or absorb it and then re-radiate. Normally speaking, depending on construction, exposure, glass surface, etc., 10 sq. ft. of heating surface, or 0·5 watt per cub. ft. of space, is all that is required, so that in a room containing 2 500 cub. ft., 25 sq. ft. of panel surface would be required, say 12 ft. 6 in. × 2 ft. or 16 ft. 6 in. × 1 ft. 6 in. The maximum rating for this panel surface would be 1 250 watts for continuous use during extreme weather and, say, 800 watts for normal use. Due to the low temperature of the surface, the percentage of heat lost by convection is extremely small and, due to the location of the panels in the ceiling, this is still further reduced. Herein lies the secret of the marked economies and consequent low current consumption obtainable by the panel system, i.e. it is unnecessary to warm the air to any appreciable extent and hence the usual loss of heat, due to ventilation, is very largely avoided. Further, as the author states, experience shows with ample radiant heat an air temperature of 50–55° F. is very comfortable, whereas with warmed air 62–65° F. is desirable. As a matter of fact, the solar thermometer is a more reliable indication of comfort than the ordinary air thermometer, when the radiant method of heating is employed. Panel heating, using hot water as the medium, has been thoroughly tried out in such buildings as the Midland Adelphi Hotel and Royal Liver Buildings, Liverpool; Magnet House, Bush House and Australia House, Kingsway; the Banqueting Hall, Wembley, and Messrs. Harvey Nichols of Knightsbridge, and it is now being installed in Devonshire House, Messrs. Thos. Cook and Sons, and Messrs. Swan and Edgar's, Piccadilly. Records prove that the fuel consumed is 66 per cent of that used in the hot-water radiator system, due to the facts enumerated above. When electricity is used as the heating medium the cost of maintenance is nil, since due to the low operating temperature of the conductors (approx. 150° F.) no deterioration takes place, i.e. there are no elements to renew. Clearly the panel method of warming should be of great interest to all electrical engineers, as it places in their hands a really practicable and economical method of employing electrical energy for heating purposes. The most recent installation, available for general inspection, is at the Cinema de Paris, in Charing Cross-road, the total connected load being 30 kW. Regarding the economic possibility of "all-electric" houses in connection with Government housing schemes, I recently addressed a questionnaire to some 30 members of my staff and employees, inquiring the total amount paid by them for coal, gas and electricity for heating, lighting, cooking and hot-water supply purposes. The replies indicated that the majority resided in 5-roomed houses or flats, i.e. living-room, parlour and 3 bedrooms, and the average total amount paid was £16, the maximum being £19 12s. and the minimum £13 5s. The weight of coal

used in the living-room range averaged 2 tons, and if this is priced at £5 it means that for this class of house the average family has approximately £11 or 2 640d. to spend on electrical energy. The number of units or kWh available for £16 or 3 840d. and also for the above sum, at different average costs per kWh, is shown in Table D.

TABLE D.

Pence per kWh	1·00	0·875	0·75	0·625	0·50
"All-electric" (£16 or 3 840d. per annum)	3 840	4 400	5 120	6 150	7 680
With coal range (electricity £11 or 2 640d. per annum)	2 640	3 020	3 520	4 220	5 280

Averaging the estimates for the annual consumption of electrical energy (kindly supplied to me by the Electricity Departments of Marylebone, North Tees, Hackney, Gateshead, Woolwich and Glasgow) a figure of 3 500 kWh per year is obtained. (These figures practically all apply to houses fitted with a modern combined water heater and cooker fixed in the living-room.) It would therefore appear that if the all-electric scheme is to be applied successfully to the Government type of house, the average price for electrical energy must not exceed 0·75d. per kWh.* It is useless, in my opinion, to talk to the man who earns £4 per week about the labour-saving and other advantages to be derived from the use of electrical energy, if it costs him more than his present method, since he has not the surplus cash to pay for the advantages.

Mr. A. F. Harmer (*communicated*): In the introduction the author compares (comparisons are always odious) modern electrical apparatus with Early-Victorian coal grates. Blackleading is unheard-of now, and, as regards pollution of atmosphere, I have proved, with a modern coal grate which I fitted a year or two ago, that the decorations keep cleaner than those in the adjacent room which is entirely electrically heated; in my opinion this is due to the fact that all floating dust is carried up the flue and is not distributed around the walls, etc., in a circular manner as with the electrical heater. On page 298 the author states that "cut flowers may last a month or even longer." Here again I find that flowers last longer in the coal-heated room, due, no doubt, to the much better ventilation; the coal fire is, of course, an open one. The author makes a great point about garbage disposal, but neither I nor anybody I know have ever used the coal fire for this purpose, especially, as the paper seems to indicate, the sitting-room grate. Local methods of collection have always been very efficient; moreover, refuse collection is included in the rates. Regarding Section (7) "Cooking," I have yet to learn that a strong cabbage boiled electrically smells any more attractively than when boiled on a coal fire, rather the reverse in fact, as there is no flue to carry off the odour; all my cooking is done electrically. The remarks "educated and refined women . . . make cooking attractive to many intelligent people" I find particularly uncalled for; surely any woman worthy of the name takes a pride in cooking, however done. Of course, if electricity is converting "educated and refined" females into true women, then we engineers have something still further to be proud of. I am sufficiently enthusiastic for the future of electricity to believe that it will "get there" without the aid of such very dubious and antiquated comparisons as the author puts forward. I note that he thought it advisable to arrange flues for ventilating purposes; electrically-heated rooms without flues are insufferable. I agree that the human body appreciates the heat (and light) rays of the sun or glowing fire; for this reason I have replaced all my "hot-wire" heaters with the old-fashioned (but the best) lamp radiators. On page 289 the author says "the house was built to be a home and not a showroom," yet in Fig. 4 he illustrates the most appalling fuse-redundant distribution board that it would be possible to make. Four, and not 31, ways would have been sufficient. In conclusion I give the total annual costs of heating and cooking in a 6-roomed cottage, in the district where the author used to reside, and where I have endeavoured to use as much electrical apparatus as possible, consistent with economy and comfort. All cooking and lighting is electrical; water is gas- and coal-heated; heating is coal and electrical. I have had to give up the use of motors for domestic purposes owing to a separate and higher rate for current, together with the nuisance of an extra meter.

Apparatus:—4½-kW cooker, separate small grill, toaster, iron, kettle, and 5 heaters. Lighting—25 points.

Costs:	£ s. d.	
Coal (2 tons)	4 14 6	
Gas	1 10 0	at 3s. 8d. per 1 000 ft.
Electricity—		
Cooking and heating	3 14 2	at 1d. per unit.
Lighting ..	2 6 6	at 4½d. per unit.
	£12 5 2	for the whole year 1924–5.

For the year 1923–4 the total units were 1 per cent higher.

The lighting voltage is 25, consequently I have not found it necessary to renew any lamps since 1913 (12 years); some still in use date back to the time when metal filaments were first made.

Mrs. M. L. Matthews (*communicated*): Some time ago I made inquiries as to the cost of installation of electric light in my house and was informed that it would be roughly £60. In such a case the problems with which the housewife is faced are as follows:—

* Since this figure was calculated it has been stated in the *Electrical Review* that tests taken in all parts of the country show an average of 5 350 kWh for the all-electric and 4 166 kWh for the one-coal-fire 5-roomed house or flat.

Is the sinking of such a sum justifiable in view of the possibility of the yearly bill for heating and lighting being increased ? Will the appreciation of the property due to the installation, and the reduced maintenance charges, offset the expenditure ? In the event of the house being sold, is it likely that the purchaser will take over the installation, and, if so, at what depreciation ? Also, she may have a conviction that manufacturers will revise all their ideas of cooker and heater designs. She does not know the answers to some of the questions I have raised, but she does know that she would enjoy the comfort, the cleanliness and labour-saving healthfulness of even a modest electrical outfit, to say nothing of washing machines, vacuum cleaners, etc. The present-day value of my house is £1 000, rental value £56 and rateable value £40, and the foregoing represents the electrical position of many thousands of its type over a very large area served by the electricity supply undertaking I have in mind. Surely supply undertakings could arrange to have sufficient capital available to enable them to let out on hire an adequate supply of electrical heating and cooking apparatus to prospective customers on such terms as would provide an equal division of the risk. At present the tendency of undertakings seems to be to encourage the consumer to buy the apparatus while they reap the returns in the payments for current consumed.

Mr. F. Tremain (*communicated*) : Has the author considered the provision of a fixed vacuum cleaner with convenient outlets on each floor for the attachment of hose ? I have been very desirous of providing this facility in my own house, which is similar to a very large number of two-storied villas now being erected, but the cost of such appliances, used in the smaller cinemas for instance, was prohibitive. I have not got further than providing the foundations on the promise of an engineering friend to produce a suitable small machine. Pressure of more profitable business has, however, prevented progress beyond the design of the machine and the production of castings. The machine would have been placed under the stairs and only about 9 ft. of metal pipe would have been required to reach the first (and only) upper floor. The estimated cost in quantities was £25 to £30, including a ½-h.p. motor. Exhaust was designed to be in the adjoining side entrance and would overcome the objectionable, if not injurious, odour experienced with most portable cleaners using a bag. As regards heating and hot water, I am of the opinion that in cold weather some form of preheating is essential. High charges for power in my district drove me to the installation of an " Ideal " domestic boiler, and to tolerate one coal fire. The smallest size boiler stoked with No. 3 washed coke, and kept going day and night with very slow combustion, provided for more hot water than is required in a small household. The difficulty is to keep the fire going slowly enough to prevent the water boiling, which is objectionable. These boilers should therefore be associated with at least one radiator near the front door so as to heat the air entering that way, as the boiler fire heats it from the back of the house. In my conservatory a small 600-watt workshop heater with three-heat control maintains a temperature of 40–45° F. when it is freezing outside and lessens the duty on the 2-kW radiator in the drawing-room, so that only half the heat available there is as a rule required. As the cost of running the heater is only 1s. 6d. a week at 1¼d. per unit this arrangement is economical. Two geysers are used loaded at 6 and 5 kW respectively in bathroom and scullery, but are not used simultaneously. The former provides a 10-gallon bath in about 15 mins., raising the water 50 deg. F. for about 2d., and the latter raises a gallon of water 50 deg. F. in 1 minute—costing about half a farthing. My total costs for heating, cooking, geysers (5 months in the year) on a rateable value of £47 are about £23 a year, including coal and coke. Were I fortunate enough to live in a neighbouring district, or with a two-part tariff, the cost would be under £20 a year. It should perhaps be added that during nearly 2 years' use the costs for renewals were nil, whilst the total equipment provides a maximum load of 0·75 kW for lighting and about 25 kW for other purposes.

[The author's reply to this discussion will be found on page 328.]

South Midland Centre, at Birmingham, 2 December, 1925.

Mr. F. J. Moffett : I presume that the fixed charge given by the author, viz. £12 10s. per annum, is intended to be the equivalent of the kilowatt maximum demand. In the author's " all-electric " house the maximum demand will be far higher than in the ordinary house in which lighting forms the major portion of the load, since in addition to the consumption of units for lighting there will be a heavy consumption for heating and cooking. Would the tariff be profitable to the supply authority if many consumers had a maximum demand of this value ? On page 298 the author states that the coal burnt at Dalmarnock generating station for each unit delivered at his house may be taken to be 2·24 lb. This means that the thermal efficiency from coal bunker to electric fire is roughly only 12 per cent. If an ordinary coke-fired hot-water boiler were used for the heating and hot-water supply, the thermal efficiency would be 5 or 6 times as high, say 70 per cent. A large proportion of the 16 or 17 tons of coal could therefore be saved, since the bulk of the author's current consumption is for heating and hot water. Incidentally the cost of heating and hot water would be lower. It does not appear to me that from the point of view of economy of fuel the use of electric energy for heating is justified. Raw coal is used in the generating station, but in a hot-water boiler such as that described above, coke can be used quite efficiently, thus enabling the gas and other valuable products to be utilized.

Mr. E. J. Jennings : The benefit to the supply undertaking of a steady night load, such as is called for in a hot-water scheme, cannot be exaggerated, and at ½d. per unit should yield a good profit. The drying

closet is very ingenious and should appeal strongly to the housewife. Cooking by electricity has been proved in every case to be an unqualified success, and even at 1½d. per unit is making headway in Birmingham. Undoubtedly the "all-electric" idea can only be properly developed with a two-part tariff. In Birmingham we are experimenting with two alternative tariffs of a two-part type, one being the ordinary rateable-value basis, and the other having the capital and fixed charges based on the assessed lighting requirements; in both cases the running charge will be ¾d. per unit. We are just at the point of completing our experimental period of one year, and when the figures have been considered there is every probability that a two-part tariff will be adopted in this city early next year. The paper is a valuable contribution to the question of development of the domestic load, but the author gives no information as to the first cost of equipping his "all-electric" house. The first cost of equipment, and wiring on such an elaborate system, must have run to a considerable figure and further information on these points would be of interest. I doubt whether many would be prepared to put so complete an installation in houses that are already built; the upheaval and expense would be too great. There is a danger in pushing the "all-electric" idea too far. It might be wiser in the long run to allow for one coal fire, and use electricity for cooking and partial heating, rather than risk dissatisfaction by going out for entire domestic electrification in the first instance.

Mr. W. Wilson: The paper is particularly valuable because the author has "gone the whole hog," in contradistinction to the great majority of users of domestic electricity. In my own case, although I have equipped the house for electric cooking as well as lighting and a certain amount of heating, the lack of a suitable tariff has prevented the adoption of a complete heating scheme and hot-water supply; the charges being made according to the author's second scheme, but with a price per unit averaging just three times that imposed in Glasgow, even without taking into account the extra low night rate there. My experience, however, fully endorses the claims and recommendations of the author; and it is very much to be hoped that other supply undertakings will follow the good example of those in the vicinity of Glasgow, by adopting a two-part tariff, with figures approximating to those quoted in the paper. With regard to water-heating, I have known this problem to be solved fairly satisfactorily about 15 years ago by a supply undertaking which agreed to charge a comparatively low flat rate for a 600-watt heating element; this was inserted in an ordinary domestic hot-water cylinder and kept continuously switched on for 24 hours a day throughout the year. There is no doubt, however, that the arrangement arrived at jointly by the author and the Glasgow Corporation is the most satisfactory that can be imagined, and when its general adoption is facilitated by those responsible for our power supply it will remove the last difficulty in the way of the "all-electric" house. The opinions expressed by the author to which I should like to accord the strongest support are those dealing with the design of cooking apparatus. I agree entirely that our oven designers are still copying an older apparatus the features of which are dependent upon its having to be stoked with coal and placed so that its hot hob can be accessible for cooking utensils. A discussion was held on the same subject in connection with a paper * by Messrs. Griffiths and Schofield and in the discussion thereon I made some remarks, which need not be repeated here, advocating an improvement commended by the present author. During his reading of the paper he showed a sketch of a cooking bench designed for self-contained apparatus, and I hope that he will publish this illustration in the *Journal*. This method is such as to employ to the full the peculiar advantages of electric cooking, and will save a very large proportion of the power lost, due to the avoidance of the use of the hot-plate. The latter is probably the worst piece of electrical apparatus used for any purpose. It is extremely wasteful, as was shown in a test that I carried out recently in which the amount of current used to boil a kettle was exactly four times as great with the ordinary hot-plate as with the self-contained electric kettle. It is also almost impossible to tell when it is switched on, and there is therefore the certainty, at any rate when operated by a domestic servant, that it will be left connected to the circuit quite frequently after the cooking utensils have been removed. I observe that the author specifies open hot-plates, and in this I again agree with him. They are more efficient than the ordinary closed pattern, and they do give some indication as to when they are in operation; but I am convinced that the correct procedure is to avoid the use of any hot-plate as far as possible, and to employ self-contained electrical apparatus, such as the kettle, saucepan and frying-pan. Two objections to the use of these are advanced by those concerned in producing electric cooking plant. First, they say that domestic servants are accustomed to washing ordinary cooking utensils in a bowl of hot water, and they cannot be prevented from treating the electrical apparatus in a similar manner, with the result that the insulation is spoiled. The other objection is that most utensils have to be inverted when their operations are finished in order to empty them of their contents; and that the electric utensil is unduly heavy for the purpose. The first argument I regard as frivolous, whilst the second, if it is of importance, should be met by the design of lighter heating elements. Neither objection should have sufficient strength to prevent the adoption of this type of apparatus, and the securing thereby of increased economy, rapidity, cleanliness and convenience. It is my opinion that the accusations of expense so generally made against electric cooking are almost entirely due to the use of the hot-plate, for the economy of the electric oven is well known, and was in any case proved by Mr. H. Gray in his paper † read in 1911. With regard to the details of the wiring, I am not altogether in agreement with the author's methods, although this may be a matter of opinion. My own preference is for screwed-conduit construction, which is perhaps due to a long residence in a country with a dry climate, where the methods advocated by the author would not be permitted on account of fire risks.

* "Some Thermal Characteristics of Electric Ovens, and Hot-Plates," *Journal I.E.E.*, 1921, vol. 59, p. 361.

† "Electric Heating as Applied to Cooking Apparatus" *ibid.*, 1911, vol. 47, p. 249.

Mr. H. Joseph: I am able from my own experience to confirm the general result of the author's figures. I have at various times used electricity (*a*) for lighting only, (*b*) for lighting and heating, and (*c*) for lighting, heating and cooking. I have not, however, had an opportunity of trying it for water-heating and I do not intend to do so until I can obtain a tariff approaching that which the author enjoys in Glasgow. I have come to the conclusion that whether coal, gas and electricity are used for the three services or whether electricity alone is used, there is very little difference in the cost, but that the last is infinitely preferable for all other reasons. For water-heating, however, it must be admitted that, in spite of all that the author has said, an economical kitchen range with an efficient boiler or a self-contained circulating boiler is difficult to improve upon. An unlimited supply of hot water is available at all times at a very low cost both in fuel and initial outlay. I should like to ask the author why the "all-electric" house is deemed not to require a scullery and why the washing and cooking must be done in the same room.

(*Communicated*): When the author says that only 3 to 4 per cent extra capital cost is entailed as a result of his all-electric equipment my feeling is that this is only correct because his building costs were very heavy owing to special requirements in various directions. Whilst congratulating him on what is no doubt a perfect equipment, it must be said that, where money is no object, perfection is not difficult to attain. If, however, such a service as he requires demands, in some cases, four or five power circuits in one room, one 20-way, one 8-way, one 6-way and two 3-way distribution boards in a comparatively small house, then he is putting the proposition beyond the reach of the majority of people.

Mr. R. H. Rawll: The author refers to a two-part tariff for residential purposes in operation in Glasgow. This tariff consists of a fixed annual charge and all the units consumed both for lighting and power are charged at one rate. I am of the opinion that consumers in general will look upon such a tariff very much more favourably than having to pay different rates for lighting and power. The average consumer cannot understand the fairness of such a method of charging as the latter, and any tariff which will increase his confidence in the supply undertaking serving him with current should certainly be encouraged. The co-operation of the architect and electrical engineer in the design of a house is very essential if electricity in the home is to develop along correct lines, and the author very rightly lays stress on this consideration. In this connection I should like to point out that only in a very small percentage indeed of the houses being erected to-day is a definite place alloted to the fixing of the supply undertaking's service apparatus. In most cases we have to hide them away inside pantries, etc., or else place them in sight in halls or rooms, where, even if they are enclosed by boxes or cupboards, they still constitute an eyesore, apart from taking up valuable floor-space which is an important point considering the limited space available in modern houses. I am glad the author makes a point of having the distribution boards fixed in an accessible position. In an extraordinary number of houses the fuse boards are located either high up near the ceiling or else tucked away in dark recesses, so as to make the replacement of a fuse a matter of great inconvenience and difficulty. The author states that since the cost of energy for lighting purposes is relatively small the cost of the lamps is an important factor, therefore it might be a sound policy to run lamps at less than the rated voltage. I do not quite follow his reasoning on this point. Does he mean to imply that a 260-volt lamp is cheaper than a 250-volt lamp of similar candle power (the pressure in Glasgow being 250 volts, I believe)? Personally I should think there is very little difference in price. Reference is made in the paper to the advisability of research and investigation into the possible utilization of separate cooking utensils each with its own self-contained heating element. This is certainly a matter on which research is necessary, and in this connection I should like to see a greater recognition on the part of electric cooking apparatus manufacturers of the point of view of the womenfolk. We electrical engineers may design cooking apparatus, but, after all, the ladies have to use them. Perhaps the newly-formed Electrical Association for Women will provide a channel for the useful discussion of this subject. The author prefers the storage system of water-heating with immersion heaters to the installation of several electric geysers in various parts of the house where hot water is required. I agree with him for the reasons he has stated; but there is another decided disadvantage of the use of electric geysers from the supply undertaking's point of view. These geysers are usually of the order of 6 or 7 kW, and since they are used only for a few minutes at a time the switching on and off of such apparatus causes a considerable fluctuating pressure on the network, with the resultant flickering of the lamps connected thereto. Main engineers do not mind constant loads, however large, but what they do object to is the rapidly changing load, and therefore the storage heating system has their decided approval and preference as compared with the geyser principle. I agree that the installation of a few small radiators is more effective as regards warmth than one large radiator. It must, however, be borne in mind that the disposition of the furniture in a room often precludes this method being adopted; the cost of the duplication of heating appliances is another serious disadvantage. It is true that the heating load will reach its maximum in the evening in winter, but I cannot agree that since this occurs after the afternoon peaks the domestic heating load is not troublesome to the power station. Although at the afternoon peak the domestic heating load has not itself reached its maximum value, yet it is quite large enough to make itself very seriously felt on the network. Fig. 8 shows the load curve for 24 hours in the summer. The average load appears to be in the region of 7 amperes with occasional kicks as high as 30 amperes. It would be interesting if the author could give the corresponding figures for the winter, when the radiator and other heating appliances would be in circuit. The author appears to have been very fortunate in inducing the Glasgow Corporation to take all his load on a 2-wire service. In most residential net-

works such a load as the author takes, if connected to one outer conductor only of a 3-wire system, would cause a most inconvenient out-of-balance current in the neutral of the distributor, and to avoid this the load would be balanced as evenly as possible across both outers of the system. The author does not mention a new form of electric heater which has recently been placed on the market. This consists of a resistance wire in the form of a long solenoid fitted into a steel tube. These tubes are made in various lengths and take approximately 60 watts per foot run. They have been found very useful in keeping the temperature of a room at a pleasant heat, and for such purposes as towel-drying rails, etc. They are, of course, examples of the convection principle of heating but, as far as I know, they are not as oppressive as the usual hot-water system.

Mr. A. S. Dean: One aspect of the subject which has not been dealt with is the possibility of applying the electric principle to artisans' dwellings. The Housing Society with which I am associated has just completed the first part of an experiment that will be of interest. The society has built by direct labour three houses to precisely the same plan and specification except in the matter of details affected by the installation of electrical appliances. In one case the house is of the ordinary type with electric light only. In the second case one coal fire with hot-water circulation attached is provided, other heating, lighting and cooking to be done by electricity; in the third case the house is "all-electric." The first comparison of the cost of construction was made before adding the cost of any electrical appliances or even the wiring for electric light. The variation in cost of the foundations up to the damp course, owing to the difference in site-levels, was allowed for and the costs of combined drains were also averaged. The result at this stage showed that the "all-electric" house is considerably the cheapest, leaving a generous margin between its cost and that of the ordinary house for the provision of electrical appliances. The second part of the experiment will consist in estimating as accurately as possible the costs of running these houses. The City of Birmingham Electric Supply Department has consented to hold a demonstration in the "all-electric" house daily for the period of a week, and during the demonstration to obtain figures of consumption that will, no doubt, be of considerable value. The society had realized the many apparent advantages of what is termed the "all-electric" house, but as reliable figures as to cost and expense of running were not available in this district it was thought that an experiment might usefully be made. The comparative figures of cost of construction, cost and type of electrical equipment installed, and the estimated running costs will be published in full in the near future. Whether the society will be able to build any considerable number of houses of this nature will depend to some extent upon the cost of electricity.

Mr. A. J. Milne (*communicated*): Realizing the many apparent advantages of what is termed the "all-electric" house, and reliable figures as to building and expense of running costs not being available for Birmingham, it was thought that an experiment should be made. The result of the first part of this experiment I am able to publish by the courtesy of Mr. A. S. Dean, Secretary of the Woodlands Housing Society, Ltd., Bournville, which Society undertook the building of the various houses. The second part of the experiment will take the form of a comparison of records of the costs of running the different types of houses over a period of 12 months. These figures are not yet available. The houses are what is known as the "subsidy" type, the purchase price of the "all electric" house being £500, inclusive of electrical equipment. Building by direct labour, three houses were erected to the same plan and specification except where details are affected by the installation of electricity. In the first case the house has ordinary coal fires with gas laid on for a gas cooker, and to bedroom fireplaces for gas fires if required. Electric light only is installed. In the second case the house has one coal fire in the kitchen, with hot-water circulation attached to provide water to sink and in bathroom. All other heating, lighting and cooking will be done by electricity. In the third case the house is "all electric." These houses have the same accommodation, which includes a large living-room 16 ft. 5 in. by 11 ft., combined kitchen and scullery, and three bedrooms: also a bathroom upstairs. It might be noted here that in the case of the electric house considerable extra space is available in rooms which have no chimney breasts.

Building costs.—As to the question of cost of construction, the first comparison should be made without including the cost of electric appliances and wiring for electricity. It has been thought advisable to take an average of the cost from damp course in each case, thus making allowance for the variation in site-levels. The average cost of combined drains is also taken for the same reason. When the experiment was put in hand it was decided, as the "one coal fire" house and the "all-electric" house were to be built as a pair, to provide a chimney for a coal fire in the kitchen in both houses. A flue would thus be available in case the "all-electric" house should prove a step too far in advance of the existing demand for electricity. It is certain, however, that in the near future the cost of electricity in Birmingham will be such as to make this type of dwelling an economic proposition. Allowance has been made for the flue in arriving at the cost of the "all-electric" house. Table E shows the variation in cost of the various items and it should be borne in mind that some of the variations are probably due to the different time taken by different men to do parts of the work and that there has been a slight variation in cost of some of the materials. It has not been thought necessary to give actual total costs. Instead of giving the pounds in hundreds, tens and units, only the units are shown, which in total show the actual difference comparatively as regards net increases or decreases. The saving in cost on the ordinary house with electric light only in the case of the "one coal fire" house is therefore £20 16s. 2d., and £66 2s. 4d. in the case of the "all-electric" house. In explanation of Table E it should be specially noted that the remaining building costs, not given for various reasons, are common to all the types of houses referred to and do not affect the net saving or net increase in costs.

Layout of houses.—No mantelpiece or overmantels are provided in the case of the " one coal fire " and " all-electric " houses. Air bricks are arranged for in each room. The distribution board, etc., are fitted in a cupboard beneath the stairs.

Wiring.—The wiring has been carried out in screwed conduit. In the kitchen switch-sockets are provided for radiator, iron, kettle, etc. Pilot lamps are in circuit with the cooker, wash boiler and hot-water geyser. In the living-room, points are provided for radiator and table lamp. A radiator plug is fitted in each bedroom.

Lighting.—One 100-watt gas-filled lamp carried in an enclosed unit gives the requisite amount of light in the kitchen. The living-room is lighted by a 12-in. bowl fitting carrying a 100-watt lamp. The stair lights can be controlled from the hall or the landing. In the principal bedroom two lighting points are provided. A ceiling switch is included, so that the main light can be independently controlled from the bed. It is also arranged for the radiator to be controlled from the bed. One lighting point is provided in each of the other bedrooms and the bathroom.

Clothes washing.—A wash-boiler with 3-heat control is installed. The washer is rated at 3 kW and consists of a tinned copper container lagged to avoid heat loss.

Cooking.—A cooker will be hired from the Corporation of Birmingham Electric Supply Department. These cookers are of the usual type, the oven being surmounted by grill and hot-plates.

Hot water.—In the case of the " all-electric " house, a 15-gallon hot-water storage tank provides hot water for the bath and wash basin. The tank is fitted with a ball valve at the top. This operates in an entirely independent chamber, which is heat-insulated from the main bulk of water, and consequently is not working under disadvantageous conditions. The tank is fitted with a small constant heater (300 watts) and a separate booster heater (2 kW), the latter being of the combined switch and immersion-heater type. The 300-watt loading is sufficient to raise 18 gallons of water through 100 deg. F. in 24 hours. An independent geyser is installed for use in the kitchen; this is fitted over the sink and is connected by means of a flexible tube to the cold-water supply, when required. With regard to the " one coal fire " house, it can be arranged, if desired, to fit a 3-heat control auxiliary electric water heater, so that hot water can be obtained either by (1) the coal fire range only; (2) electricity entirely; or (3) a combination of both methods.

Heating.—The following are provided: A 3-kW radiator with 3-heat control for use in the living-room; a 2-kW portable fire with a 1-kW boiling ring attached for use in the kitchen, and bedrooms in case of sickness; and a small bedroom radiator. As a general guide it is necessary to allow 1–1½ watts per cubic foot of space. No definite rule can be laid down as, for instance, a bedroom is not usually required to be so warm as a living-room, and further, a great deal depends upon

TABLE E.

	Case 1 Electric light only	Case 2 One coal fire	Case 3 All electric	Remarks

the number of doors, windows, etc., in the room. It is false economy to install a fire of too small power; it is much more economical to switch the radiator "full on" for a short time and maintain the temperature by cutting down the heating units, as one can so easily do with electricity. For large rooms it is advisable to install one or more radiators to give a better distribution of heat.

Running costs.—As already stated, sufficient data have not yet been collected to give definite running costs, but it is anticipated that the average weekly consumption of the "all-electric" house will be of the order of 100–120 units, and 80 units in the case of the "one coal fire" house.

Conclusion.—Although in many cases the "all electric" house has proved to be both popular and economical, its adoption will naturally depend very largely upon the tariff offered by the local electric supply undertaking. In Birmingham, with the present tariff, the "one coal fire" house is undoubtedly the most popular and is economically sound. As a guide to those who are desirous of converting their present electric lighting system to an "all-electric" installation, it may be noted that the cost of changing over the house with electric light only, referred to above, is £22 10s. if carried out in screwed tubing and vulcanized rubber cable; and £16 15s. if wired with lead-covered cable. The saving in decorations, cleaning, etc., need hardly be enlarged upon.

[The author's reply to this discussion will be found on page 328.]

North Midland Centre, at Leeds, 8 December, 1925.

Mr. S. D. Jones: The housewife, the manufacturer, the contractor, and the supply engineer are all deeply interested in this question. The author says nothing about the cost of installation, and whether such cost would be practicable in the general run of houses. It is to be noted that the author's is an "all-electric" house. Many people are now talking of electric houses with one coal fire. In Bradford they are claiming to reduce the smoke nuisance by having only one fire, forgetting that most working men have only one fire in their houses. Thus if they still have one fire the smoke nuisance would still be as bad. Then there is the question of heating houses, i.e. whether it should be by hot-water radiation or electric radiator. The question of the diversity factor in different neighbourhoods, in suburbs or in working-class districts is, I believe, a very important point. Fairly large houses like the author's will, as a rule, be surrounded by a fair amount of ground, and that will bear on the question of mains necessary to supply a district of such houses, as more and longer mains will be required. Would it not be a good proposition to have all-electric houses in working-class districts where the current density of the mains will be greater?

Mr. R. M. Longman: I was originally induced to use an electric cooker because of the smell which my gas stove produced. In numerous houses the authorities who provide the gas stoves on hire do not take the trouble to provide a waste pipe for the fumes, nor do they take much care in selecting the proper position for the gas stove. After wiring my electric cooker myself on a Saturday I got a sister-in-law, who had never seen one before, to do the cooking. I switched on all the elements on Sunday morning to make sure that they were all right, and instructed her how to operate the switches. The dinner was cooked quite satisfactorily. The experience that my wife has gained of the electric oven is such that she will never willingly use any other form of cooker. The author carries the system of wiring at several points to rather an extreme. On page 291 he states that the switches on the skirting board are arranged to be operated by the foot. Does it matter how they are kicked? I am in favour of the rotary type for all heating circuits because they break circuit very reliably. Many of the tumbler switches are not satisfactory, particularly on a 3-kW load. Most electrical engineers will confirm the author's experience regarding bells. His method of water-heating is most interesting, but the heater appeared to be fixed half-way up the tank in the lantern slide exhibited. Is this correct or is there an additional one at the bottom? I have used electrical water-heating for the past 5 years. In each case the heater has been fitted to the hot-water cylinder in the bathroom, a circulator being used in the one case and an immersion heater in the other. Both have been entirely satisfactory, and the first has now been in operation about 5 years. A 2-kW immersion heater is fixed one-third of the way up the 25-gallon cylinder and has proved a great boon whether the kitchen fire with its boot boiler is in use or not. A 3-heat switch is of course included. Two baths may be obtained in rapid succession and the heater is quite sufficient alone for washing days. If the full heat is switched on when rising, the water will be sufficiently hot to enable operations to be commenced immediately after breakfast. The provision of dual control from the kitchen as well as from the bathroom would be an advantage. This system of water-heating is a particular boon during the summer months, when it also assists the supply undertaking. The heater may also be put on the low-heat elements in series throughout the night, thus increasing the life of the elements. I note that the author uses 15 gallons of hot water per person per day; this seems rather an excessive amount. The costs for radiation heating seem to be rather low, but the cooking costs are somewhat higher than I am experiencing for a household of six. In Leeds the tariff of 15 per cent of the rateable value, plus ½d. per unit, is a great advantage, and whilst I have not installed meters on all the circuits, space being much too valuable, I am fairly confident that the cooking does not cost us more than 1d. per person per day. We have two enclosed boiling rings but should prefer one open and one closed. When properly used the enclosed ones are much more economical and for numerous services, such as cooking potatoes, etc., the heat may be switched

off directly the water boils. Much, of course, depends on the actual person operating the cooker. Anything that will ease the burden of cooking should be strongly advocated and helped forward by all authorities. In the reports of many medical officers of health, including that for this city, much of the ill-health and sickness is attributed to the low standard of feeding, largely due to the use of pre-cooked food, tinned food, etc. The more universal adoption of electric cooking should reduce this considerably, with very beneficial results. By the omission of fireplaces a considerable amount of space in the room is saved and the rooms are made much more convenient for fitting carpets. The corners of the room on the same side as the fireplace will also be much warmer than they usually are with the ordinary open fireplace. I fully agree with the author on the question of the radiant type of heater. Personal experience has demonstrated this very effectively. The type of heater which is provided with a reflector has a greatly increased efficiency, but some makers have entirely missed the point by placing the reflector to reflect the glow of a lamp with a little imitation coal filling, the actual heater being placed quite away from the reflector.

Mr. H. Moss: As a contractor I am particularly struck with the question of the wiring of the author's house. The whole installation is controlled, I understand, by a 50-ampere switch. On that the author has something like 36 or 37 15-ampere circuits. It would be interesting to know what is his maximum load at any particular time, because I feel that the main switch is somewhat on the small side. Although he uses large conductors in many instances, in others he appears to have economized unduly. In Bradford a 3/·036 cable is loaded to carry 7 amperes, not more. I gather from the paper that the author is loading his 3/·036 cables much more heavily. If that is so, he has overloaded his cables with his heating circuits. Another remarkable thing about his wiring is that if he puts only 3 or 4 lights in, he uses the same size of conductor for ½ ampere as he does for his radiator circuits. Has he any reason for using the one size to carry two such different currents, one possibly 10–13 times as great as the other? Not many people would incur the expense of a tough-rubber cable for their bell circuits, although this would undoubtedly make the best job. In my opinion, the switching is somewhat overdone in having lights controlled from 7 points, as it must be rather costly. With regard to the question of plugs, I quite agree with the author that it is a great advantage to have a fair number of heating points or lighting points by means of plugs in the rooms, but some would think that he has rather too many. I was rather surprised that the author had put in a wash boiler instead of a washing machine. The former takes an hour to wash the clothes, whereas an electric washing machine would do the same work in 10 minutes. I am somewhat doubtful about his drying closet. If he lives in a dusty area, in a dry period I think that the fan will draw in a tremendous amount of dust. It would be of great interest if the author would state what ratio the electrical installation bore to the total cost of the all-electric house. We are quite aware that builders, housewives, architects, and everybody concerned with the matter have a bad habit of cutting down the installation costs to the lowest possible level. In this case the author apparently has spent money quite freely, and it is hoped that he will reap a great reward from it. The success of "all-electric" houses will no doubt depend in the future on the rates at which we can buy current, and as these rates vary in different towns in the country it is very difficult to make a comparison. Sometimes it is difficult to make the ordinary householder understand what these rates are, and I should like to see a flat rate for all domestic purposes.

Mr. G. Mott: The author has told us that he spends something like £41 per year in electric lighting, heating, cooking, and so on. I take it that with the capital charges this amounts to about £1 a week. He is buying the day load at 0·5d. per unit, and his night load at 0·375d. per unit. I happen to be Chairman of a Gas Committee, but at the same time I am not absolutely opposed to electricity; rather, I may say I am progressive. At the same time I have learned a good deal about the usages of electricity from the paper and the discussion, and I can quite see that, from the author's point of view, electricity is the only means of lighting or heating a house. At the same time it must be remembered that at the present time the smaller type of houses is inhabited by people who are not in the author's favourable position. They may be called upon to pay 14s. or 15s. a week in rent and rates, and they cannot afford to pay more than a very small proportion of the costs given in the paper. What can these people conveniently afford to pay with an ordinary wage of £3 10s. or £3 5s. a week? What can they get in the way of electricity? In Ilkley the rates are fairly high, viz. 8d. per unit for lighting, 2½d. for power, and 1d. for cooking. The ordinary working man cannot afford to install electricity at these rates. Otherwise I think that the scheme is an excellent one. After all, as has been said before, health comes first, but we cannot all afford to go as far as the author has done to this end.

Mr. A. F. Carter: As the owner of an all-electric house for nearly 2 years I am in a position to corroborate the author's figures. The house contains 8 rooms and the annual consumption is just under 10 000 units. Under the local tariff this works out at 0·56d. per unit. One of the difficulties of the conversion of an existing house is the capital cost, and I think that much more could be done by the supply undertakings in providing facilities for the hire-purchase of the complete electrical system. Some two years ago I tried to borrow money from a building society for the purpose of building an all-electric house, but they refused to lend unless flues and fireplaces were put in, as they considered that the electric house would be a failure. My experience with 10–15 ampere interlocked 3-pin switch-plugs has been unfortunate, mainly due to flimsy construction and lack of breaking capacity where one pin is earthed. Flexible cables also are difficult to obtain in the 3-core heavy-capacity sizes and are not altogether satisfactory when obtained. The question of lamp renewals is a fairly serious one, and in future I think I shall adopt the author's plan of underrunning. The cost of energy for water-heating at 0·5d. per unit is not excessive,

but it does not encourage the user to give a 100 per cent load factor, which he could easily do. I think it would pay undertakings to supply, say, 500 watts of energy continuously day and night at a figure of, say, 35s. per quarter; this works out at about 0·4d. per unit. Three hot-plates are desirable on any cooker, one of which should preferably be of the enclosed type having a fairly small loading for simmering purposes. A large amount of trouble now experienced with open rings would be avoided if an instantaneous circuit breaker were installed at the source of supply. The breaker can be set at 75 amperes and still trip out and clear the cooker open hot-plate circuit—when a short-circuit takes place due to the boiling over of a saucepan —before the 10-ampere fuse will blow. In fact the tripping is so quick that invariably the element is uninjured and the slight delay in putting in the breaker allows the short-circuit to dry out owing to the stored heat in the hot-plate. In fact I think that the day is not far off when supply undertakings will install in private houses a padlocked instantaneous circuit-breaker set to trip at, say, 10 kW and give a supply for domestic purposes at a fixed figure per annum based on some form of tariff such as the rateable-value system.

Mr. C. N. Hefford: With regard to the heating of water, I do not agree that ½d. a unit is too much, especially in the smaller and medium-size house where the quantity of hot water that will be required will be less than that provided for in the author's scheme. One thing, I think, which we must bear in mind with regard to these electrical houses is that we are trying to put into the hands of the public a very simple machine. We do not improve matters if we are going to arrange it so that the occupiers have to consider when they will switch the heat on for the water, and arrangements have to be made for somebody in the house to switch it off on rising in the morning. I wish to emphasize that point, because electricity here is very cheap and I cannot understand why electrical engineers should go out of their way at every opportunity to make the general public think that it is dear and that it must be used sparingly. Another point is the provision of separate utensils. Here again we have to place something simple in the hands of the housewife. She wants something to-day to resemble a gas cooker as closely as possible. The early electric cooker involved too much thought. People who are busy with cooking and domestic work generally do not want to think; they want to do things almost automatically. The author has, I think, brought out that point rather well when he says that, after all, the working of the house will be judged more from the point of view of comfort and ease of working than the cost, and this affects the question of separate utensils with their plugs and unwieldy lengths of flexible cord. A stove is needed which will give heat and on which any of the usual utensils can be put, possibly somewhat modified but of the usual shape. We are sometimes told by people that they like electric cookers very much, but that they cannot see any flame. That shows the temperament of the people who are using these appliances. They are not yet sufficiently educated to use properly the cooking utensils which I think have been rather suggested by the paper. Then again there is the question of portable radiators in a bedroom. I am not in favour of them. If one is in the fireplace, or whatever takes the place of the fireplace, it occupies a certain place to which one is accustomed. It is quite easy to have the armchair by the radiator. The maximum of comfort is reached by having a switch near the bed, so that the fire can be switched off when not required. The separate charge for night energy is likely to introduce complications. In most towns at night newspapers are published, ice factories are run, and possibly continuous chemical processes. How can any concession be made to people who switch on and off at a certain time, unless it can be extended to the other people who are using it during the same hours and produce an equally good result so far as the power station is concerned? I agree with the author that electric houses will eventually have to be specially designed. We are suffering to-day of course from the necessity of having to adopt a type of house which is specially designed for something quite different from electricity. That condition imposes a very great handicap, but I am not sure it is not justifiably asked for. We do not find many men who will build a house primarily designed to use electricity and nothing else, as the author has done. The burning of refuse is a very real difficulty. It is one we should like to gloss over. The Medical Officers of Health are taking up a very strong attitude on this point to-day. We have to provide some efficient means of burning certain classes of rubbish within a few hours of it being formed. A number of electric houses, I hope, are to be built in Leeds. It is almost entirely on that account that we have arranged to provide in those houses one open coal grate in which rubbish of that character can be immediately destroyed. Failing that, I think there is nothing else to do at present but provide a coke fire of a certain type, thus introducing a complication which the housewife would not appreciate. We have to get rid of our rubbish. Until the sanitary authorities are prepared for more collection, and provide a different type of bin, that difficulty can only be met by some form of fire. A previous speaker mentioned that in the artisan class of house there is only one fireplace and suggested that we are not going to do much in the direction of providing a smokeless house if we leave them one fireplace. Surely that is not so, because the great amount of smoke from the chimney of that house is produced mainly by cooking and the heating of water in the boiler behind the fire. If the occupier is going to use that fire, at any rate during the summer months, only on such occasions as he has to get rid of a little rubbish it will possibly be for a matter of only two or three hours. We have had to do it in my own house—it is the only way of getting rid of certain rubbish during the summer. The draught behind the hot-water boiler in the kitchen grate is sufficiently keen to burn it. The smoke from the artisan's house will be very much reduced even if we leave him his one fire, by providing him with electrical appliances for heating the bedrooms and heating his water, when his fire is not available, and also for cooking. The schedules of cost on page 297 are particularly interesting to me. If we take a

house in Leeds having an assessment of £50 a year, and assume an annual consumption of 16 000 units—which I estimated some 6 months ago when attempting to arrive at a figure—the actual cost would be a few shillings less than that shown in Table 3. The author's house is, I think, somewhat larger, but how many people live in it ? Can the author give us any information as to the size of the vertical flue or ventilator, and also the size of the inlet and the outlet of the room ? Are they adjustable ?

Miss M. M. Hancock : I am particularly interested in the paper and this discussion, as I am just arranging for an all-electric house. It is a subsidy house and there is no convenience for a drying closet, and I am afraid I cannot afford any room for the purpose. The drying will have to be done in the kitchen. Would the author recommend a radiator or a fan or a combination of the two ? Has he found any particular medium more suitable than another for blacking underneath the cooking utensils ? I am trying to run the house without a maid and be at business in the day time. I started off originally with the idea of a slow-combustion stove, some sort of coke-boiler. I tried to find some form of coke-boiler that would keep alight all day and night and that would be labour-saving in every way. I found that instead of saving labour I should be adding to it. I found that if I used coal it would clinker, and that if I used coke I should get the fumes, and if I was not very careful the draughts would put the fire out during the day time when I was out, and that in any case I should have to clean the stove out every day. There was another consideration ; I found that I should have to keep a second supply of anthracite coal or coke, and also keep coal for my ordinary fireplace. On account of space in subsidy houses the coal store will barely accommodate a ton of coal as a rule, and to divide that into two would mean that I should have to have somebody in the house very frequently to take in a load of coal. After visiting the Liverpool all-electric house in August I decided that it would pay me to have an all-electric house because, like the author, I am quite willing to pay for convenience. In Wakefield, where I live, there is no flat rate. It is only by special application to the Corporation that I am on an experimental basis, and they estimate that I shall use about 6 000 units per annum if I have a friend to share the house. That will cost, on their rating, approximately £26.

Mr. H. J. Hodsman : If any doubts as to the theoretical possibility of the all-electric house previously existed they have now been removed, but is it desirable that the all-electric house should be encouraged as a domestic institution on a civic or national scale ? I have in mind the problem of supplying the needs of the 120 000 or so houses in Leeds. Look at it first from the consumer's point of view. While recognizing the advantages of cooking by electricity the disadvantages must not be overlooked. In this connection I should like to draw attention to the need for continuity of supply. Almost every Sunday my supply of electricity fails between 12 and 1 p.m., a very important time in the household. Turning to domestic heating, I am glad to notice that much has been made of the necessity of adequate ventilation, which too often is overlooked, but I would invite a more quantitative examination. On approaching this subject one ought first to study the work of the physiologist on the hygiene of heating. Much has been done on this problem, especially by Prof. L. Hill of the Medical Research Council, whose conclusions show a marked leaning to open-flued fires so far as British conditions are concerned, in that they combine heating by radiation with adequate ventilation. The coal fire would meet the physiologist's point of view very well in this particular, but it has the disadvantage of causing labour and producing smoke and dirt. Strange as it may seem, Prof. Hill's conclusions are favourable to the normal type of gas fire, as being on the whole the best available solution of the problem. It is true that electrical heat if used freely enough can be made to supply the aeromotive force to cause a ventilation equal to that of a gas or coal fire. If it is desired to ventilate in this way, however, it will be necessary to supply electricity at a figure in the region of 0·3d. per unit (and below in some districts) to provide the consumer with a combined heating and ventilating service equal to that obtainable by the use of a modern gas fire. So far as heating water is concerned, the problem is most severe for the electrician. I supply my own needs by means of a coke-boiler and I am quite satisfied that this gives me much better value for money, considering not only the hot water but other attendant conveniences; for instance, the disposal of kitchen refuse, a very important matter, as Mr. Hefford has so far recognized as to concede the necessity for one solid-fuel fire in his scheme of all-electric houses in Leeds. The coke-boiler solves this problem and at the same time provides an adequate supply of hot water. This, I think, is a substantial advantage from the point of view of public health. The general question I wish to raise is: Is it right so to deprive the general householder, especially when of small means, of the opportunity of getting better value for his money by limiting him to the use of electricity ? I think it will be agreed that the all-electric house will not become general in the sense outlined at the beginning. Thus Mr. Hefford himself finds it necessary to install one coal fire in his scheme of all-electric houses. That being so, how is the smokeless city to be attained ? One is thus driven back to fuel heating, and if this is to be smokeless we must employ our carbonization industries more extensively. Other considerations, such as the supply of liquid fuels and other necessities of civilized life, add further weight to this conclusion. Now the carbonization industries differ from the electrical industry in obtaining a number of products, chief of which is the gas. If we are to obtain carbonized fuel at a reasonable price, this gas must secure a market, and the market where it can be used most effectively and to the best financial advantage is the domestic market. What applies to the gas industry applies with equal if not more force to the metallurgical coke industry, which seeks ever more clamantly to find in the town's gas industry a sale for the gas necessarily produced. By this means it is hoped to cheapen the coke so essential to the iron and steel and to the engineering trades of the country. Indeed, it was recently stated that cheaper coke is vital to the iron and steel trades. I submit that, viewed from the standpoint of national

well-being, no good purpose will be served by any interference with the natural development of the industries of carbonization, be they the existing high-temperature industries or any low-temperature industry that might be established in the future. I suggest, therefore, that electricity should not be applied to purposes for which it is not naturally fitted and that the possible repercussion on the general industry of the country should be considered. I believe that some electrical engineers expect that the general adoption of domestic electrification would benefit the supply industry, and perhaps cheapen electricity. In America, which is supposed to be a pattern as regards the generation and supply of electricity, it is quite common for a public utility company to operate the supply of both gas and electricity in one city. They continue, nevertheless, to build new gasworks and extend old ones. I do not propose to explain this, but I suspect that they find, in a country liable to great variations of temperature, that the domestic load might become a nuisance if pushed to extremes, and that it is preferable to cope with much of it by means of the gas supply. I have recently been discussing the same point with the official responsible for the public gas and electricity supply of the city of Munich, who was engaged upon a tour prior to extensions of the Munich city gasworks. Munich is supplied from hydro-electric stations in the Bavarian Highlands, and yet the cost of electricity in general there, so far as I could gather, is not materially less than in Leeds. For domestic purposes, however, the charge in Leeds seems to be the more favourable to the consumer. The tariffs in Munich are evidently not drawn to favour the domestic consumer and, as already mentioned, an extension of the gas supply is in preparation. The electricity supply industry is based largely upon the use of low-grade small fuel obtained at much below the average cost of production of coal. This is only possible because the domestic consumer pays so much more than the average. Now, if the all-electric house became national the house-coal consumer would be abolished and therewith the subsidy which he pays to-day to the electrical industry. The power station would have to pay the average cost of production of the coal used, and presumably that cost would have to be met by increased charges. That again is a reason for asking whether the all-electric house would be so helpful to the electricity consumer in general. The author seems to brush aside such questions as irrelevant because the normal consumer does not inquire about coal conservation, thermal efficiency, and economic questions. Is this an attitude to be endorsed? As technical men it is our duty to examine technical problems from every point of view, so that our considered decisions may furnish sound guidance to those responsible for public funds—national or local—and to those faced with important decisions concerning housing problems.

Mr. D. M. Buist (*communicated*): The author has certainly proved the all-electric case for the 10-roomed house, but supply engineers, as a body, are more concerned with the 4- or 5-roomed house, as it is from this type of house that about 90 per cent of the domestic load will come. To make this size of all-electric house pay both supplier and consumer, the initial and running costs will have to be much lower than they are at present. This means: (1) That only such essential apparatus as cooker, fires and water heater can be installed; (2) that the initial cost of such apparatus must be wholly, or partly, paid by the savings effected by the architect in elimination of chimney breasts and the coal cellar; and (3) that the tariff must be a minimum. So much has been written of late upon this subject, and so many different opinions have been expressed regarding the various details of it, that one cannot see the wood for the trees. From the fact that about two undertakings per week are now extensively taking up the domestic heating and cooking load, one must not assume that instant success will be achieved by such undertakings, and that all that has to be done is simply to connect up and let the revenue pour in. The subject, in its details, is peculiar to each undertaking, and consequently I consider that, instead of following others blindly, each undertaking should first equip a number of houses experimentally, as some towns are doing, and thus feel the pulse of the local public upon the subject, and also at the same time enable the supply engineer to ascertain for himself which makes of apparatus are, in his opinion, the best. Glasgow, a pioneer in the matter, adopted this experimental course and, although *all* that they have done cannot be universally followed by other undertakings, their experiences have afforded many lessons. Glasgow, in common with other cities, has proved the necessity for retaining one coal fire, with boiler attached, in the living-room of 4- or 5-roomed houses, chiefly in order to obtain an adequate hot-water supply, and also to heat economically the one room which is used more than the others in such houses, and lastly (and by no means least important) because the "romance of the coal fire" has a very strong influence with the public, rather than with the engineers who, after all, are only required to supply the public with what it demands. The three objections to the all-electric house, enumerated by the author on page 289, are of greater importance in 4- or 5-roomed houses than in 10-roomed houses. Other equally important difficulties in the smaller houses are: (1) Clothes washing and drying; (2) the provision of a cooker as safe, as speedy and as simple as the gas cooker, and also one which requires as little intelligence to use; and (3) the provision of ample hot water at all times and for all purposes. It is a far cry to the day when the artisan with a family of three or four and an income of £3 to £4 per week will be able to afford to adopt electricity for all purposes, but progress in that direction is sure although, at present, inevitably slow.

Mr. R. A. Thwaites (*communicated*): Looking at the problem of the terms of supply to an all-electric house from the point of view of a sales engineer, I venture to think that if the all-electric house becomes established on a large scale the tariffs such as offered by Glasgow and Leeds will prove unremunerative, and either the fixed charge or the unit rate will have to be increased. One speaker using the Leeds Corporation's supply has mentioned that his average cost for 10 000 units worked out at 0·56d. per unit. I find that a power

user in Leeds having an annual consumption of 2½ million units per annum is required to pay 0·66d. per unit, and it is difficult to justify supplying the domestic consumer at such a highly preferential rate. I understand that the Glasgow Corporation, however, make it a condition that the average price shall not fall below ¾d. per unit. So long as the number of all-electric houses is few, this aspect of the question is relatively unimportant, but let us assume Glasgow with 20 000 all-electric houses, each with an average consumption of 10 000 units per annum. We then have an annual consumption of 200 000 000 units (an amount greater than the present total sales of energy in Glasgow). If the average rateable value is even as high as £80 per annum the average price on the present tariff would be 0·75d. per unit, compared with which the average price obtained by the Glasgow Corporation for the year ending May 1925 was 1·64d. per unit. In other words, the occupier of an all-electric house would be paying less than half the average price paid by other consumers (including large power consumers). This might be justified if the whole of such domestic load were off-peak, but such is not the case, and taken to the limit the domestic load might even create a peak of its own and necessitate offering power for motors at low rates in order to fill up the new valleys. Whilst admitting that I am enjoying the benefits of a similar tariff in Leeds, I feel that it behoves those of us who have a hand in the framing of tariffs to look ahead and see if we are not tending to cut the prices for domestic load too much. With the author's remarks concerning cookers in general, and hot-plates in particular, I am in entire agreement. From figures collected it would appear that the consumption for cooking is about 4½ units per day for the cooker, and ½ unit for each person. The drying cupboard is an interesting feature, and it would be of interest if the author would, in his reply, give a sketch showing the detailed arrangement of this. The author was very wise to provide so many plugs; my own regret is that I installed too few. He suggests that an all-electric house often saves one maid-servant, and my wife assures me that in our own case this certainly is so. As the total cost of a maid is not less than £80 per annum, this is a very strong point in favour of the scheme and is usually overlooked.

[The author's reply to this discussion will be found on page 328.]

North-Western Centre, at Manchester, 15 December, 1925.

Mr. S. J. Watson: The author suggests the possibility of electric cooking being transferred from the kitchen to the dining-room, but I think it is essential to cook food as far as possible from the place where it is to be eaten. The most important point in connection with the all-electric house is the provision of hot water. I have no hesitation in saying that upwards of 90 per cent of the fuel burnt in an ordinary domestic house is used solely for the purpose of providing a hot-water supply. In Salford we are building at the power station, to accommodate some of the key men, four houses which we call all-electric, although this term is not quite correct. No provision is being made for a coal fire in the bedrooms or sitting-rooms. We have had the courage of our conviction that the coal fire is not necessary and therefore we are not providing concrete round the chimney breast or a chimney breast itself, and I am given to understand that we save somewhere about £15 a room—that is the cost of the fireplace, the preparation for it and the proportion for chimneys. The only fireplace we are putting in those houses is one, in a sort of kitchen sitting-room, with a boiler at the back, so that the fire will not only warm the room but also—I think this is a point of some importance—burn the debris which accumulates in a house. In the strictly all-electric house described by the author no arrangements are provided for dealing with debris, but I think it is essentially a matter to which attention should be given. The boiler will be connected to a cistern in the usual way, but we realize that there may be times when the fire will not be wanted and therefore it is proposed to put immersion heaters in the tank so that, whether there is a fire or not, hot water may be obtained for washing-up or for baths. Where there is a young family a more ample supply of hot water is required than is generally thought necessary. In these houses a washing boiler and cooking stove will be provided, together with radiators in the best rooms and another which can be used in any of the upper rooms in their turn. The houses will therefore be entirely electric apart from the one fire I have mentioned. The author refers to a two-part tariff. Those of us who are engaged in the electricity supply industry will entirely endorse this remark that if any progress at all is going to be made in the use of the supply for domestic purposes it is absolutely essential that a two-part tariff should be applied and the tariff consisting of a charge based upon the rateable value, plus a very low charge for each unit consumed, is one of the best in vogue. The undertaking with which I am associated has adopted a tariff of 12 per cent, plus a running charge of ¾d. per unit. It may not be without interest to mention how we arrived at the secondary charge of ¾d. per unit. At the works we have a canteen and when I went there some three years ago I found that all the cooking was done electrically. As no figures were available showing a comparison with gas, I arranged for a gas stove to be put in and since that time we have cooked one week by gas and one week by electricity. The result has shown absolutely conclusively that electricity at ¾d. per unit for cooking purposes is comparable with gas at 3s. 6d. per 1 000 cub. ft. The author exhibited a lantern slide showing a load curve for August, but in that month very little heating is required. I suggest that he should have supplemented that curve with one for about the middle of December when the weather is cold and a larger quantity of heating is required. He also remarked that the domestic load would not make much, if any, difference to the maximum demand, but I am afraid I cannot accept that suggestion because

it naturally follows that if a large number of domestic appliances for heating, hot water, etc., are connected they will add to the total load. Cooking is the only domestic supply on which any considerable diversity occurs. On a cold day all the radiators will be on and this will add to the load on the station. It is unfortunate that no very definite figures are yet obtainable in regard to the diversity of the cooking load. I have seen figures put forward showing it to be as high as 10, and others showing it to be as low as 3 or 4. I imagine that the diversity of the cooking load is really somewhere in the region of 7. That is based on the results obtained by an undertaking which has put in a considerable number of cooking stoves during the last few years. The total cost per annum for the all-electric house shown on the lantern slides was given as £43. Bearing in mind that the cost includes the equivalent of all the coal that would be burnt as fuel, I am certain it is not exorbitant. On the other hand it is really extremely economical and a very sound proposition.

Mr. J. L. Carr: I agree with Mr. Watson that the domestic use of electricity can only develop extensively provided a suitable two-part tariff is adopted, and in that connection I should like to make one or two suggestions from personal experience. I have observed that the lighting consumption in the winter quarters is approximately double that obtaining in the summer quarters, and it is interesting to see from Fig. 7 that the total consumption for an all-electric house is in approximately the same proportion. In this district the standing portion of the domestic charge is divided into four equal parts. As one who has some knowledge of the subject I can appreciate that, taken over the 12 months, this has no influence on the average charge, but for the benefit of the lay man it would be a distinct convenience if the standing charge were arranged differently, say one-third of the total annual charge for each of the winter quarters and one-sixth for each of the two summer quarters. By doing this the consumer's bills would be strictly comparable with those previously obtained by running on a fixed cost per kWh. Although it may seem of little importance to some engineers, it would be a distinct convenience to the average consumer for the purpose of comparing costs year by year. Mr. Watson informs me that that method is now adopted in Salford. There are several points in connection with the installation which call for comment. I was surprised to see that in place of what we consider to be the best practice in the wiring of a new house—that is, solid-drawn heavy-gauge steel conduit—the author has adopted the hard-rubber-sheathed cable. In the case of the conversion of an existing house for domestic use there is some excuse, and possibly very good reason, for using one of the various systems of surface wiring at present on the market, but in the case of a new house, where the cost of erection is a negligible portion of the total cost, most engineers will agree that the sounder job is one in which heavy-gauge conduit is used. I appreciate the author's point with regard to the number of wires concerned, but if a suitable conduit is used I do not think that should be a very serious consideration. The grouping of distribution boards will not appeal to many installation engineers as being altogether satisfactory; probably a much sounder job would have resulted by installing a section board to which each sub-section or distribution board would be in turn connected, thus localizing interruption in supply in the event of serious faults occurring on any part of the system. The question of the number of points in a room is referred to by the author. It is my experience that with a limited number of plug points in one room a certain amount of inconvenience is experienced, because it happens that after one or two plugs have been installed the furniture is removed to another part of the room, and some of the plug points are covered up and are not available for use. The diversity of the load in different rooms is quite sufficient to enable three or four small plug points to be looped if necessary. In that connection I have found it very useful to install one or two 15–20 ampere plugs in each room, and a larger number of 10-ampere plug points to allow of the use of small portable appliances such as small radiators or portable lamps. The author mentions some of the merits of electric cooking, but I think that publicity departments should confine themselves more to the recommendations that are made with regard to cleanliness, ease of operation, etc., than to making statements similar to those found in many makers' catalogues, where it is often stated that the cost of the electricity used can frequently be saved by the reduction in wastage of the meat. Those statements cannot in my opinion be justified, the saving in the meat being largely due to the smaller amount of water evaporated—not to the particular kind of heating, but to the design of the oven. The question of the reliability of hot-plates is a very important one in connection with the development of the cooking load, and in going over some records for the past few months I have been agreeably surprised to find that by the use of a protected type of hot-plate the total percentage of hot-plate failures has been considerably reduced below that anticipated. That raises another point mentioned by the author, i.e. in connection with the radiant heat from hot-plates and the effect of blacking the bottom of utensils. With the protected type of hot-plate the proportion of radiant heat is comparatively smaller than would be expected in a purely open type of hot-plate, and the benefit to be obtained by blacking the bottom of the pan is consequently considerably reduced. From a few rough experiments I have made I am convinced it is really not a good proposition to black the bottoms of the pans, for several reasons. First, the total amount of radiant heat developed is only a small proportion of the total input. Second, by blacking the bottom of utensils, particularly aluminium pans, such as one normally purchases when acquiring an electric cooker, one sacrifices a great deal in the clean and bright appearance of the equipment. Third, with black-bottomed pans one naturally has a distaste to placing them upon tables for ease of manipulation after cooking. The point made by the author in regard to the use of self-contained utensils is one with which I am in agreement to some extent and I find it a distinct convenience to provide a limited number of vessels with self-contained elements. In the present stage of development the average consumer cannot be expected to provide

himself with expensive appliances of this sort, particularly when they are so liable to break down. I am of the opinion that the development of the use of such appliances, whilst considerably reducing labour and inconvenience in connection with electric cooking, can only proceed if the supply undertakings, which in many instances hire out the electric cookers, will undertake to supply and maintain them for the consumer. In that connection it has to be remembered that considerable expense is incurred by the careless use to which such appliances are subjected by the average consumer. The total cost mentioned by the author struck me as being extremely low for an all-electric house, and I was somewhat astonished to find that my own figures, using gas for cooking, electricity for lighting and limited heating, and coal for general heating, were *per capita* practically similar to those given in the paper. During the past year, when the gas has been cut off altogether, they have been very little different from what they were before.

Mr. G. F. Sills: I consider that electric kettles take an unnecessarily long time to boil water. I have one which is rated at 1 000 watts, and it takes 12 minutes to boil 3 pints of water from 60° F. If kettles cannot be supplied with elements up to 2 kW, then an alternative, where an electric cooker is also available, is to supply one hot-plate of the cooker with a 2½ kW element in place of one 1½ kW. This enables the kettle to be boiled in about 7 minutes, and is the practice of at least one well-known corporation. The kettles, in addition to having fusible plugs at the bottom, should also be of the whistling type; this would prevent a good many kettles from being allowed to burn out. An interesting feature of the paper is that the bell wiring in the author's house is carried out with C.T.S. wire. The bell system in houses is usually extremely unsatisfactory. With reference to the position of plugs for radiators, etc., in houses specially built for all-electric supply and without any of the usual type of mantelpiece, I can quite see that the switches should be on the skirting board. Most of the power consumed in houses for a long time to come will be used in existing houses which have the ordinary mantelpiece, usually wood, and it would be much more convenient if the switch controlling the plug of the radiator, or the combined switch and plug for the radiator, were fitted on to the side of the mantelpiece close to the wall. The position would enable one to switch on at least one element of the radiator without bending down every time. I have found from experience that if a 230-volt iron is put on a 200-volt circuit it will not burn out and yet it will get hot enough to do ironing, provided it is not one of the smallest sizes. In connection with the supply from Manchester, after studying the Norwich system I came to the conclusion that I could get my current for cooking for nothing, because my bill for lighting and cooking on the Norwich system would be no larger than that for lighting only on the standard charge for lighting only. One of the lantern slides showed a fire which threw the heat towards the floor, and I gathered that the author did not favour this type of fire. I am not sure whether he was referring to a particular make, but I have come to the conclusion that it is much more efficient to throw the heat down, as unless the floor is warm one does not feel comfortable in the room. I have over 17 kW connected to the mains and am quite satisfied that on the basis of 20 per cent pre-war rateable value, plus ½d. a unit, one cannot go wrong in using electricity.

Mrs. H. C. Lamb: I can speak with confidence of the comfort which electricity brings into the home. I have used nothing but electric fires in the dining-room and in the bedrooms of my house for over 8 years, and have found them exceedingly satisfactory. I believe that it is only necessary to obtain the right type and size. The author says that he has a small dustbin which is emptied twice a week. Even if we could persuade the dustman to come twice a week—of which I am doubtful—would the cook be satisfied with that? She knows there is some animal refuse and vegetable refuse which must be destroyed at once, and she would not be satisfied to see it merely left in the dustbin for three days at least. If we have an all-electric house, why not have an electric furnace to burn the refuse? The electric oven and griller I have found to be entirely satisfactory, and I shall never wish to use anything else. The only objection seems to be the cost of the electricity. People think it is expensive, but that idea must be corrected. Where is the maid's sitting-room in the author's house? It seems that she has to use the same room as that occupied by the boiler, the sink, the oven and the washer. I do not think that sort of a room is quite suitable for a maid, and if the other rooms are going to be made comfortable the maid's room also must be included. It would have been better to have made a bigger scullery, where all the work would be done, and a little rest room where she might get away from her work.

Mr. A. Philip: The main drawback to electric cooking is the time taken to heat anything by means of hot-plates, but as regards their efficiency it is rather surprising to see such low values mentioned as 20 to 25 per cent. From the results of tests on a considerable number of different types of plates it appears that values below 35 per cent must be considered poor, whilst 40 per cent is an average figure for good types. One enclosed hot-plate, fitted in a light-weight stove, has the unusually high efficiency of 50 per cent. It should be noted that the method of test, which was intended to approximate to practical working conditions, gives figures which necessarily err on the low side. As regards the construction of hot-plates, the partially enclosed type appears to be best from the point of view both of efficiency and protection, whilst the open type is not at all to be recommended. High efficiency can be attained in general by the following:—(1) Reduction of the amount of metal used in the construction of both the hot-plate and the top plate of the stove; (2) reduction of clearance between the heating element and the cover plate to a minimum; and (3) if possible heat-insulation of the hot-plate from the top plate by a small air-gap. Loading and temperature are of course other factors to be considered. A partial solution of the hot-plate difficulty lies in the use of separate pans with immersion heaters, the efficiency here being from 80 to 90 per cent, but their initial cost is high

and they are probably somewhat difficult to clean. Reliability is mentioned several times in the paper, and apparently no provision has been made for emergencies in the author's house, but interruptions in supply do occur from time to time, and it does seem necessary to have some alternative, such as a small cooking stove and a few lamps, run by gas or oil, for use in emergency in an otherwise all-electric house. As regards domestic supply in general, my personal opinion is that the use of electricity should be extended and increased for all purposes other than water-heating and continuous room-heating, which are extremely wasteful from the point of view of conservation of fuel.

Mr. H. C. Lamb: The author is a consumer of an up-to-date and progressive undertaking, but it would not have cost him more for electricity if he had built his house in Manchester. The rate would have been practically the same. There is, so far as I know, no really all-electric house in Manchester, but we have many that are mainly electric, some of which have a consumption even greater than that of the author's, and at least one exceeding 20 000 units a year. One of the speakers in the London discussion said that it was all very well for the Glasgow Corporation to supply this one house at that price, but had there been a thousand such houses the department would undoubtedly have supplied them at a loss. I think the speaker was, however, mistaken. If the load curves of the thousand houses were identical, or if the supply undertaking had nothing but a domestic load to cater for, the houses certainly could not be supplied at the price given in the paper; but a varied class of load is required to give maximum economy, and it is the high diversity factor of the domestic demand which makes it possible to supply the electricity at a comparatively low price. Mr. Watson remarked that little or nothing was known with regard to the domestic diversity factor, but a great deal of reliable information has been published in the United States, and some information now being collected in Manchester will be available before long. Another very important factor in connection with the provision of a domestic supply at this price is that the demand is largely before 9 a.m., between noon and 2 p.m., and after 5 p.m. I agree with Mr. Watson in doubting the statement on page 298, which reads: "Thus the all-electric house in question has an aggregate consumption of about 30 times the lighting consumption, and this practically without increase of station plant." I am afraid that could not be true of an all-electric house, but it might conceivably be true of a house mainly electric; that is to say, a house possessing at least one coal fire for heating purposes. I have seen load curves from such houses which bear out the statement that the chief demand occurs at the time of day most convenient to the power station.

Mr. W. Eccles: In 1913 I had my own house fairly completely equipped. My enthusiasm lasted for 4 or 5 years, but latterly I have left the various appliances more or less in the hands of those who have to use them. It may be that I am still under the influence of the reaction from the original wave of enthusiasm, but it is more probable that I am really unbiased in the matter. My start, like the author's, was due to my thinking that I ought to have the courage of my convictions, and that courage was aided and abetted by the Manchester Corporation Electricity Department, who then offered an unlimited supply of 200-volt direct current at $\frac{1}{2}$d. per unit plus an annual charge of, I believe, $12\frac{1}{2}$ per cent of the rateable value of the house, which is about two-thirds the size of the author's house. In my house I have in all 16 heating points on 5 circuits, each 7/18 S.W.G. in conduit, and a cooking circuit for oven, hot cupboard, grill and four boiling-plates. For equipment I had nearly everything that showrooms of those days could show, and some things they did not stock, absorbing altogether 17 kW, but I did not in the least intend to have an all-electric house, as I did not then believe that it was economical or the easiest house to work. The energy consumed in the first year was 4 000 units, and in this connection it interested me very much when in a friend's house in Norway, where the tariff was per kW of maximum demand per annum, irrespective of the units consumed, to find that they had used some 4 800 units in a year on a maximum demand of $1\frac{1}{2}$ kW, whereas I had an actual maximum of 9 kW and a consumption of 4 000 units. In other words their load factor was 7 times greater than mine. It illustrates how very greatly tariff controls load factor. I am rather disappointed that the author should have been so revolutionary as to construct an all-electric house and dispense entirely with coal and gas. The result is that he has demonstrated that an all-electric house is a possibility at a more or less reasonable cost, but he has not helped nearly so much as he might have done to demonstrate the most economical equipment for a home which has to be worked either by the housewife or by the present-day maid-servant with the least possible effort or friction. If, however, the author never intended to install the most economical equipment, then I think he should have stated this clearly in his paper, as great injury can be done to the progress of the use of electricity in the home by claiming that it can do something which can be done better by either gas or coal. For instance, I am certain that the general heating of the house and the boiling of water in the kitchen can be done in this country, given properly designed arrangements, much more cheaply and effectively by means other than electricity. Furthermore, from the country's economic point of view, people should be encouraged to use low-grade energy, such as gas from which all by-products have been extracted, or coke, for water-heating, etc., and to conserve high-grade energy such as electricity for its proper uses. For these reasons the paper does not register an advance in general science and is of very little use to the general public. Taking next the point of view of those who have to operate such a house—and here my criticisms must involve the general design of the house as well as its equipment—I would fully endorse and underline Mrs. Lamb's remarks that the kitchen might be all right as a workroom but is no place for anyone to sit in in comfort. Such a house ought to have a small sitting-room for its staff, as otherwise it is a complete failure from the point of view of their comfort. Now look at the kitchen as a workroom and imagine the preparation and serving of a meal,

an operation which occurs at least four times per day. Those who have any experience of such things will see at once the entire lack of thought in the design and layout of this kitchen. It is necessary to pass through two doors to reach the larder; the cooker is at the maximum possible distance from the sink; the light is in the best position to make shadows where work is being done; the table, apparently not shown, looks as though it ought to be on wheels as it must be in the way anywhere, and especially with two doors opening inwards into the kitchen. The cupboard accommodation, too, must be scarce. I would say that the space used by this layout, i.e. 18 ft. by 12 ft., if used properly and thoughtfully would provide all that is necessary, allow for a small sitting-room for the maids, and reduce the work by at least 30 to 50 per cent. A larder of 20 cub. ft. capacity is ample to store all the perishable food that is likely to be kept in stock, but I see that the one provided is 8 times this size. This is, in my opinion, a sheer waste of space and a cause of needless walking. There is no reason why the cook should have to walk more than two steps to get anything required, and the majority of her requirements should be at hand and without needing any appreciable movement. The same remarks apply to the pantry, where everything required for the dining-room—excepting only hot cooked food—should be at hand and where all dish-washing and putting-away should be done. It will be seen that the proper place for the larder is in the wall between the cooking place and the pantry and it should be accessible from either side. In the bedrooms the lighting is very ordinary and not very thoughtfully arranged. The best arrangement for getting light where it is required at the dressing-table, bed and wardrobe, is to have those articles of furniture fitted with lights and switches, and supplied from the nearest wall plug. This allows for the rearranging of the furniture to suit the most fanciful housewife, and yet ensures the light being on the spot required. One general light controlled from the doorway is of course required in each room and from the bed, if one could be sure of the location of the latter. A purely non-electrical point is that of water supply in the bedrooms; this is such a labour-saving requirement that I cannot understand why it is omitted, as it apparently is. Ceiling sockets in the dining-room are most useful for table cooking and special-occasion lighting, and the only satisfactory and reliable bell push at the dining-table is one suspended from the ceiling. Referring to the electrical layout, the first outstanding item is that no less than 31 fuses are used and yet it has to be admitted that all portable lamps, vacuum cleaner, toasters, portable fans and light apparatus generally are practically unprotected. Personally, I should have protected the main wiring by 5 or 6 fuses at most and have devised some means of protecting the apparatus separately and in such a way that in the event of a fault it would not get blown up. It is the apparatus and not the cable that requires protection. I should never recommend anyone to have important electrical fittings in the house for cooking, heating, etc., unless there were a good service of repair men available with an ample supply of spare parts to draw on. The author mentioned this point but, in my opinion, did not emphasize it sufficiently. Its absence in my case was the cause of a gas cooker finally replacing the electric cooker originally installed. If the great untapped domestic load is to be developed, supply undertakings must push the sale of current more effectively by helping in the design and layout of houses to suit and by assisting the lay man to get a properly designed installation. Manufacturers must design apparatus capable of withstanding abuse and of being easily repaired. Electrical engineers generally must study the working of their homes and produce efficient designs for their lay friends.

Mr. W. D. Watson: Is the author's hot-water cistern of the type free from divisions, allowing the incoming cold water to mix freely with the already heated water, or is it made up of compartments enabling the user to draw off a cistern full of hot water before the cold water is allowed to mix with it and so cool it down? In regard to the author's use of unprotected rubber-sheathed cable, on the score of "safety first" is it not imperative that all cables should be mechanically protected? Nails used by householders are sooner or later sure to puncture the insulation. I have calculated the cost from the heating curve in the paper and I find that in the 6 winter months about 4 600 units were used, whilst the consumption for the rest of the year was only 1 314 units. In my district current is supplied at ½d. per unit for domestic hot water and central heating thermostatically controlled, 1d. for domestic utensils, radiant fires, etc., and 4¾d. for lighting. If the author's house had a system of central electrical heating of the "linear" or "tubular" type, the cost for the winter months to keep his living-rooms and kitchen at a temperature of 57°–60° F. would have been about £9 5s., leaving the balance (amounting to £9 15s.) for boosting-up purposes in winter and also for the small summer load at a charge of 1d. per unit. I calculate a net saving of about £4 10s. per annum based on experiments I am now carrying out. A house so heated is in my judgment far more comfortable than one heated entirely by radiant fires.

Mr. G. A. Proctor: Taking the figures in the paper, the cost of a full domestic electric service for a house having a rental of £100, viz. £43 a year, is remarkably low, less than half the rental values. Taking actual figures of a more modest house of £30 a year rental, using electric light, gas for cooking and washing, and coal for heating, the cost worked out as follows: electricity £4, gas £3, coal (5 tons at 45s. a ton) £11 5s., making a total of £18 5s. 0d. Comparing those figures the author has proved that the all-electric house is a practical proposition. The all-in cost of the electric flat referred to in the paper, rental about £40, is £14 18s. plus £2 for the hire of a cooker and 2 fires. Those figures again prove that the complete electric home is a commercial proposition. As regards the entire elimination of coal fires in the home, it would be interesting to have the views of the sanitary authorities on the question of the disposal of household refuse.

Miss E. E. Wilson: Mr. Eccles said that all his apparatus seemed to need constant repairs. I am in the position of having to leave my all-electric flat all day, the household duties being carried out by a

maid, and so far none of the apparatus has had to be repaired.

Mr. A. L. Lunn: In the introduction to the paper, the author mentions the adverse criticism received from electrical engineers when the scheme for his "all-electric" house was discussed. I have much in common with him on this point, as just over 2 years ago, when deciding to adopt electric heating and cooking, several of my engineering friends hinted that I should rue it. As one who is partly responsible for a supply of electricity, I considered that I was doing a disservice to our industry unless I was prepared to use our own products; therefore I went ahead with my scheme and now, after 2 years, I am more than satisfied with the venture. My own case may be somewhat unique, as all our cooking and the baking of bread, cakes, pastry, etc., is done in the home. The house contains 7 rooms, 2 on the ground floor, and kitchen, 3 bedrooms on the first floor, and 1 large attic bedroom. Previously, electricity was only used for lighting, ironing and vacuum cleaning, all cooking being done by gas and heating by coal fires. During the past 2 years all cooking and heating have been done by electricity, with the exception that a coal fire is used in the kitchen for heating water. When deciding upon this scheme I naturally expected that it would cost more than the previous arrangement for improved conveniences, etc.; I therefore kept records for comparison. After what I have heard during the discussion in regard to water-heating, I intend to adopt this too as soon as possible. In Manchester we are fortunate in having a very low tariff—a fixed charge of 20 per cent on the pre-war rateable value of the house, plus 0·5d. per unit—and my average cost for the 12 months ended December 1924, including the fixed charge (which is £4 13s. per annum) for 6 495 units, works out at the low figure of 0·673d. per unit. I estimate that I shall have consumed 7 078 units during this last 12 months, and the average cost for this, including the fixed charge of £4 13s. per annum, is 0·657d. per unit. Comparing my previous year's working, that is, using gas for cooking, coal fires for heating, and electricity for lighting, ironing and vacuum cleaning, the total cost per annum was £24 18s. 4d. For the first 12 months, using no gas, and coal only in the kitchen, the semi-electric house cost £26 15s. 2d., made up as follows:—

	£	s.	d.
Fixed charge	4	13	0
Cooker hire	3	0	0
6 495 units at ½d. per unit	13	10	8
Coal	5	11	6
	£26	15	2

This shows an increase of £1 16s. 10d. For that amount we have a radiator available in every room, including the bathroom and hall. I do not think it is necessary for me to mention the advantages of having radiators in the bedrooms, particularly during the very cold weather; and, apart from this, what we have saved in cleaning alone is well worth £1 16s. 10d. per annum. This last year has shown an improvement over the previous one, the total cost for the semi-electric house being £25 4s. 9d. Comparing this with 2 years ago, the increased cost is now only 6s. 5d. and, considering what we have had for that increase, it is well worth it. In col. 2 on page 291 the author mentions the use of a standard lamp on a circuit fused for 15 amperes. It is not advisable to put some of the small apparatus on a 15-ampere circuit. If ladies are using electric irons or vacuum cleaners, and a short-circuit were to develop on the flexible cable, they would be startled and lose confidence in using these appliances. It is preferable to have an intermediate plug box with a small fuse in circuit (as light as possible) between the appliance and the radiator plug. The gas was cut off at my house 18 months ago, and since then we have been dependent on the electricity supply. For over 2 years we have not had a coal fire in any room in the house, except in the kitchen. I have proved this scheme to be quite satisfactory, and if more engineers would have confidence in their own industry the electrical appliances would be improved by their experience and our smoke problem would be partly solved.

The Author's Reply to the Discussions at London, Birmingham, Leeds, and Manchester.

Prof. S. Parker Smith (*in reply*): There are, in all, 10 discussions to be replied to, and I am desirous of dealing with all points as far as possible. In order to lighten the task of the reader, repetitions will be avoided wherever possible. For this purpose a few general questions will be dealt with collectively, and later the remaining points raised by the several speakers.

At the outset I should like to make a general acknowledgment of my indebtedness to all who have contributed to the discussion. The information contained in these contributions is in many ways not only supplementary to, but of greater value than, that given in the paper. Had such information been available 3 or 4 years ago, my task in designing the electrical equipment of my house would have been incomparably easier.

In response to requests, it is hoped that a curve similar to that in Fig. 8, but taken for a winter's day, will appear in my reply to one of the later discussions.

A few points will now be dealt with collectively.

Waste of national resources.—No member of the Institution needs to be told that electrical energy obtained from a coal-fired station working at about 20 per cent efficiency is not the most efficient method of obtaining heat for domestic purposes. Nevertheless, one speaker after another has supplied figures which prove that, with the tariffs on which the paper is based, there is roughly no difference between my costs and those of similar houses using gas, coal and electricity. At the same time the many savings obtainable with the use of electricity are admitted. How is this to be explained? Though the number of heat units brought to the house is much smaller in the case of electricity

than with coal and gas, the utilization of the former is much better. An electric fire and an immersion heater have efficiencies approaching 100 per cent, for all the convected heat from an electric fire adds to the warmth of the room, whilst the losses from a well-lagged tank are small. Also the electric oven uses heat more efficiently than the other ovens do. Again, the stand-by losses with electricity are negligible, whereas a coal fire may have to burn all day whether it is needed or not. True, many forms of heating give a warmer house than is obtained with electricity; but is this necessary? So long as the persons are warm and there is no discomfort, what complaint can be made? In addition, greater comfort results from occasional heating in bedrooms, bathrooms, etc., where electricity is available. It may be said, however, that all this evades the charge of wasting national resources, and that it is no answer to say that with electricity the waste occurs in the power station instead of in the house. Yet some weight must be given to this point. The fuel in the station costs about 15s. per ton against 40s. in the home—part of the latter represents avoidable distributive costs. Now let us see what it means when we use a coke-fired boiler for hot water. The coke has to be ordered and stored; the boiler has to be maintained, cleaned and stoked all the year round. The saving, accepting Miss Fishenden's figures, would be £5 to £9 per annum, according to circumstances. Personally, at the risk of being called extravagant, I think it is worth this sum for the comfort, convenience and reduction in labour. A home cannot be designed on the same lines as an office or a factory. We are not expected to burn coke in our grates instead of coal, though it might reduce smoke and assist certain industries. Here also we must be allowed to choose the form in which we buy our heat units. The fact that so much less labour is needed in the home without increasing the overall costs should not lead us into making a fetish of economy. Life is more than economy. What cheerless places our homes would be if economy alone ruled our lives. At the moment we can be happy that electricity with all its advantages can be obtained without increase of cost. Lastly, may not some service accrue to the community by reducing the demand for domestic servants; also is it not a national service to reduce all unnecessary distributive costs—some 10s. to 20s. per ton on coal and coke?

Extravagant installation.—Many speakers, especially contractors, have questioned what to them appears to be the lavish way in which the house has been wired. Now it must be remembered that most electrical engineers with whom the scheme was originally discussed condemned it outright; also that financially it was a very serious venture for me. Critics must not be surprised therefore that I was prepared to take no risks. As a designer I knew many of the pitfalls, such as cheap material and shoddy work, and I determined to give the scheme every chance. The latest edition of the Institution Wiring Rules proved a sound guide and every effort was taken to do the work as it should be done. As regards the switching of the lighting circuits, I am convinced that the enhanced convenience is well worth the small extra cost. The fusing of the power circuits is not so easy to settle. Ought the simplicity and convenience of interchangeability to be readily sacrificed; and is a 5-ampere fuse a much greater protection for an appliance taking, say, 100 watts, than a 15-ampere fuse? There may well be room for differences of opinion on such points.

Capital cost of installation and appliances.—It is hard to see why members of this Institution should require this information to be given in the paper. Full details of the layout are given and costing of any desired part is a simple matter for any electrical engineer. Each case must be worked out according to requirements. The paper is intended to give details of running costs for the several services, for it is here that a degree of uncertainty has prevailed hitherto.

Smoke abatement.—The amount of sunshine in these islands is all too little, especially in winter; and of the small quantity available it is claimed that city smoke—four-fifths of which is produced by domestic chimneys—robs us of about half its healing (ultra-violet) rays. Is it too much, therefore, to regard preference for the coal fire as being somewhat selfish? Who knows whether the present movements will not compel us to provide cleaner homes in healthier surroundings for our people? Should not altruistic thoughts of this kind make us very cautious in advocating the retention of one coal fire?

The last coal fire.—Many speakers advocate the retention of one coal fire—some for romantic reasons, others for obtaining a supply of hot water, others for burning refuse, and yet others for occasional use. The domestic labour problem seems to be dealing pretty effectively with the romantic side. The use of a coal fire for obtaining hot water is not so easily disposed of, especially in districts where the charges for electricity are on the high side. In such cases it may be better to fit an immersion heater in the hot-water tank for use in summer and to lag this tank to reduce losses. Also, for occasional heating in spring and autumn, the electric fire becomes a logical adjunct of high tariffs. In my opinion, however, it is desirable to go the whole way where tariffs make this possible, for in such cases experience tends to show that the cost of electricity alone is less than that of electricity and coal. Certainly the retention of a coal fire in the kitchen alongside an electric cooker may cause complaint on account of cost. The disposal of refuse appears to be a thorny problem. Some speakers agree with me that removal of refuse is paid for in the rates and ought to be properly done by the local authority. A larger number, however, are horrified at the idea of allowing garbage to accumulate for, say, a week. The personal equation is evidently important in this connection. As a result of inquiries I am inclined to believe that the facts are not always correctly understood. Many people imagine that their refuse is burnt on the premises, when actually it is thrown into the bin. In artisan classes refuse is often burned on account of its fuel value. In a house with one coal fire (and that fire in the sitting-room) the burning of refuse must be very objectionable. It must be remembered that in an all-electric house the total quantity of refuse is less than in a house where coal is used. Should, however, the householder insist on burning his own garbage, I should suggest than an

incinerator is preferable to a coal fire. The smoke question alone would justify this opinion. To light a fire daily in summer to dispose of refuse would entail too much cost and trouble for most people. In some countries, nuisances from garbage—arising from smell or mosquitoes—are prevented by depositing the garbage in old newspapers, which can be twisted up before being thrown into the refuse bin.

Tariffs.—It has been clearly proved that the success of the all-electric scheme is dependent upon suitable tariffs. It should, however, be particularly noted that the tariffs existing in Glasgow are not unique. Many other cities such as Hastings, Liverpool, Manchester, Sheffield, Leeds, Wolverhampton, Worcester, etc., have practically the same rates for domestic consumers; though power companies are not so progressive.

Living in a cool atmosphere.—This point has been ably argued—some have urged the hygienic advantages of a comparatively cold atmosphere, whilst others find warmed air more comfortable. My experience may be peculiar, but even in the coldest weather the house has not been chilly nor has there been discomfort from cold walls. It should be mentioned that (weather permitting) in winter as in summer there is generally an open window in every living-room and bedroom. The figures given in the paper, viz. 50°–55° F., were taken, if my memory is correct, from an article of Miss Fishenden, written for a special number of a journal, as being the comfortable temperature with ample radiant heat. I confirmed these figures and used them to replace somewhat higher figures of my own.

All-electric dwellings for artisans.—It would be very disappointing to find that the all-electric idea cannot be applied to artisan dwellings with the Glasgow and similar tariffs. Fortunately, figures are given which show that the case is feasible. In Table A, Prof. Barker gives 3 180 000 B.Th.U. per person per annum as the number of heat units needed for heating, hot water and cooking in an artisan's home. Let us increase this to 3 400 000 B.Th.U. (= 1 000 units of electricity) to allow for the low efficiency of the electric cooker. Mr. Grierson found that the average annual cost in 5-roomed houses for these services was £16, or about 6s. per week. This sum would be just sufficient for a household of 5 persons each using 1 000 units per annum with energy at 0·75d. per unit. This figure of 5 000 units per annum is also confirmed by the figure of 5 350 kWh in the footnote on page 312. Moreover, these figures will be improved in future by higher cooking efficiencies. It can easily be seen that the problem is within the bounds of practical discussion. Thus where energy is offered at about ¾d. per unit overall, the workman's house ought to be seriously considered. For example, the fixed charge of a 5-apartment house in Glasgow is £5 4s. per annum; so that at ½d. per unit and an expenditure of £16 per annum, the yearly consumption would be 5 184 kWh.

Cooking utensils with self-contained elements.—It is difficult to predict at the moment whether such utensils will replace boiling-plates. My experience has proved that their use has practically halved the consumption for cooking—a saving of nearly 30 units per week. When it is remembered that such pots will be nickel-plated, mistake-proof, readily replaceable, suitable for hiring out, etc., one is almost encouraged to believe that they have a future. Moreover, a frying-pan with built-in elements, and a light oven of low heat capacity, may also serve to reduce consumption still further. It is important not to be too conservative in our ideas —let us first produce the right articles before we condemn the principle. In response to several requests, the sketch embodying my ideas is reproduced in Fig. A. The oven, pots and fry-pan are interchangeable at any of the 3-heat points. A grill and an enclosed boiling-plate for ordinary pots are also provided. The metal-top table provides the earthing device. It is intended to dispense with flexible cables and provide simple mechanical interlocks. The pins, etc., are shown exaggerated to make the ideas clear.

In reply to Col. Crompton, in theory there is no need for a fireplace. Actually in Great Britain people prefer to sit round a fire (or fireplace). At the same time, there is no reason to have only the one fire. In many cases it is better to distribute the heating, and

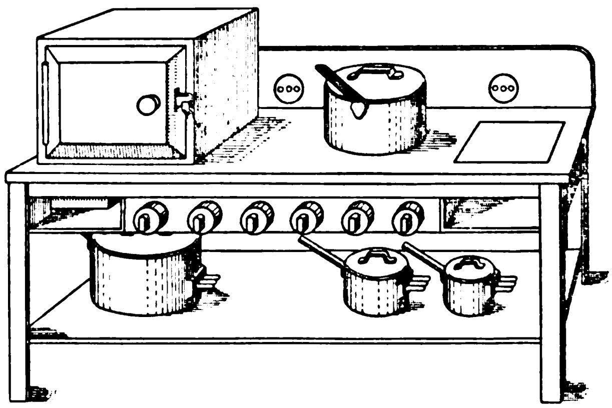

FIG. A.—Suggested cooking table with utensils with 3-heat self-contained elements, portable oven, grill and closed boiling-plate, designed to secure speed with safety and economy.

this can easily be done although one fire is fixed. On the other hand, too much stress cannot be laid on the convenience obtainable from the portability of the electric fire, for this is one of the unique advantages of electric fires, particularly when employed for occasional use, as in bedrooms, etc.

The disadvantage mentioned by Dr. Ferranti of having nowhere to throw odds and ends is more apparent than real. In summer such odds and ends would not be tolerated in the fireplace—the coal fire as a handy receptacle is available only in winter. Perhaps we can learn a lesson from Mr. Baldwin. In his rectorial address to the Edinburgh students the Prime Minister admonished his hearers to learn from the sailor who refrained from spitting on the deck. Thereby the sailor not only avoided giving unnecessary labour, but also strengthened his self-control. (It was not stated that the sailor refrained from spitting.) I agree that the value of the service of the electrical supply to me is much greater than what I pay for it. We owe Dr. Ferranti a debt of gratitude for his interesting account of the efficient use he is making of the heat in

the jacket water of his engine. The one serious criticism of his scheme seems to be its high capital cost.

The Association of which Miss Haslett is director can do much to disillusion women about the high cost of electricity for domestic purposes, and to educate them as to its advantages. Too much emphasis cannot be laid on the necessity of a good maintenance service. Users must be assured that they will not be let down.

Everyone will be obliged for the important and authoritative evidence put forward by Prof. Barker, who has given such close attention to this subject. I think, however, that he carries economy in the home too far. Surely we are not to be asked to run our homes like a factory or an office! I cannot see how the costs given in the paper can be misleading, for the corresponding consumptions are also given. The success of the scheme clearly depends on the tariffs, and judging by results the costs are about the same as given by other speakers using other methods. In what way is it misleading to give the public the impression that a 10-roomed house can be run on electricity for £40–£50 a year? It is being done in Glasgow, and the ½d. per unit tariff exists in many other cities. From the heat units tabulated by Prof. Barker (Table A) the well-to-do man is allowed 11 million, the artisan 3 million, whilst I use 8 million—a figure in close agreement with Prof. Barker's experiments. Thus my mode of living is quite normal on Prof. Barker's own showing. If anything, Prof. Barker has rather proved to the populations of Manchester, Liverpool, Hastings, Sheffield, Wolverhampton, Worcester, Leeds, etc., that they can do the same as people in Glasgow if they wish. I do not agree that the losses in heating up a given quantity of water in 10 hours are 10 times greater than the loss in heating up in 1 hour. I fail to see any connection here. Moreover, the costs have not been based on rates of ⅜d. or ½d. per unit, but on the overall rates of 0·637d. for the total consumption and 0·791d. for the day consumption. Prof. Barker asks not for costs but for the total B.Th.U. per annum per person expended in producing the various services. Surely Table 2 satisfies these requirements, for has he not obtained therefrom figures for Table A?

I am much indebted to Major Henrici for the figures in Table B, particularly as items such as kindling and matches are included. It is balance sheets such as these that are necessary for proper comparisons to be made. The case cited here serves to show that with the rates in question the several costs are competitive. Without wishing to exaggerate what electricity can do, I can assure Major Henrici that the saving in labour is very considerable.

Valuable comparisons are given by Dr. Margaret Fishenden, showing again that my results are reasonable and competitive. The figures given by Miss Fishenden on costs of the several services are much appreciated. With respect to the efficiency of electric boiling-plates, the figures which I gave were obtained from tests made by me for heating about 2 to 3 pints of water from cold. The testing of boiling-plates is a very difficult problem indeed, and the very greatest care must be taken to get correct results. Moreover, the conditions of the test must be laid down with the closest precision. It is hoped that my results will shortly be published. No discomfort was caused from insufficient heating, and it was always possible, by placing fires where they were needed, to avoid unpleasant sensations due to unequal heating.

In reply to Mr. Gooch, it is not clear in what way the electric fire offers less comfort than the coal fire. The human body needs warmth, preferably in the form of heat rays, and this the electric fire gives. Is it not almost asking too much of the all-electric house that it should show great financial advantage over the ordinary house? If it is as good financially we ought not to complain, for there are many non-financial benefits which improve living conditions.

In reply to Mr. Coxon, there is a great deal to be said for the ideal of moving away from the city into rural districts. The lack of rural and railway electrification compelled me to build my house within the boundaries of a city instead of among some of the most delightful country in the kingdom.

In reply to Major Carter, not only do I find an irrepressible tendency to dispense with the grids of the boiling-plates, but with the boiling-plates also. I trust that these will soon be replaced by more efficient vessels, such as pots with built-in elements. At the same time I do not understand why Major Carter's cooking consumption should be so large, especially as grids were dispensed with. I am inclined to believe that the storage tank is relatively more efficient than Major Carter estimates. It must be remembered not only that hot water is distributed in the house, but that the consumption in the paper includes a certain amount of emergency heating of water. Electric fires of the modern types have given remarkably little trouble.

In reply to Mr. Driver, it may not be long before electric appliances for cooking will be free from imitation. Already light, low-consumption aluminium ovens are on the market. The improvements to the boiling-plates consisted in raising the elements, lightening the grids and blackening the bottoms of the cooking utensils. Self-contained utensils need not be very heavy—no heavier, say, than black pots used for coal fires. Possibly the aluminium utensil has spoilt us somewhat. The cost of cooking appliances as outlined in the paper (light oven, self-contained cooking utensils, cooking table with grill and an enclosed boiling-plate) seems to be about the same as the cost of an electric range of the table type. A thermostat could easily be fitted to the hot-water tank, and probably would be in future designs. Mr. Driver's remarks show, however, that he understands my position too readily to expect me to introduce any unnecessary source of trouble. Without wishing to indulge in heroics, caution is natural when one has his " back to the wall." A trial of two tanks was made, and it was found better to use one only. If no rebate is obtainable for night load, there is a strong inducement to have a low-consumption tank continually in circuit. Efficient lagging, however, is more than ever essential where energy is not cheap. Thus any tank in which the water attained a steady maximum temperature of, say, 150° to 200° F. when no water was drawn off would have very large losses. Mr. Driver's remarks about contractors will be widely appreciated.

Prof. Fortescue is correct in saying that care is needed in an all-electric house to prevent waste, yet my figures do not represent "stint" in any way. It is not unreasonable to request that hot water be not allowed to run to waste and that boiling-plates and fires be switched off when not required. Already many cities have the same favourable rates as Glasgow, and it is to be hoped that rural districts will soon be in a similar position.

I agree with Mr. Grierson that flexible cords across the floor are inconvenient and dangerous. Much can be done to avoid this by spacing the sockets round the rooms and placing the appliances near, though not necessarily close to, the walls. The panel system described is full of interest, but I am not able to say whether this method of heating would be acceptable in homes. The table given by Mr. Grierson is very instructive and it is hoped that the figures given in the earlier part of my reply will show that the artisan's home can also be worked all-electrically.

It is welcome news to hear from Mr. Harmer that blackleading is unheard-of now. The speaker's coal fire which produces less dust than an electric fire must be almost unique; if, in addition, it would not pollute the outside atmosphere, neither neighbours nor anyone else would have much to complain of. With such fires the advocates of economy would get a cool reception. It is not myself but my critics who speak so much about garbage disposal—on this point Mr. Harmer and myself are in complete agreement. Let the rate collectors collect the refuse, and if they wish to burn it for its fuel value, good will result. I had no intention of offending women in my remarks on cooking. The fact is that many women do find cooking unattractive. The oven thermometer and the clock, combined with the cleanliness of electric utensils, should introduce new ideas about cooking and thereby make it more attractive to many intelligent women (and men) who, whether they like it or not, must do it. However much I may agree that "any woman worthy of the name takes a pride in cooking," this is the type of remark which in my opinion would be "uncalled for" in advocating scientific cooking. I do not know in what way lamp fires are better radiators than hot-wire fires—radiation is a function of temperature difference. It had not occurred to me that my distribution board makes my house a showroom, nor is it clear to me how 4 ways could satisfactorily replace 31 ways.

In reply to Mrs. Matthews, the hiring out of costly appliances (on a commercial basis) is becoming more and more common, but there are many articles now on the market that have been thoroughly tried out. Many of the queries raised might well condemn conversion to electricity on purely economic grounds—it is when one attaches importance and value to comfort, cleanliness and labour-saving healthfulness (to use this lady's own words) that one begins to regard the problem in the same way as other problems in life, such as clothing, holidays, etc.

In reply to Mr. Tremain, I have not found it needful to devote any time to the development of vacuum cleaners for the home. There are many reliable cleaners on the market, and the possible existence of an objectionable odour has not previously been brought to my notice.

In reply to Mr. Moffett, supply undertakings appear to be able to cope with a fair domestic load without increasing their plant—this would seem to be the basis of their keenness in pushing low tariffs for such load. I have made the efficiency (from coal) of my fires appear as low as possible—even now the figure is no worse than that of a common coal fire. The coke-fired boiler with 70 per cent efficiency must be unique. Yet with all my inefficient appliances many speakers have shown that the total costs are no greater than with other modes of running a house.

In reply to Mr. Jennings, it seems to be a pity that a great, modern city like Birmingham should introduce its new domestic tariffs at ¾d. per unit when ½d. per unit has been adopted by so many other municipalities. Surely this fact alone will hinder many people going the whole way—the high tariff is the only danger apparent to me in the "all-electric" idea. I would ask Mr. Jennings seriously to consider how far it is justifiable to use electricity in the home when the rates are such that it is too costly to use for everything.

I find myself practically in complete agreement with Mr. Wilson. I have included the sketch of my idea of an electric cooker in Fig. A on page 330. Doubtless a much more efficient oven than the present one can also be built.

I can only ask Mr. Joseph in return why "any" house needs a scullery. What poor efficiency to use a scullery for only a few hours per week. Washing with electricity can be done without filling the place with steam, by proper heat control. If my example appears extravagant, it has been shown by speakers in the discussion that an all-electric house can be built cheaper than an ordinary house. Every care was taken to avoid unnecessary expenditure, but a sound job was insisted upon.

In reply to Mr. Rawll, by "under-running" lamps is meant running them on a voltage lower than the rated voltage, the intention being to reduce renewals by lengthening the life of the lamps. For this to be effective, of course, the cost of energy must be small. Mr. Rawll points out the objection to geysers, and it is clear why preferential tariffs cannot be expected for such appliances. Surely with a loading of only 6 to 7 kW, merely a trickle of hot water would be obtained. It is hoped to include a daily load curve for winter in the reply to a later discussion. Possibly the most practicable way to balance the load would be to connect a similar house on the other side of the system. As far as I am aware, the local substation is not inconvenienced by my load.

Many readers will be indebted to Mr. Dean for his pioneer work and for his courtesy in permitting Mr. Milne to publish the comparative capital costs of the ordinary house, the electric plus one coal-fire house and the all-electric house. It is to be hoped that the Birmingham Electric Supply Department will encourage the scheme.

The comparative figures given by Mr. Milne are just what architects and other interested people need. The care with which the figures are given inspires

confidence, whilst the costs of electric appliances can easily be added, as these are well known. Of the £66 saved in building the all-electric house, some £16 to £22 will presumably go in wiring, leaving, say, £44 to £50 for electric appliances, which should be ample, especially as some of them would be hired. Apparently, therefore, the total costs would not be very different for the three different types of houses. Similarly the cost of my house could have been reduced to about that of an ordinary house by omitting chimney breasts, etc. The average weekly consumption, estimated at 100-120 units, should be enough for 5 or 6 persons in the household, and it is hoped that electrical energy will be obtainable at an overall cost of about ¾d. per unit.

In reply to Mr. Jones, it is probably true that leaving one coal fire per house will not reduce the smoke nuisance in winter. Perhaps some scheme could encourage the all-electric idea in densely-populated areas.

In reply to Mr. Longman, the quick-break switches worked by the toe are very satisfactory. Switches were apt to get damaged during building, but since they have all been put in order there has been practically no trouble. The main heater for the tank is at the bottom, the three-heat rotary switches being placed half-way up for convenience. Fifteen gallons of hot water per person per day may seem ample, but some people clamour for more. The cooking consumption —1·27 units per person per day—is perhaps nearer the average figure than the usually quoted 1 unit. However, there seems to be no reason why this figure should not be reduced to about one-half.

In reply to Mr. Moss, it is doubtful if the load on the house ever remains at 50 amperes for any length of time. The switch is so robust that I should not hesitate to overload it by 100 per cent for a short time. The I.E.E. rules allow 3/·036 cable to carry 10·3 to 12 amperes—how is it then overloaded with a 2- or 3-kW, 250-volt fire? The 15-ampere switch is the nearest and proper standard. The lighting circuits are not wired so much for heating as for voltage-drop, but they can be safely used for any appliances. I am glad that Mr. Moss agrees that tough-rubber cable makes the best job for bells. Would it not then be better to use it and stop people saying that electric bells are always going wrong? True, the wash-boiler takes longer than the washing machine to do the same work, but it is quite satisfactory for a small household and costs perhaps one-quarter as much as the machine. No trouble has been experienced from dust in the drying-closet—even if this were so, the air could easily be filtered at the intake. Because I have tried to do the work properly, it is a mistake to suppose that money has been spent freely.

The rates quoted by Mr. Mott are doubtless out of the question for all-electric artisan homes. Lighting and cooking alone seem to be possible.

It is pleasing to hear from Mr. Carter that a consumer of 10 000 units per annum can get his energy at 0·56d. per unit. Flexible tough-rubber and ordinary cables are on the market.

In reply to Mr. Hefford, unless some inducement be given to the consumer to install a storage tank and to heat water during the night, it is fairly certain that it will become part of the peak load, and possibly in the form of, say, a 30-kW geyser. Why not? Now there is no difficulty about the switching. A thermostat and time clock would do all this automatically—nothing could be simpler. In my opinion, separate cooking utensils would be simpler than boiling-plates, and there need be no flexible cables at all—all utensils would be interchangeable. Further, our success will not be complete in cooking until we have discovered and applied the true merits of electricity—even though this may entail educating the public. This point applies also to the portability of the fire. There are other functions to perform in the bedroom besides undressing —for example some folk use a washstand, others a dressing-table, yet others, both. Surely it is better to have a portable fire than a portable washstand or dressing-table. With regard to preferential rates for night load, my argument would be as follows. In order to induce certain classes of consumers to take night load, it must be remembered that such consumers are not tied down to take their energy at any stated time. If, therefore, such processes are to be carried on at night time, some concession will have to be made. There is no need to limit the application to water-heating; nor need such concessions be extended to processes which must take place during the night—after all, the station has to be kept running for these consumers, often at a big loss. It will be interesting to see whether the open coal grate now being installed in the new houses in Leeds, primarily for burning rubbish, will really be used for that purpose. Frankly I doubt it. Why should a fire be lit in an electric house in summer just to dispose of "certain classes of rubbish within a few hours of it being formed." Unless Leeds folk differ much from other folk the inspection staff of the Medical Officers of Health must have a busy time, especially in summer. With regard to smoke, which is the greatest nuisance in winter, I cannot see how the artisan can be expected to reduce his smoke in winter, provided he is given his coal fire. As stated in the paper, there are 6 persons in my household. The vertical flue is 9 in. × 9 in.; the inlet is the size of two bricks and is adjustable; the outlet is a grid 6 in. × 7 in. and is always open.

In reply to Miss Hancock, black priming paint is suitable for blackening the bottom of utensils, but it is hoped that in the near future such makeshifts will be superfluous. I certainly should not advocate them for general use. It is interesting to learn that energy is being offered at a fraction over 1d. per unit. If the house is to be closed during the day, 6 000 units per annum seems to be a very liberal estimate. For drying clothes, the fan is probably more useful and certainly more economical than the radiator.

In reply to Mr. Hodsman, continuity of supply is all-important—to cut off the electricity supply between noon and 1 p.m. every Sunday is intolerable. As far as I am aware, the supply to my house has not been cut off since I entered on the 12th July, 1924. Ventilation is certainly important, but here again facts should not be overlooked. At certain periods many people have neither fires nor open windows—this condition is widely tolerated, as is also the sleeping in rooms with

closed windows. I do not agree with this practice and my method of ventilation has proved satisfactory. Coal fires often produce too much draught and the feet suffer in consequence. An open window may well be advisable when there is no fire, whatever the type of house. The ventilation question ought not to give any trouble if properly attended to. The householder should be able to decide for himself whether he will use electricity for all purposes—though public opinion in the future may place restrictions on the burning of raw coal. It is hard to see why householders should be asked to shoulder the burdens of vested interests (the term "vested" seems to be more justified than "national"). In what way is the electrical engineer interfering with the natural development of the industries of carbonization? As yet there would seem to be no low-temperature process developed on a commercial scale, and it is quite possible that power engineers may be first ready with economical methods of producing liquid fuels and other necessities of civilized life. Perhaps the future generating station will prove the best means of treating coal and utilizing gas and coke; and it is certainly going too far to say that electricity is being applied to purposes for which it is not naturally fitted. As regards America, it may well be that the gas industry is much less developed than in Great Britain. With respect to Germany, Mr. Hodsman should know that hydro-electric power is often more costly than steam power. As for the public, since when was it the custom for the German Reich to look after the domestic consumer? Nationalization, or socialization, as understood in that country, has not brought cheap electricity to the individual. Mr. Hodsman's argument about the householder subsidizing the power station is apparently what he is advocating for the gas industry, so that the poor consumer would have to pay in any case. It is not admitted, however, that the domestic coal user is subsidizing the electric industry. The fuel used by power stations is not suitable for domestic uses and is bought in large quantities without high distributive costs. Whilst there is no intention to brush aside national problems, it would be stupid to arrest development because of academic discussions.

The criticisms of Mr. Buist are well worthy of attention, as they contain much solid foundation. The use of a coal fire in an artisan's home to furnish an abundant supply of hot water is probably a stronger argument than that based on refuse and romance. From figures given earlier in my reply (p. 330), I have tried to show that the all-electric case is not hopeless for the artisan.

The question of tariffs raised by Mr. Thwaites cannot be so easily dismissed. If the supply engineer is convinced that much of the domestic load does not entail increased capital outlay, he is right to develop his load accordingly. Glasgow has dropped the ¾d. limit—there is no logical justification for a limit of this nature. I should not underrate the importance of the arguments on the ultimate effect of a large domestic load, but are we not looking too far ahead? Who knows what the position will be when the all-electric house becomes general or even common? Should not the cooking consumption of ½ unit per person per day read 1 unit? The drying closet is drawn to scale in Fig. 3 and is as high as the kitchen. The fan is near the ceiling.

I agree with Mr. Watson that it is nicer to have food cooked in the kitchen and eaten in the dining-room, but facts ought to be faced. Mr. Watson himself speaks of "a sort of kitchen sitting-room" in the houses for which he is responsible. Is this not the practice in most houses throughout the country? Even in larger maidless houses, are there not many minor operations which can be done conveniently and more comfortably in the warm living-room? Such operations can be carried out in nickel-plated utensils (kettles, percolators, pots, etc.). Obviously the kitchen must be used when much cooking is to be done. Mr. Watson's method of arriving at a tariff does not seem to be logical; also the comparison was made only for cooking.

In reply to Mr. Carr, surface wiring has not been used in the house. It is possible that the preference for conduit may give way to more modern and cheaper methods of wiring. Whilst I do not advocate blackening the bottom of cooking utensils, I disagree with most of Mr. Carr's remarks in this connection.

In reply to Mr. Sills, I do not consider 12 minutes to be too long to boil 3 pints of water, nor can I see how any improvement would result with a 2½-kW boiling-plate. Mr. Sills really needs a heavily-loaded geyser. With my switches, practically all bending is avoided. There is a danger in throwing too much heat down—carpets may be scorched or floorboards may be warped.

An incinerator would doubtless solve Mrs. Lamb's difficulty, though I do not know many people who would use it. An all-electric kitchen with white-enamelled basins, nickel-plated and copper utensils, electric fire, polished woodwork, etc., is a very different place from the ordinary kitchen. Moreover, there is no difficulty in keeping such a kitchen free from dirt or smell.

I disagree in general with Mr. Philip's remarks on boiling-plates—the trouble is really deeper and affects the principle employed. Immersion heaters are said to cause certain foods to burn. Before entering the house, emergency devices seemed to be desirable, but experience has proved the contrary to be the case. From the results obtained, it is hard to see how water-heating and continuous room-heating are extremely uneconomical.

It seems to me that if Mr. Lamb once grants the one coal fire, he not only loses the main source of domestic revenue but really defeats his own argument. So long as a consumer goes the whole way, the supply undertaking knows its position clearly, respecting mains and plant. The occasional user is the uncertain factor. On a cold or foggy day, when the peak loads are worst, many of these occasional fires will be used to assist coal fires, to warm kitchens, bedrooms, and so on. This is inviting trouble, and eventually it will entail additional plant with small earnings. To my mind, Mr. Lamb's facts all favour the all-electric house.

In reply to Mr. Eccles, the paper describes an all-electric house and shows that such a house can be run economically. It is not part of my profession to

investigate the most economical way of running a house—which probably I should run away from—nor to design kitchens, larders and so forth. Suffice it to say that none of the imagined faults seems to have been observed by anyone who has lived in the house. Doubtless many pioneers have passed through the same experience as himself, and it is possible that people nowadays are benefiting by their efforts. Perhaps Mr. Eccles was asking too much of electricity, but it is a pity that he gave up the fight, especially as supply undertakings are beginning to appreciate the need of a good maintenance service.

In reply to Mr. Watson, cold water enters at the bottom of the tank as hot water is drawn off at the top. Very little mixing occurs—of course the inlet water should be suitably baffled. It is a simple matter to place rubber-covered cable in open conduit in the short, exposed runs where a nail is likely to be driven into the plaster.

It is interesting to learn from Mr. Lunn that in Manchester a consumption of 6 495 units works out at 0·673d. per unit. In Glasgow this was about the cost per unit for a consumption of 16 584 units, of which 6 043 units were charged at 0·375d.

CROSS-BREAKING STRENGTH, STIFFNESS AND OIL ABSORPTION TESTS FOR HARD COMPOSITE DIELECTRICS.

SUPPLEMENT TO "DIRECTIONS FOR THE STUDY OF HARD COMPOSITE DIELECTRICS" (REF. B/S1).*

[REPORT (REF. B/S2) RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION.]

PREFACE.

In Clause 8 of Ref. B/S1, the cross-breaking strength is expressed in terms of a constant k derived from the usual formula, but requiring division by six to give the stress per unit area.

It has been suggested that it would be more convenient if the clause were modified so that the cross-breaking strength were expressed in terms of stress per unit area, also the units being the pound and square inch. The adoption of these units will bring the revised clause into line with the usual practice of the E.R.A. with other classes of insulating material.

To meet the views expressed above, Clause 8 of Ref. B/S1 has been revised as shown herein.

The opportunity has been taken to include a test for stiffness or rigidity which has been adopted in the study of other classes of dielectrics. This does not involve a separate test, as the necessary observations can be readily made whilst the cross-breaking strength test is being carried out.

When Ref. B/S1 was issued a suitable test for the determination of the effect of oil on hard composite dielectrics had not been developed. As the result of investigation the oil absorption tests given herein have been adopted by the Association.

REVISED CLAUSE 8 OF REF. B/S1.

Note.—In the following clause pounds and inches have been adopted so as to conform to the usual practice of the E.R.A. with respect to other classes of insulating material.

* See *Journal I.E.E.*, 1922, vol. 60, p. 565.

(a) Cross-breaking Strength at Normal Temperature.

The material shall be tested at a temperature from 15° C. to 20° C.

The specimen shall be of the shape and dimensions shown in Fig. 9 (see Ref. B/S1) and shall be set up for testing generally in the manner indicated in Fig. 10 (see Ref. B/S1). When it is impracticable to obtain a specimen of the dimensions shown in Fig. 9, the alternative specimen shown in Fig. 11 (see Ref. B/S1) may be employed, which shall be set up as indicated in Fig. 12 (see Ref. B/S1). The load shall be increased gradually at the rate of 20 pounds per minute until the specimen breaks.

The cross-breaking strength at normal temperature is computed from the following formula :—

$$C = \frac{6WL}{BD^2}$$

where C = cross-breaking strength in pounds per square inch.
W = breaking load in pounds.
L = cantilever length in inches.
B = breadth of specimen in inches.
D = thickness of specimen in inches.

(b) Cross-breaking Strength at Grade Temperature.

Note.—The test is carried out as described in Clause 8 (*b*) of Ref. B/S1, and the cross-breaking strength is computed as shown in (*a*) above.

Stiffness or Rigidity.

Note.—The following additional test is suggested for application to hard composite dielectrics. The necessary observations can be readily made whilst the cross-breaking strength test is being carried out.

(*a*) *Young's Modulus at Normal Temperature.*

The material shall be tested at a temperature from 15° C. to 20° C.

The specimen shall be of the shape and dimensions shown in Fig. 9 (see Ref. B/S1) and shall be set up for testing generally in the manner indicated in Fig. 10 (see Ref. B/S1). When it is impracticable to obtain a specimen of the dimensions shown in Fig. 9, the alternative specimen shown in Fig. 11 (see Ref. B/S1) may be employed, which shall be set up as indicated in Fig. 12 (see Ref. B/S1).

A measurement shall be made of the distance of the unsupported end below datum point as follows :—

An inside micrometer shall be clamped above the stirrup and connected to a battery and low-reading voltmeter, the circuit being completed through the stirrup. The micrometer screw shall be turned until the circuit is closed (as indicated by the voltmeter) and the micrometer reading shall then be taken.

Small equal increments of load shall be applied and the corresponding increments in deflection measured immediately. Each increment of load shall be applied as soon as the deflection for the previous load increment has been read. Readings shall only be taken for the range during which the increment of load is proportional to the increment of deflection. The load at which the deflection departs from proportionality (yield point) shall be noted, and the stress, computed from the formula given in the revised Clause 8 (*a*) above shall be stated.

Young's modulus E shall be computed from the following formula :—

$$E = \frac{4L^3w}{BD^3y}$$

Where E = Young's modulus of elasticity in pounds per square inch.
L = Cantilever length in inches.
w = Average increment of load in pounds.
B = Breadth of specimen in inches.
D = Thickness of specimen in inches.
y = Average increment of deflection in inches.

(*b*) *Young's Modulus at Grade Temperature.*

A specimen similar to that employed in (*a*) shall be set up as described in (*a*) without loading, and a measurement shall be made of the distance of the unsupported end below datum point as before. The specimen shall be heated for two hours at the grade temperature of the material and shall then be loaded and the increments of deflection measured as described in (*a*).

Oil Absorption Tests.

Hard composite dielectrics intended to withstand insulating or lubricating oils shall be tested to ascertain the change in weight after a specimen has been immersed for 24 hours in the appropriate oil given below at the grade temperature of the dielectric.

Mechanical deterioration is accompanied by relatively high absorption or by loss of weight, but the investigator should report any observable changes.

The dimensions of the specimen shall be approximately 15 mm cube, or a sample of equal surface area (viz. 13·5 cm²) shall be tested. The test shall be carried out as follows :—

The specimen shall be weighed, immersed in oil at the grade temperature for 24 hours, then removed from the oil, rinsed with petrol and dried. The change in weight shall be expressed in grammes per sq. cm. computed on the surface area of the specimen. Three specimens of the material shall be tested, and the maximum, minimum and mean values of the oil absorption number obtained as described above shall be stated.

(*a*) Transformer oil which shall comply with B.S.S. No. 148 for Class A light grade oil.

(*b*) Lubricating oil, which shall consist of a mineral oil with 20 per cent of blown rape oil, and shall comply with the following specification : *

Specific gravity at 60° F. (15·6° C.) .. 0·92 (approximately).

Closed flash point .. Not less than 370° F. (188° C.).

Viscosity .. .. ..

Temperature	Time of outflow of 50 cm³ in Redwood viscometer, secs.	Absolute value, centipoises
200° F. (93° C.)	75	15
300° F. (149° C.)	38	7·5

Acidity, calculated as oleic acid .. .. Not more than 1 per cent.

Loss in 2 hours at 212° F. (100° C.) (determined as described below) .. Not more than 0·3 per cent.

The oil shall be free from mineral acid.

The loss at 212° F. (100° C.) shall be determined by heating 9 grammes of oil in a flat-bottomed porcelain dish approximately 2½ inches diameter and ¾ inch deep.

* This oil is a standard lubricating oil, and is readily obtainable.

THE VARIATION OF EFFICIENCY WITH SIZE, AND THE ECONOMIC CHOICE OF ELECTRICAL MACHINERY.*

By D. J. Bolton, B.Sc. (Eng.), Associate Member.

(*Paper first received 17th July, and in final form 23rd October, 1925.*)

Summary.

The paper consists roughly of two parts—an examination of the efficiency of electrical machinery of varying sizes, and an application of the results to the problem of economic choice. In the former section it is shown that wherever there is more than one kind of loss a large machine will have a higher efficiency than a small one, by an amount which is roughly predicable. It is further shown that this efficiency can be maintained with little or no diminution when the machine is suitably under-run, depending on the kinds and proportions of the losses. This makes it possible to calculate the cost of improving the efficiency of a given service to any required degree through the employment of larger plant than is physically necessary.

Applying this to the selection of apparatus to fulfil a given service at the least total cost, the cases considered are squirrel-cage induction motors, small d.c. motors and single-phase transformers. Placing all items on an annual basis, the rates of change of the various charges with reference to the frame size are worked out for a range of sizes in each of the three cases. These rates of change form an index by which the most economical size can readily be estimated for any conditions of service, and the method of doing this is fully explained in the paper.

The results suggest that where the hours of service are long or energy is expensive a far larger or more efficient machine is justified than would normally be employed. Where such improved efficiency is proposed, the method here developed makes it possible to calculate the particular degree of improvement which is economically justified in any case. Such a calculation should be an essential feature of the design (or failing this, the selection) of all apparatus for long-hour service.

Table of Contents.

(1) Introduction.

An attempt is made in this paper to develop a general method of choice of electrical machinery on economical grounds, the word "machine" or "structure" being used in the widest possible sense to indicate any piece of apparatus performing a definite tangible service and capable of being independently chosen. For this purpose it is assumed that the service is in all respects fixed and known, i.e. the type of machine, output, speed and other particulars as well as the hours of service and cost of energy. It will further be assumed that there is no qualitative difference between the various alternatives available, so that the choice is merely of the most suitable size.

A warning should be made at the commencement, that just as economics is a less exact science than physics, so the branches of engineering based on the former will inevitably be less exact than those based on the latter. With this qualification in mind, two rough generalizations may be made with regard to electrical machines of all types except the very simplest. These are, first, that a large machine is usually characterized by a higher efficiency than a small one of the same type, and, second, that this efficiency can usually be maintained even when the large machine is under-run so as to give a smaller output.

In order to give a precise meaning to the above it will be necessary to define exactly what is meant by a "larger" machine and by "under-running": but, leaving this for the moment, it will be evident that if the above statements are true there are two entirely different methods of choosing a machine to perform a given service. The normal method is to select a machine having just sufficient iron, copper, etc., so that (when giving the output aud occasional overloads required) the temperature-rise, centrifugal and dielectric stresses, the commutation and the regulation are all kept within satisfactory limits. This may be described as the *physical* choice, and it will be obvious that in no case can a machine be installed smaller than this size. But if a bigger machine would have a higher efficiency at the required output, it might be more economical in the long run to install it for this reason, and such a decision would then be a specifically *economic* choice. As the two sets of criteria are quite unrelated it is evident that both calculations should be made, and the machine chosen should be the larger of the two, whichever that is.

An electrical machine may be compared in this respect with a leaky vessel such as a slightly porous balloon. If too big a load is put upon it, it will burst and be destroyed, but long before this point is reached considerable leakage is taking place. Hence, if the cost of the inflating material is great compared with that of the balloon material, it may be cheaper not to load it up to its physical limit.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

A single instance will serve to show how considerable is the cost of this leakage in comparison with the cost of the plant itself. A 40-h.p. 1 000-r.p.m. 50-period squirrel-cage induction motor having an efficiency of 88·5 per cent can be bought for about £70 at the present time. Such a machine, running for 8 hours a day and 300 days a year with energy at a uniform price of 1d. per unit, in a useful life of 20 years consumes nearly £7 000 worth of energy—equivalent in cost to 5 new motors every year of its life. Moreover, whilst the bulk of this energy is transformed into useful work, the sum actually wasted in machine losses amounts every year to £38 15s.—more than half the price of the motor. If this efficiency could be improved even by so much as ½ of 1 per cent the energy saved would be worth £2 a year, which could be capitalized over a 20-year life as equivalent to the lump sum of £25—sufficient to pay for a very generous increase in the copper and iron sections.

The small amount of attention paid to efficiency in its economic aspect is due very considerably to the difficulty of calculating, in any particular case, what degree of efficiency improvement would be worth while, and (when calculated) the difficulty of requisitioning such a machine. These two difficulties have been attacked in this paper on the lines of establishing a general criterion of the economic degree of efficiency, visualizing for this purpose the employment, not of special high-efficiency machines, but of standard machines built for a greater output than that required.

(2) Physical Ratings—Heating and Densities.

It was stated above that before attempting to prove the generalizations there made it is necessary to define the terms used, since it is impossible to study the effect of taking a less than normal output from a given machine until one knows what determines the normal output. The physical rating of any given frame may be defined as that output which can be taken, for the period and under the conditions specified, without the temperature-rise exceeding some figure which is considered safe from the point of view either of internal deterioration or of external danger. In addition, there is frequently an overload requirement for a short period, which may be a question of commutation or electric strength as well as temperature, and there is sometimes a requirement as to regulation, but for the most part it may be said that size is roughly determined in the great majority of cases by temperature limits.

It will be noticed that not one of the above limits concerns either the current or the flux densities employed, and yet the surprising thing is that over a wide range of sizes of any particular type of machine, a given temperature-rise corresponds fairly closely to a given set of current and flux densities. This is one of those coincidences which are normally taken for granted, but which are not nearly so inevitable as they seem.

The close correspondence which exists between densities and temperature-rises is illustrated by the fact that a d^2l formula is frequently used to estimate the frame size of a rotating machine to comply with a temperature specification, although the formula that output is proportional to d^2ln is based on the assumption of fixed densities and has no connection with temperature-rise. In order to discover why the two largely go together, it will be well to take actual cases, bearing in mind that with given densities the losses are each proportional to the volumes of the active materials.*

Taking as a starting point the assumption of fixed current and flux densities, consider first a constant-speed rotating machine. It is easy to show that if the specific electric loading is fixed, the output of such a machine is proportional to the d^2l of the armature or rotor, so that if d and l are both doubled the output will be increased 8 times. On the other hand, the amount of iron in the magnetic path and the copper in the slots and end connections will only be slightly more than 4 times what they were, and hence the losses † will only be increased in this smaller ratio. As the rotating surface is just 4 times what it was and the peripheral speed is greater, the machine will thus be able to dissipate these losses with approximately the same temperature-rise.

Hence the correspondence between densities and temperature-rises is in a sense a happy accident ‡ due to the fact that the output (with fixed densities, speed, and dimensional proportions) is proportional to rotor volume (or d^3) whilst the losses and cooling capacity are both proportional to surface (or d^2).

(3) Efficiency and Size.

Two things result from the above. Not only can designs be carried out on a basis of fixed current loadings and flux densities for a wide range of machines complying with a single temperature specification, but it also follows that the efficiency of a large machine must always be inherently better than that of a small one, and by a definite and ascertainable amount. For if the output is proportional to d^3 and the losses to d^2 the ratio (losses/output) will be proportional to $d^2/d^3 = 1/d = 1/\sqrt[3]{\text{Output}}$.

The extent to which this is borne out in practice can easily be discovered from any range of machines of the same type. Thus, in the author's previous paper § a range of shunt motors from ¼ h.p. to 15 h.p. was listed, together with their efficiencies, from which can be calculated the ratio (losses/output), since this is equal to the reciprocal of the efficiency, minus one. Multiplying this figure by the cube root of the output (h.p.) gives a fairly uniform figure of approximately 0·4 in each case (see col. 8 of Table 3 on page 345). Not only is there no perceptible tendency for this figure to vary with the machine size, but also the range of fluctuation is remarkably small, i.e. 25 per cent for a change in size of 60 times. Similar figures are here listed for a range of

* With constant frequency and flux density the iron losses can always be expressed per cubic centimetre of iron, whilst the copper loss $= I^2R = \frac{I^2l\rho}{A} = \left(\frac{I}{A}\right)^2 lA\rho$, so that this loss is also proportional to volume (lA) when the current density (I/A) is constant.

† The friction and windage losses are more difficult to estimate. The former will increase less than proportionally with the increase in weight, whilst the latter will increase both because of the surface and because of the greater peripheral speed. These losses will therefore also be slightly more than 4 times what they were, but it will be noted that in any case they dissipate themselves with little or no effect upon the winding temperature-rise.

‡ If the word "accident" be objected to, the position may be put the other way round by saying that in the design of a rotating machine the active materials are grouped round a cylinder to an approximately fixed depth or density, so that the losses shall always keep pace with the cooling powers of the cylinder.

§ *Journal I.E.E.*, 1924, vol. 62, p. 901.

squirrel-cage motors (col. 8 of Table 1 on page 344), and a similar constant connection is obtained, although in this case there seems a tendency for the figure to increase with the frame size, thus suggesting that the root index should be somewhat higher than 3, due possibly to an increase in the specific electric loading.

In the case of transformers, if a uniform winding depth or loading were maintained as in rotating machines, the same law would hold, and the output would be proportional to the volume, or d^2l, of the iron core. But as it is customary also to increase the winding depth proportionally with the increase in the core (so using the whole of the " window " space) the output will go up at a greater rate than this.

By considering a simple transformer such as the ring type, it is easy to see that if d is the core diameter and if all the dimensions are varied in the same proportions, the iron cross-sectional area will be proportional to d^2 and the copper winding space to d^2, so that the output will be proportional to d^4, whilst the weight of both copper and iron, and therefore the losses, will be proportional to d^3. Hence the loss ratio (losses/output $= 1/\eta - 1$) is proportional to $d^3/d^4 = 1/d = 1/\sqrt[4]{\text{Output}}$. In a similar way it has been proved for all the commercial shapes of transformer, both shell and core types, that if all the dimensions are increased in the same ratio to a times their previous value, the output will be a^4 times and the loss ratio will be $1/a$ times its original value.*

It is therefore evident that if the heat-dissipating surface were only that of the transformer iron and windings, the temperature-rise would tend to get steadily worse as the size increased, since losses are proportional to d^3, whilst surface is only proportional to d^2. This is what actually happens in the case of air-cooled transformers, and explains the virtual upper limit of size unless the densities are correspondingly reduced. In the case of oil-immersed transformers the radiating surface is that of the whole tank, and it is comparatively easy to proportion the size of tank and amount of oil either to the kVA capacity or to the actual watts lost.

The above statements must be modified slightly on account of change in the space factor. Thus the effect of doubling d will be to quadruple the winding space and to allow 4 times as many turns of the same size of wire. If, however, the current is to be increased rather than the pressure, a larger section of wire will be employed, giving a better space factor ; so that the ampere-turns will be increased in the ratio of, say, d^3 rather than d^2. This will give an output of $d^2 \times d^3 = d^5$ times, an iron loss of d^3 times, and a copper loss of d^4 times. Hence the total losses (which can, of course, be distributed as desired) will lie between d^3 and d^4, say $d^{3\frac{1}{2}}$, giving a loss ratio proportional to $d^{3\frac{1}{2}}/d^5 = 1/d^{1\frac{1}{2}} = 1/(\text{Output})^{0\cdot3}$.

In confirmation of the above, the loss ratios $(1/\eta - 1)$ for the single-phase transformers listed in Table 4 were plotted logarithmically to a base of rated kVA, and gave an index of 0·31, and the amount of individual deviation is shown in the last column of Table 3. A similar line of three-phase transformers was also plotted and showed an index lying between $\frac{1}{3}$ and $\frac{1}{4}$; and, moreover, in each case the index showed a tendency to approach $\frac{1}{4}$ in the larger sizes, where the change in space factor would naturally be less marked. A further confirmation of the above reasoning was obtained in the case of the single-phase series by plotting (logarithmically) the iron cross-sectional area against the kVA output, which gave an index of 0·4, i.e. the iron cross-sectional area is proportional to $(\text{output})^{0\cdot4} = (d^5)^{0\cdot4} = d^2$, as it should be.

It is needless to point out that the generalized reasoning and the few examples here given are in no sense put forward as an exact proof of the law followed, and in fact the precise form of this law is immaterial to the main object of this paper. What is important is to note that the efficiency of the larger machine is inherently better and by a definite predicable amount, this amount being roughly given both for rotating machines and transformers in the statement that the loss ratio is inversely proportional to the output raised to a power lying usually between $\frac{1}{3}$ and $\frac{1}{4}$.

Another criticism which may be raised is that the process of explaining the index figure relating to transformers would appear to upset the figure arrived at for rotating machines, since in these also the space factor should improve with size. The two cases, however, are not parallel. In transformers the whole of the available window space is utilized, so that the space factor becomes a determining factor in the output obtainable from a given frame, whilst in a rotating machine a poor space factor can always be compensated for by increasing the slot depth : the limit here is not the space but the cooling capacity and therefore the electric loading.

(4) Efficiency on Under-running.

In what follows it will be convenient to define the maximum or rated output of a frame in terms of fixed current and flux densities, on the understanding that this will give approximately fixed temperature-rises. Such a definition gives a precise meaning to the two generalizations laid down at the commencement, and the first of these, namely that a large machine is characterized by a bigger efficiency than a small one of the same type, has been illustrated and to some extent proved in the foregoing paragraphs. It now remains to examine the second and more difficult proposition concerning the maintenance of this higher efficiency when the machine is under-run.

Unfortunately the simplest type of machine which can be used for illustration purposes—the " single loss " structure such as the electric cable—does not conform to either of these rules. In this case the larger machine, running at the same current density, has just the same efficiency as the smaller one, but, on the other hand, under-running *increases* the efficiency, so that the net effect (upon which any possibility of economic choice of size depends) is the same as with more complex structures. That is to say a larger machine used on a smaller load will have a higher efficiency than a smaller one giving its full capacity.

* A. P. M. Fleming and K. M. Faye-Hansen: *Journal I.E.E.*, 1909 vol. 42, p. 396.

One of the most useful classifications of the losses in an electrical machine is as follows :—

Losses dependent upon the current and virtually independent of the pressure.

Losses dependent upon the pressure and virtually independent of the current.

Losses independent of both current and pressure.

With this grouping the total losses can be expressed as

$$c_1 I^a + c_2 E^b + c_3$$

where a, b, c are constants, I and E the line current and pressure respectively, and a and b have each very approximately the value 2. In a similar way the efficiency can be generally expressed as

$$\eta = 1 - \frac{\text{Losses}}{\text{Input}} = 1 - \frac{c_1 I^a + c_2 E^b + c_3}{EI \cos \phi}$$

This may be illustrated by considering any rotating machine such as a d.c. shunt motor. The first group of losses, namely those represented by $c_1 I^a$, covers the armature copper losses. These are strictly proportional to the square of the armature current with constant resistance, but the difference between armature current and line current is not great, and, moreover, this discrepancy will probably be balanced by the positive temperature coefficient of the windings.

The second group of losses, represented by $c_2 E^b$ includes the whole of the shunt field losses and the iron losses, as can be seen by considering the effect of a change in pressure. Thus, suppose the line pressure to be halved, with the current and speed unaltered. The field losses, being equal to E^2/R, will be quartered, and the field strength, with constant permeability, will be halved. (If the permeability is not constant some field resistance must be introduced to bring the field strength down to slightly less than half what it was.) The back E.M.F. with the same speed can thus be made slightly less than half its previous value, so that with half the line pressure the difference between the applied and the back E.M.F. will be unaltered, and the same current will flow.

The flux density B is thus roughly proportional to the line pressure E, and, furthermore, it has recently been shown * that the iron losses of a d.c. machine can be most accurately assessed by coupling hysteresis and eddy losses together, and that they are very approximately proportional to B^2, that is $b = 2$ in the above formula. Finally, if c_3 represents the constant friction and windage losses, it will be seen that the whole of the losses have been accounted for.

It will be noticed that the " pressure " items are not strictly independent of current, owing to the difference between applied and back E.M.F., and for this reason the formula is most accurate when pressure and current are being varied simultaneously.

In the case of a series motor the field losses come into the $c_1 I^2$ group, and if the pressure alone is varied the field strength must be artificially changed to correspond. In the case of machines in which part of the current is induced, this latter will not be exactly proportional to the line current, but, in spite of these various discrepancies, the above formula, with $a = b = 2$, represents most cases with a sufficient degree of accuracy for economic calculations.

On the basis of this formula it will be convenient to group electrical machines into three classes according to whether they have one, two or all three of the possible kinds of losses. There will then be :—

Simple or homogeneous machines having only one kind of loss (i.e. copper or iron) ;

Complex static machines having two kinds of loss (copper and iron) ;

Complex rotary machines having all three kinds (copper, iron and frictional).

The nearest approximations in practice to machines of the first class will be found in current conductors and in iron-cored reactances. Thus in a cable (neglecting the slight dielectric losses dependent on E) the losses are proportional to I^2, and in a choking coil (neglecting the magnetizing-current losses dependent on I) the losses are proportional to E^2, i.e. in each case there is substantially only one class of loss.

The first point to note in a simple structure such as a cable is that the efficiency can always be raised by increasing that item of the supply upon which no losses are dependent. For, expressing the efficiency of a cable as $1 - (I^2R)/(EI \cos \phi)$, it is clear that this can be indefinitely increased by increasing E. As a rule, however, this method is inadmissible, since the pressure is fixed by the nature of the service. With regard to variations in current, the pressure remaining constant, it will be seen that the efficiency can be expressed as

$$1 - \frac{IR}{E \cos \phi} = 1 - \frac{I}{A} \cdot \frac{l\rho}{E \cos \phi}$$

where l is the length and A the cross-sectional area.

Thus, if the length is fixed, a large cable will have the same efficiency as a small one working on the same current density, but, on the other hand, if the large cable is under-run to give the smaller output, its efficiency will be increased. The possibility of economic advantage to be gained from the employment of a cable larger than that physically necessary was first pointed out by Lord Kelvin in 1881, and as the subject has been fully treated by subsequent authorities, no more need be said regarding this particular application.

Turning to machines of the second class, much the most important is the static transformer, the efficiency of which can be expressed as

$$\eta = 1 - (c_1 I^2 + c_2 E^2)/(EI \cos \phi).$$

It is obvious from this formula that if the transformer is under-run by reducing E and I in the same ratio, the full-load efficiency will be maintained intact, provided that the power factor is not affected. Thus any particular size of transformer can be regarded, not as something capable of giving a certain output, but as something having a certain efficiency. If a higher efficiency is required, then a larger transformer must be employed. A further point is that if at full load the two groups of losses are not equal, the efficiency

* *Journal I.E.E.*, 1924, vol. 63, p. 47.

can actually be improved by under-running, provided this is performed in suitable proportions. Instead of considering this in detail, however, it will be more advantageous to study the more general case given below, of which the transformer can be regarded as a particular instance.

The third class of machine (having all three varieties of loss) can be taken to include every type of rotating apparatus in which copper, iron and frictional losses occur. The efficiency can be written

$$\eta = 1 - (c_1 I^2 + c_2 E^2 + c_3)/(EI \cos \phi)$$

and it will be evident that if the line current and the line pressure are each reduced in the same ratio, the efficiency will fall owing to the presence of the constant frictional losses c_3. On the other hand, if either of the variable losses is bigger than the sum of the other two it will be possible to under-run in such a way as to reduce this larger loss and keep the efficiency as high as or even higher than on full load.

Thus suppose that the current loss is n times the sum of the other two, that is $c_1 I^2 = n(c_2 E^2 + c_3)$. Furthermore, suppose that it is desired to reduce the output, and therefore the input, in the ratio $1/m$ without impairing the efficiency, this reduction being accomplished purely by reducing the current. Assuming that the power factor is unaltered, the total losses must also be reduced in the same ratio; and calling the two currents I_1 and I_2 we have :—

$$\frac{I_1}{I_2} = m = \frac{c_1 I_1^2 + c_2 E^2 + c_3}{c_1 I_2^2 + c_2 E^2 + c_3} = \frac{c_1 I_1^2 + (1/n)(c_1 I_1^2)}{(1/m^2)(c_1 I_1^2) + (1/n)(c_1 I_1^2)}$$

$$\text{or } m = \frac{1 + (1/n)}{(1/m^2) + (1/n)} = \frac{n+1}{n} \times \frac{m^2 n}{n + m^2} = \frac{m^2(n+1)}{n + m^2}$$

$$\text{or} \quad m(n+1) = n + m^2 \quad \text{or} \quad (m-1)(m-n) = 0$$

$$\text{whence} \qquad m = 1 \quad \text{or} \quad m = n$$

The meaning of the above is that either $m = 1$ (no reduction at all) or $m = n$, i.e. the output can be reduced in the ratio which the current loss bears to the sum of the other two losses. If reduced by a greater amount than this the efficiency will be lower, whilst if reduced by a less amount the efficiency will be higher than at full load. Thus in a squirrel-cage induction motor the copper losses at full load are frequently about $1\frac{1}{3}$ times the sum of the iron and frictional losses, and such a machine can be run at $1/1 \cdot 33 = 75$ per cent of full-load current without loss of efficiency. The maximum efficiency will then occur at about $87 \cdot 5$ per cent of full load and will be slightly greater than the full-load efficiency.

Exactly the same formula would apply if the losses proportional to E^2 were n times the current and frictional losses, and in this case the machine would have to be under-run by reducing the pressure while keeping the current constant. Unfortunately, in a d.c. machine this would generally be inadmissible on account of commutation.*

* No mention has been made of the case in which the indices a and b are not each equal to 2. The likelihood of this occurring is hardly sufficient to justify a detailed calculation, but in general terms it will be obvious that where the index of the variable being reduced is greater than 2, the efficiency on under-running will be better maintained than it otherwise would have been, and *vice versa*.

If neither of the variable losses exceeds the sum of the other two, no under-running will be possible without loss of efficiency. In such a case it will be well to see what mode of under-running gives the least fall in efficiency. Putting the efficiency at full load $\eta = 1 - (c_1 I^2 + c_2 E^2 + c_3)/(EI \cos \phi)$, where I and E are the full-load line current and pressure, let I be reduced in the ratio $1/n$ and E in the ratio $1/m$, where n and m are variables but nm = constant, c, the known degree of under-running. Then the new efficiency becomes

$$\eta = 1 - \frac{c_1 \left(\frac{I}{n}\right)^2 + c_2 \left(\frac{E}{m}\right)^2 + c_3}{\frac{E}{m} \times \frac{I}{n} \cos \phi}$$

and putting $nm = c$ or $m = \frac{c}{n}$ we get

$$\eta = 1 - \frac{c_1 I^2 n^{-2} + c_2 E^2 (n/c)^2 + c_3}{(EI/c) \cos \phi}$$
$$= 1 - \frac{c}{EI \cos \phi} \left\{ c_1 I^2 n^{-2} + \frac{c_2 E^2 n^2}{c^2} + c_3 \right\}$$

Assuming that $\cos \phi$ is unaffected by the under-running, this can be differentiated with respect to n, giving

$$\frac{d\eta}{dn} = 0 - \frac{c}{EI \cos \phi} \left\{ -2c_1 I^2 n^{-3} + \frac{2c_2}{c^2} E^2 n + 0 \right\}$$

$$\text{This is zero when} \quad \frac{c_1 I^2}{n^3} = \frac{c_2 E^2 n}{c^2} \quad \text{or} \quad n^4 = c^2 \frac{c_1 I^2}{c_2 E^2}$$

$$\text{And as } n = \frac{c}{m}, \quad m^4 = c^2 \frac{c_2 E^2}{c_1 I^2} \quad \text{and} \quad \frac{n}{m} = \sqrt{\left(\frac{c_1 E^2}{c_2 I^2}\right)}$$

Hence the best ratio of current reduction to pressure reduction is the square root of the ratio (full-load current losses)/(full-load pressure losses).

(5) Method of Economic Calculation.

Before proceeding further, it will be well to consider the bearing of the foregoing on the economic question, i.e. the question of paying more for a machine than is physically necessary, in order to obtain a higher efficiency. There are two distinct ways of increasing the efficiency of a machine of any particular output, which may be called the qualitative way and the quantitative way. The former consists in employing the same size of frame but using higher-grade steel and better insulation, thus giving lower iron losses, a higher space-factor and therefore more copper and less copper losses. The quantitative method of improvement consists in employing a larger frame and therefore more iron and copper, thus decreasing the flux and current densities and therefore the losses.

The latter method of efficiency improvement is less sure than the former, since the larger frame will involve slightly more frictional loss, which may nullify some of the gain. It has, however, two advantages, the first of which is that any individual purchaser, knowing his own requirements but having no influence with the manufacturers, may practise it and select the machine

size which is most suitable for his particular conditions. The second advantage is that it involves no departure from standards, either in quotation or manufacture, so that it is possible to make a general survey of the advantages of economic choice, ranging over a large number of possible alternatives, without any information beyond that supplied by the makers' price list.

The quantitative method of improving the efficiency, by under-running a larger frame, has therefore been made the basis of this paper—which has so far been devoted to a general consideration of the efficiency question. It must, however, be understood that the quantitative method usually puts the worst side of the case for economic choice, and that where this method indicates an advantage to be gained from under-running, there will usually be a much greater advantage in qualitative improvements wherever these are commercially practicable.

Bearing this in mind it will be assumed that in all the cases considered and within the range of under-running proposed (usually not to a greater extent than down to 75 or 50 per cent of the rated output) the full-load efficiency can be maintained intact. It has been seen that this is true of static machines and of machines having small friction or large iron or copper losses, provided the under-running is suitably proportioned. It is not true of other machines, but as the paper is intended to explore the general possibility of economic choice, it can generally be assumed that (especially where qualitative improvement is possible) an effect at least as good as that implied in the above assumption can always be obtained for the same or less cost.

A further advantage of the method here employed is that, in reference to quality, only one or two changes are possible with any given frame, so that the range of choice in this direction is definitely limited. Problems involving this kind of action therefore usually consist in the choice between two or three specific alternatives. In this paper, on the other hand, a method is indicated whereby the general effect of efficiency-increases over a large range of possibilities can be investigated, and the exact point found up to which they can profitably be carried in any particular case.

Since economic choice and physical choice are quite unconnected, it is essential to consider each of these separately, and for this purpose any particular size of frame will be regarded as something having a definite efficiency whatever the load on which it is used, and, for the time being, physical limits will be entirely neglected. The general lines of such an economic calculation were indicated in the author's paper in the *Journal* (vol. 62, p. 901) and consist in deciding on a basis of comparison and then summing on this basis all the costs likely to be affected by the change in question.

Taking as a basis annual costs or "charges," it will be assumed that when a large frame is installed instead of a small one the only increase in cost is the annual interest and depreciation on the larger machine, and the only decrease is the lessened cost of the machine losses. These two varying charges can be regarded as the dependent variables in the problem, one of which increases and the other decreases with an increase in the independent variable (the frame size). Graphically, the last-mentioned forms the base on which two curves can be plotted whose sum will indicate the position of minimum cost or economic frame size. This base could therefore be scaled in frame dimensions, maximum output, or other suitable unit, and in the author's previous paper several different scales were experimented with. But as a basis for a general consideration of all types, machine first cost is found to be the most suitable unit, and this has therefore been adopted throughout this paper.

In what follows, the first cost is denoted by F and the combined rate for interest plus depreciation by r. (If the machine has a salvage value at the end of its useful life, r must be adjusted in the manner explained in the previous paper, and if other items, such as insurance, are affected by the choice of frame size, these may also be included in r). The total capital charges which are relevant to the choice in question are then represented by Fr, i.e. this is the annual cost of owning this particular machine instead of any other.

The other item of cost which will vary in the problem is the cost of the energy wasted in machine losses, which will be inversely dependent upon the efficiency. The best way of expressing the efficiency from this point of view is by means of the ratio, losses/output, which has already been referred to as the loss ratio. In the calculations which follow, the losses will be in watts and the output in horse-power or kVA. (This makes the calculations more convenient, and avoids unduly low values and the appearance of a large number of cyphers in the rate-of-change expression.) The loss ratio, denoted by Q, will therefore be found from $[(1/\eta) - 1)] \times 746$ in the case of the motors and $[(1/\eta) - 1] \times 1\,000$ in the case of transformers.

The importance of the quantity Q lies in the fact that, for any structure having this efficiency, the losses at any particular load can be obtained by simply multiplying Q by the load. The cost of the energy usefully converted in the machine is thus omitted from the problem, and the cost of the energy wasted is given by $Q \times$ horse-power output $\times$ hours of service per annum $\times$ cost (£) of energy per kWh divided by 1 000. Moreover, the last three items are constant relative to the frame size, and are mutually replaceable in the sense that, for example, 40 h.p. for 8 hours a day is just the same economically as 80 h.p. for 4 hours. It is therefore well to have a composite term for the product of these three, and calling this product the Power-Service-Price (P.S.P.),* the loss charge becomes $Q \times \frac{\text{P.S.P.}}{1\,000}$(£).

Hence, omitting all those items which are unaffected by the choice of frame size, it will be seen that the total annual expenses involved in obtaining the required service can be expressed as the sum of the capital and loss charges $Fr + Q \times \frac{\text{P.S.P.}}{1\,000}$. If these two are plotted to a base of F, the former will be a straight line rising with F, whilst the latter will fall as F increases, since the efficiency is greater, and therefore the loss (for a given horse-power) less, the greater the expenditure on frame

* Thus for a 10-h.p. motor running for 8 hours a day, 300 days a year, with energy at 1d. a unit the P.S.P. would be $(10 \times 8 \times 300)/240 = 100$ and the same figure would cover 10 h.p. for 24 hours a day with energy at $\frac{1}{3}$d. or 40 h.p. for 4 hours a day with energy at $\frac{1}{2}$d.

cost (cf. Fig. 1). The sum of the two will indicate the point of minimum cost and therefore the most economical size of frame to employ.

The only objection to this method of calculation is that it has to be repeated not only for every different horse-power but for every change in the conditions of service. In order to avoid such a recalculation and to establish a general method of solution for any machine of this type and speed, the total charge expressed above can be differentiated with respect to F, giving a rate of change $r + (\text{P.S.P.}/1\,000) \times dQ/dF$ which must be zero at the point where the total charge is a minimum.

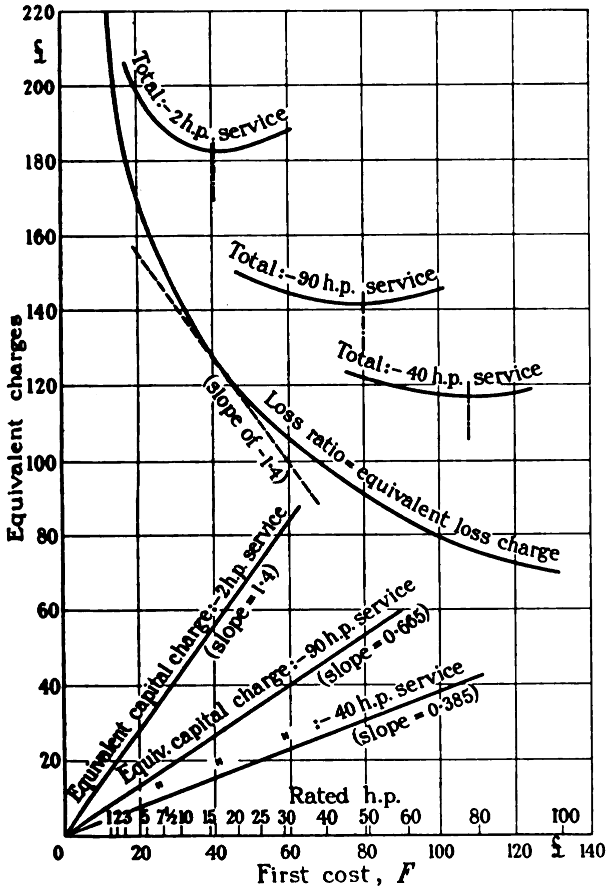

Fig. 1.—Squirrel-cage motor costs.

Hence at this point $dQ/dF = -1\,000\,r/\text{P.S.P.}$, or if the interest and depreciation are expressed per cent (r'), $dQ/dF = -10r'$ P.S.P. By finding the value of dQ/dF for a complete range of machines of the type concerned it is possible to use this to determine the most economical frame size for any power and conditions of service whatsoever.

(6) Application to Induction Motors.

The first type of machine to be considered is that of a squirrel-cage induction motor running at 1 000 r.p.m. (synchronous) on a 50-period supply. Columns 2 and 3 in Table 1 give the first cost and the full-load efficiencies for a range of frames rated at 1 to 100 h.p. at this speed, the actual figures being averaged from quotations of five or six different makers. Col. 4 gives the loss ratio, calculated from $(1/\eta - 1) \times 746$.

In order to find the rate of change of this quantity with respect to F, it can either be plotted to this base on a large scale and the slope determined graphically, or else an empirical formula can be developed and then differentiated.* Both of these methods were tried in this instance and gave results fairly similar over most of the range, but appreciably different at the lower extreme. In any actual problem, of course, the choice would only range over a comparatively few sizes, and it is probable that either the graphical or the algebraic differentiation would give equally satisfactory results. Using the graphical figures, col. 5 gives the values of dQ/dF for each value of F which corresponds to an actual frame size.

In order to illustrate the use of the above figures, three examples may be given, differing as much as possible in their data. Tabulating first the data, and then the calculations therefrom, these are shown in Table 2.

It will be noted that in not one of the above cases can the correct frame size to employ be said to be definitely specified by the results of the economic calculation. In the first case, with continuous running and relatively dear energy, the economical size is enormously bigger than that determined by heating considerations, namely 15 h.p. for an output of 2 h.p. Naturally, so big a frame as the 15 h.p. size would lose its efficiency if under-run to anything like this extent, but the economic calculation is sufficient to show that for this service a very much larger size than the 2 h.p. frame would be justified. For the 40 h.p. service also an appreciably larger size is indicated, probably 60, 70 or 80 h.p. rating, depending upon the alternatives actually available and the proportions of the losses (see later). In the case of the 90 h.p. service, owing to the small number of hours a day and the cheapness of the energy, combined with the high rate of interest, the economical size is smaller than that based on the ordinary heating rating, and the latter must therefore be chosen.

The above cases are illustrated graphically in Fig. 1. The base of this graph is the first cost F plotted to an even scale (£), and on this base are also shown the rated horse-powers of the frames obtainable at these prices. The reciprocals of the efficiencies obtainable with these frames are represented by the falling curve labelled "loss ratio," the ordinates being scaled to show $(1/\eta - 1) \times 746$. For any particular service the loss charge (£) would therefore be obtained from this curve by multiplying by P.S.P./1 000. On the same base the capital charge Fr will be a straight line through the origin, and in any given instance the two curves can be added, to see where the total becomes a minimum.

To avoid redrawing for each particular case, the ordinates can all be divided by P.S.P./1 000, the values then being termed "equivalent charges" (see Fig. 1). The loss curve is then fixed for every condition of service, and the capital curve plots Fr divided by

* By taking logarithms of Q and F and plotting them, a very close approximation to a straight line was obtained over the above range. The empirical law thus established was $Q = (F)^{-0{\cdot}48}$, whence $dQ/dF = -0{\cdot}48(F)^{-1{\cdot}48}$.

$\text{P.S.P.}/1\,000 = \dfrac{1\,000Fr}{\text{P.S.P.}}$ which will still be a straight line through the origin, its inclination varying with every change in the conditions of service and the prices of energy and capital. In the three cases listed above, its inclination will be given by arc tan 1·4, 0·385 and 0·665 respectively, and these lines are labelled "equivalent capital charges." Adding these to the loss curve gives the three totals shown, and thus indicates the frame position for minimum total cost in each case. Another way is to reverse the capital curve and bring it up to the loss curve so as to show at what point it is tangential (see dotted line, representing slope of − 1·4).

In a similar manner any other power, hours of service, or price of energy or capital, can be resolved into a factor which will at once show the economical size of frame on the assumptions made above. If the frame thus specified is not more than, say, 50 per cent larger than the size determined by the heating limit, and if there is no possibility of qualitative selection, this size may be chosen without further calculation, care being taken to purchase a higher-voltage machine so that it

may be under-run as regards pressure as well as regards current. If the economical size indicated is very considerably above the heating rating, further consideration must be given in view of the loss in efficiency occasioned by substantial under-running.

Thus in Case 2 given above (40 h.p. service) probably the best standard frame that could be chosen would be the 60 h.p. size, which would then be under-run in the ratio 1·5 to 1. Assuming that the full-load current and pressure losses are in the ratio of 2 : 1, the most economical pressure reduction will be in the ratio $\sqrt{\frac{1\cdot5}{\sqrt{2}}} = 1\cdot03$ and the current reduction will be $\sqrt{2}$ times this, or 1·46, making a total power reduction of $1\cdot03 \times 1\cdot46 = 1\cdot5$. Hence if the supply pressure is 400 volts, the 60 h.p. machine can be ordered for, say, 412 volts, and when under-run to give 40 h.p. at the

$2\frac{1}{2}$ on the larger, and such values can only be described as extraordinarily small. They mean that a large squirrel-cage induction motor giving its full rated output for 8 hours a day and 300 days a year is only economical when energy costs ½d. or less per kWh. With energy at the usual prices the most economical frame would be much bigger, whilst if the motor were required for day and night service it might be economical to have it 2 or 3 times as big.*

(7) Application to Small D.C. Motors.

The next case to be considered is that of d.c. shunt motors running at 1 000 r.p.m. and ranging from ¼ h.p. to 15 h.p. in size. The first cost and full-load efficiencies for such a range, averaged from a number of different quotations, were tabulated in the author's previous paper, and it is here proposed to apply the more general

Table 3.

15	57 8	84·2	140	0·38	20	—	0·46

lower pressure it will be found to have an efficiency of 89·8 per cent. The annual cost for capital and losses will then be £24 as against a figure of £24 16s. for the 40 h.p. frame run at its full output; and this is apart from any incidental gain such as longer life or greater overload capacity.

Referring again to Table 1, it is interesting to see whether the advantage of under-running is the same for all sizes. In order to make the values in col. 5 mutually comparable, a set of figures has therefore been worked out for lives of 15 to 20 years (col. 6) with interest at 5 per cent and salvage value 10 per cent of first cost. These figures (col. 7) give the value of $(dF/dQ) \times (1\,000\,r/\text{Rated h.p.})$ and hence show the service-price * at which each frame can economically be used to give its normal rated horse-power. It will be seen that the figures decline roughly from 5 on the smaller sizes to

method of the present paper to the same set of figures. Cols. 1, 2 and 3 in Table 3 give these figures, and col. 4 gives the ratio Q = (loss in watts)/(output in h.p.), this being obtained from $(1/\eta - 1) \times 746$. By graphical differentiation the value dQ/dF was found for each frame size and is shown in col. 5.

This value, as before, is the key to the economic solution, and from it the most advantageous size can be estimated for any set of prices and conditions of service. Thus, to take a single instance, suppose that the service required is 1 h.p. for 8 hours a day and 300 days a year with energy at 1d. a unit. The P.S.P. is 1 × 2 400

* The term "service-price" is used to indicate the annual hours of service multiplied by the price (£) of energy per kWh.

* It may be objected that the above rate of interest is abnormally low, but a change in this rate by no means makes a proportional change in the result, since the interest payment and depreciation deposits are oppositely affected (i.e. the full first cost is not really owing for the whole of the working life, but is gradually paid off, or balanced by interest-bearing deposits into a sinking fund). In the present case, if interest were at 8 instead of 5 per cent, the figure of 5 for the economical service-price on the small frame sizes (17-year life) would become 6·9, whilst the figure of 2·5 for the larger sizes (20-year life) would become 3·2. Hence it will be seen that, even if capital is considerably more expensive, the service-price at which these frames are economical for their rated outputs is still surprisingly small.

$\times 1/240 = 10$. Taking a life of 15 years with interest at 5 per cent and salvage value 10 per cent of first cost, the combined rate for interest plus depreciation is 7·7 per cent, or $r = 0{\cdot}077$. Hence the most economical size will be when the rate of change $dQ/dF = 1\,000\, r/\text{P.S.P.} = 7{\cdot}7$, and this will occur on a frame rated somewhere between 1½ and 2 h.p. (col. 5).

As in the previous case, a set of figures has been worked out assuming interest at 5 per cent and lives varying, in this case, from 12 to 20 years (cols. 6 and 7). These figures show that the service-price at which the machines can be economically employed on their rated outputs ranges from about 4 to 7, there being no discernible tendency for the figures to vary with the size. These are in general agreement with the figures found by a similar method in the previous paper, allowing for the fact that the graphical differentiation was carried out quite independently in the two cases. It will be noticed that the figure is about twice that for the induction motors.

(8) Application to Transformers.

The last case to be considered is that of a range of single-phase transformers running off a 50-period supply. The transformer, being a two-loss structure, conforms most exactly to the assumption previously made regarding the efficiency on under-running, and it is only necessary to reduce the pressure and current in the correct ratios in order to obtain an efficiency as great as or greater than the full-load value. The economic advantages of under-running can therefore be pronounced upon with more certainty than with any other structure except the single-loss type such as the cable; and, moreover, the occurrence of day and night running is more frequent than with the other types of apparatus considered. On the other hand, the normal efficiency being so high, there is less margin for improvement; and it will be found that the case for under-running is, in general, less strong than with a.c. and d.c. motors.

As before, the qualitative improvement of efficiency will not be touched upon, attention being confined to the quantitative method of installing a larger (standard) transformer. In Table 4 are shown the rated outputs, prices and full-load efficiencies for a range of single-phase transformers on 50 periods, and for high-tension pressures not exceeding 2 000 to 3 000 volts. In this case the figures given are those of a single manufacturer and not averaged from a number, as it was desired also to compare the iron sections and other particulars.

20	39 0	97·59	24·70	0·38	10·1	0·063
25	43 6	97·76	22·90	0·33	9·3	0·062
30	48 0	97·92	21·24	0·22	11·7	0·061
40	58 6	98·06	19·78	0·13	14·8	0·063
50	67 0	98·11	19·26	0·05	30·8	0·065
60	73 12	98·15	18·87	0·045	28·5	0·068
75	89 0	98·20	18·33	0·040	25·7	0·071
100	110 0	98·30	17·29	0·036	21·4	0·073

The method followed is exactly that of the previous cases, and col. 4 shows the loss ratio Q = (losses in watts)/(rated output in kVA). Differentiating graphically with reference to F gives the ratios dQ/dF in col. 5, the values shown being those which occur at values of F corresponding to the actual frames listed. These rates of change can be utilized as before to find the most economical frame size for any set of conditions.

As an example, assume that 5 kVA is required at 50 periods, with a length of service of 20 years and a salvage value at the end of this time of 10 per cent of the first cost. In the first case let it be supposed that high prices rule, that energy costs 3d. a unit and capital 8 per cent per annum, giving a combined rate for interest and depreciation of 9·97 per cent. If the service is

required for 8 hours a day and 300 days a year, the P.S.P. will be $5 \times 8 \times 300 \times 3/240 = 150$. Hence the most economical frame size will be when dQ/dF has the value $-1\,000r/\text{P.S.P.} = -99 \cdot 7/150 = -0 \cdot 66$, which occurs at the frame rated to give 7·5 kVA.

As a contrast let it be supposed that the full-load service of 5 kVA is required day and night continuously * with energy at 0·7d. and interest at 5 per cent. For maximum economy dQ/dF must now equal $-\dfrac{77 \times 240}{5 \times 24 \times 365 \times 0 \cdot 7} = -0 \cdot 6$, which occurs at the frame capable of 10 kVA (col. 5).

Referring to this last example, if the intending purchaser, after working through to the above conclusion, wishes to follow the dictates of his economic conscience, his course will be to order a transformer of 10 kVA output and for a voltage $\sqrt{2}$ times his actual line pressure, so that if he requires 400 volts he will order approximately 565 volts. (The exact figure is not important; the one given assumes that the transformer

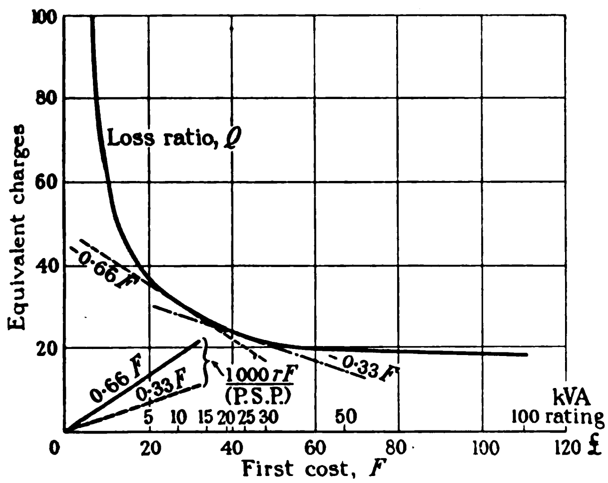

FIG. 2.—Single-phase transformer costs.

is designed to give equality of losses at full load.) When employed to give 5 kVA at 400 volts, the copper and iron will then each be under-run in the ratio $1/\sqrt{2}$ and the two losses will be approximately halved, leaving the efficiency exactly as for 10 kVA, and the total annual costs a minimum.

As in the other cases, a set of figures has been worked out with interest at 5 per cent, salvage value 10 per cent, and for a uniform life of 20 years. Working out the values $(dF/dQ) \times (1\,000r/\text{rated kVA})$ for each frame size, col. 6 gives the service-price at which each frame can be economically employed to give its actual rated output. Comparing these figures with the corresponding ones for the rotating machines, it will be noticed that the average for the transformers, namely 15, is 3 times as great as that for the small d.c. motors, and 6 times that for the a.c. machines.† Hence the advantage of under-running is notably less, and the service would have to be at full load continuously in order to present as favourable a case for economic selection as with a d.c. machine running only 8 hours a day. Another way of putting the matter is to say that, in order to establish an economic case for the installation of the next larger machine (say $1\frac{1}{3}$ times as big), the service price would have to be 20—corresponding to energy at 2d. for an 8-hour day or $\frac{2}{3}$d. for a 24-hour day.

The above can be better illustrated by means of a graph (see Fig. 2). The base of this shows first cost (£), but as regards the ordinates, no attempt has been made to scale these similarly. In fact, this graph omits the preliminary work of the previous one, and the ordinates are pure numbers, representing what may be called "equivalent charges." The falling curve plots the loss ratio Q, and the straight lines through the origin plot the values $1\,000r\ F/\text{P.S.P.}$ The steeper of the two lines represents the 5-kVA 8-hour service at 3d. a unit, and has a slope of arc tan 0·66. The reverse of this line, having a slope of −0·66, is also shown (dotted) brought up to the loss curve, and it will be seen to be tangential at the frame size rated to give 7·5 kVA. The shallower curve through the origin has a slope of just half as much and represents 10 kVA for the above-mentioned hours and price of energy. The reverse of this (chain-dotted) is tangential at the 25 kVA size and illustrates the economic point for this service.

(9) Conclusion.

Several important factors have been neglected in the above, e.g. power factor and load factor, and whilst these require fuller treatment than is possible in the present paper, one or two points may be noted here. As regards the former, the transformer efficiencies have been taken at unity power factor throughout, and, whilst this may not be the case in practice, the general relationship between the efficiencies of the different sizes is very similar whatever the power factor, provided the latter is not affected by the change in question. It is therefore doubtful whether an all-round alteration in power factor will materially affect the solutions obtained, but of course if the power factor is known it is an easy matter to use the appropriate efficiencies at this power factor throughout the calculation. With induction motors, under-running a larger machine may result in a change in power factor as well as in efficiency, and if the cost of energy includes an item for idle volt-amperes, this would have to be taken into consideration in any economic comparison.

A more serious omission is that of load factor, since it has been assumed throughout that the load taken from the plant is a constant maximum figure during the whole of the time for which it is connected. But in practice when a 40-h.p. machine is specified this is merely the maximum power required, with a mean load factor of perhaps 75 per cent, so that the economic calculations should all be based on the figure of 30 h.p. Then if 30 h.p. is the usual load and 40 h.p. merely an occasional maximum, this may be sufficiently accurate. If, however, the load varies greatly, this will not suffice, since the average all-day efficiency on a range of loads whose average is 30 h.p. cannot be found by merely computing the efficiency at a fixed load of 30 h.p.

* It is realized that this is not a likely condition (see later).

† If interest were at 8 per cent instead of 5 per cent and if all other items were unaltered, the average figure of 15 for the economical service-price would then become 20 (cf. footnote on page 345).

Hence on a varying load (since only the current loading will be varying) the required loss ratio must be calculated from the full-load pressure and frictional losses plus the R.M.S. value of the current losses divided by the mean output, and this can only be accurately determined if a load curve for the year is available. The point becomes particularly important in the case of transformers which are on full load for only a fraction of the time for which they are connected—a problem which has been considered by a number of writers on the subject of transformers. For such a case this paper cannot do more than indicate very approximately the total economic size, whilst throwing no light on the most economic proportions.

The above remarks apply with even more force to a further item which has been neglected, namely, varying costs of energy. When the cost of energy varies, the loading remaining constant, it is legitimate to take an average of the energy price over the period during which the plant is connected; but when the loading and therefore the efficiency vary simultaneously with the energy price this calculation will be inaccurate, since then the different losses will have varying degrees of importance according to the time of day at which they occur. Such a problem is considerably more complicated and it is impossible to do more than mention it here, referring to some of the authorities who have dealt with it.*

A final item which has been omitted is that of regulation. In the case of transformers this may sometimes be a determining factor, and the effect of the under-running upon the regulation will then have to be taken into consideration.

Summarizing the conclusions of this paper, it may be said that most electrical machinery can be employed at an output lower than its rated one in such a way as to give an efficiency greater than that obtainable on a smaller machine running on its full load. This fact may be made use of on economical grounds, not merely as a possible basis for action in itself, but also as a guide to the still greater advantages possible through re-designing. The method developed enables the designer or purchaser to estimate the extent to which efficiency is worth paying for, or, more strictly, the quantities of active materials which are economically justified, under any given set of conditions.

The results thus obtained show an advantage accruing to under-running a frame below its rated output in a very large number of cases with squirrel-cage motors, fewer with small d.c. motors, and still less with transformers. Speaking of the rotating machines, one can only repeat and re-emphasize a previous conclusion, that "It is not too much to suggest that such a review may lead to a complete revision of our methods of choosing motors for long-period service, future ratings being determined by economic considerations, whilst the heating properties, like the insulating properties, fix only a lower limit." *

FREQUENCY VARIATIONS IN THERMIONIC GENERATORS.

By Lieut.-Col. K. E. EDGEWORTH, D.S.O., M.C., Royal Signals, Associate Member.

(*Paper first received* 1st *September*, 1925, *and in final form* 18*th February*, 1926; *read before the* WIRELESS SECTION 6*th January*, 1926.)

SUMMARY.

The paper is divided into six parts, as follows :—

In Part I the variations of frequency which occur in mechanical oscillating systems with pendulum control are referred to. Unless the driving impulses are given at the moment the pendulum is vertical, the frequency of the oscillations varies from the true oscillation frequency of the pendulum. When the pendulum is near the limit of its swing an impulse directed inwards makes the clock go fast, whilst an impulse directed outwards makes the clock go slow. Such an effect is "reversible" because the clock goes fast or slow according to the direction in which the impulse is applied. Another type of variation is connected with the amplitude of the swing, and makes its appearance unless the amplitude is infinitesimal. Increase of amplitude always makes the clock go slow, and the effect is therefore "irreversible."

In Part II the phase relationships of currents and potentials in a thermionic generator are examined, and it is shown that the frequency of the oscillations is affected by the nature of the coupling between the grid and anode circuits. Equations are obtained which give the difference between the frequency of the oscillations generated and the resonant frequency of the tuned circuits. These equations show that the variations of frequency connected with the method of coupling are analogous to the reversible variations existing in the pendulum-controlled clock. With normal coupling the thermionic generator goes slow, with reversed coupling it goes fast, and with resistance coupling the variation disappears.

In Part III three "irreversible" variations of frequency are discussed, namely :—

(i) A variation connected with a change in the effective inductance of the circuit, which occurs when the oscillation is free instead of forced ;

(ii) A variation connected with a change in the resonant frequency of a damped circuit, which occurs when the oscillation is free instead of forced ; and

(iii) A variation associated with the presence of harmonics in the E.M.F. generated by the valve.

In Part IV certain points in the design of thermionic generators employing resistance coupling are discussed.

In Part V the design of thermionic generators using reversed coupling is discussed, and some interesting points affecting the design of untuned circuits are described.

In Part VI the experimental results obtained with various types of circuit are given, and are explained in terms of the theoretical variations discussed in Parts II and III.

The characteristics of various types of constant-frequency generator are then compared. It is pointed out that frequency variations associated with changes in the voltage of supply can be reduced below 1 part in 20 000, or 1 part in 50 000, according to circumstances.

PART I.

SOME PROPERTIES OF MECHANICAL OSCILLATING SYSTEMS.

Electrical oscillating systems driven by thermionic valves, and mechanical oscillating systems controlled by pendulums or balance wheels, have many properties in common. It is proposed to refer briefly to certain well-known properties of the mechanical systems, as the discussion will be found helpful in dealing with the purely electrical problems.

The problem of designing a standard clock involves many points of interest, but the first and most fundamental horological principle is that the impulse must be given to the pendulum at or near its zero (vertical) position. The reason for this rule may be briefly stated as follows :—

For small amplitudes the time T taken by the pen-

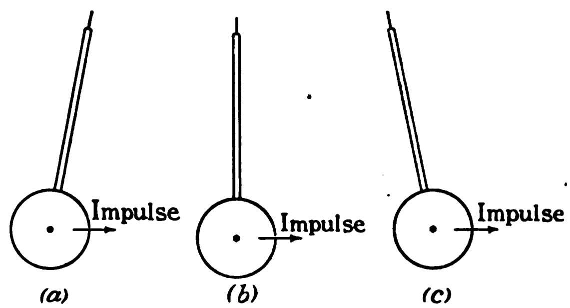

FIG. 1.

dulum to describe a complete oscillation is given by the equation

$$T = 2\pi\sqrt{\frac{l}{g}} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where l is the length of the pendulum.

If the pendulum is subject to damping, the friction will assist gravity when the pendulum is swinging outwards, and the time of the quarter oscillation will be shortened from $\frac{1}{4}T$ to, say, $\frac{1}{4}T - \tau$. During the inward swing the friction will oppose gravity, and the time will be lengthened from $\frac{1}{4}T$ to $\frac{1}{4}T + \tau$, the total time taken for the complete oscillation being sensibly unaltered.

When the loss of energy due to damping is made good by sudden impulses—as is usually the case in mechanical systems—the moment at which the impulse is given is of vital importance. There are three cases (see Fig. 1), as follows :—

(*a*) *When the impulses are imparted to the pendulum*

at the end of its swing and are directed inwards. In this case the frequency of the oscillations is greater than the natural frequency of the pendulum, the amount of the difference depending on the strength of the impulses. Increasing the strength of the impulses increases the variation and makes the clock go fast.

(*b*) *When the impulses are given at the moment the pendulum is vertical.* In this case the frequency of the oscillations is the natural frequency of the pendulum.

(*c*) *When the impulses are imparted to the pendulum at the end of its swing and are directed outwards.* In this case the frequency of the oscillations is less than the natural frequency of the pendulum, the amount of the difference depending on the strength of the impulses. Increasing the strength of the impulses increases the variation and makes the clock go slow.

When the oscillations have settled down into a steady state, the energy supplied by the impulses must equal the energy lost by the damping. Increased strength of impulse and increased damping are therefore synonymous.

The type of frequency variation which occurs when the impulses are not given to the pendulum in its vertical position may, for obvious reasons, be described as "reversible."

Before leaving the question of the clock another type of variation must be referred to. For very small amplitudes the time of swing is independent of the amplitude. When the arc swept out is not very small, however, the frequency varies slightly with the amplitude, an increase of amplitude causing a reduction of frequency. If the impulses are increased in strength therefore the clock will go slow, even if the impulses are given at the correct instant. This effect has been analysed in mathematical textbooks and need not be dealt with in detail here.

This second type of frequency variation is "irreversible." A stronger impulse can only make the clock go slow and cannot make it go fast.

It is interesting to note that in Fig. 1 (*a*) the two types of variation are in opposite senses and tend to neutralize one another.

In electrical oscillating systems the energy is not usually supplied by means of a short impulse, but is spread over at least half of the complete period. The underlying principle is, however, the same. An impulse proportional to cos θ will leave the period of oscillation sensibly constant, whereas an impulse proportional to sin θ will increase or diminish the period of oscillation according to the direction in which it is applied.

PART II.

FREQUENCY VARIATIONS DUE TO CHANGES IN ANODE RESISTANCE.

TYPES OF COUPLING.

All thermionic generators employ some form of coupling between the grid and anode circuits of the valve.

Stray capacity is inherent in all electrical circuits, and stray capacity coupling invariably exists between the grid and anode circuits of a thermionic valve. Owing to the fact that the filament is common to both grid and anode circuits, capacity coupling can have only one sense, and this type of coupling is conveniently described as *normal coupling.*

Inductive coupling may be in either direction, and inductive coupling which assists the capacity coupling is defined as normal coupling. Circuits which generate oscillations by means of normal coupling may be described as *orthodyne circuits.*

Inductive coupling which opposes the capacity coupling is described as *reversed coupling,* and circuits which generate oscillations by means of reversed coupling may be described as *antidyne circuits.*

Oscillations may be generated by means of either normal or reversed coupling, the only difference being that a stronger inductive coupling is required in the latter case than in the former.

Oscillations may also be generated by means of a resistance coupling between the grid and anode oscillatory circuits, and this type of coupling will be described in due course. Circuits generating oscillations by means of resistance coupling may be described as *rheodyne circuits.*

THERMIONIC GENERATOR WITH INDUCTIVE COUPLING.

The formulæ used in this discussion are explained in detail in the Appendix.

Fig. 2 shows a type of circuit commonly used for generating oscillations, and Fig. 3 shows the "equivalent network."

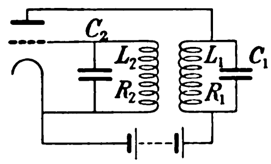

FIG. 2.

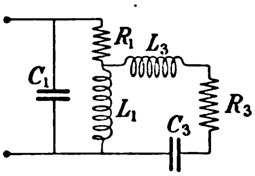

FIG. 3.

The values of L_3, R_3, C_3 are

$$L_3 = (L_1^2/M^2)L_2\sigma$$
$$R_3 = (L_1^2/M^2)R_2$$
$$C_3 = (M^2/L_1^2)C_2$$

where M is the mutual inductance and $\sigma = 1 - (M^2/L_1L_2)$.

The problem can be simplified by assuming that the energy absorbed in the grid circuit is negligible compared with the energy absorbed by the anode circuit, so that the flow of current in $L_3R_3C_3$ can be ignored in dealing with the circuit $L_1R_1C_1$.

The difference in phase between the E.M.F. across L_1 and the E.M.F. generated in the valve is given by the equation

$$\tan\phi = \frac{-2Ay + R_1}{\sqrt{(L_1/C_1)} + AR_1\sqrt{(C_1/L_1)}} \quad . \quad . \quad (2)$$

where ϕ is an angle between $-90°$ and $90°$.

In the special case in which there is no grid current, $\tan\phi = 0$ and $y = R_1/2A$, so that

$$\omega = \frac{1}{\sqrt{(L_1C_1)}}\left\{1 + \frac{R_1}{2A}\right\} \quad . \quad . \quad . \quad (3)$$

an equation which will be found in slightly different form in the textbooks.

The term R_1 is usually small compared with $2Ay$ and, for the moment, it will be regarded as negligible in the numerator of equation (2).

The circuit $L_3\,R_3\,C_3$ is an acceptor circuit, and the difference in phase between the potential across C_3 and the potential applied to the circuit is given by the equation

$$\tan\theta = \frac{R_3\sqrt{C_3}}{2x\sqrt{L_3}} = \frac{R_2\sqrt{C_2}}{2x\sqrt{(L_2\sigma)}} \quad . \quad . \quad . \quad (4)$$

Finally, the difference in phase between the potential across C_3 and the E.M.F. generated in the valve is $(\theta + \phi)$, where ϕ and θ are defined by equations (2) and (4) above.

Now the E.M.F. generated in the valve differs in phase by 180° from the variations in the potential of the grid, and this in turn is the potential across C_3. Actually the difference in phase between the potential across C_3 and the E.M.F. generated in the valve may be 0° or 180°, according to the direction of the coupling between the coils.

Therefore $\quad \tan\theta + \tan\phi = 0 \quad . \quad . \quad . \quad . \quad (5)$

and

$$xy = \frac{R_2\sqrt{(C_1C_2)}\{(L_1/C_1) + AR_1\}}{4A\sqrt{(L_1L_2\sigma)}} \quad . \quad . \quad (6)$$

The quantities on the right of this equation are essentially positive, and therefore x and y must either be both positive or both negative.

If the circuits are adjusted so that $L_1C_1 = L_3C_3$, then

$$x = y = \pm\sqrt{\left[\frac{R_2C_2}{4AC_1} + \frac{R_1R_2C_2}{4L_1}\right]} \quad . \quad . \quad (7)$$

so that

$$\omega = \frac{1}{\sqrt{(L_1C_1)}}\left\{1 \pm \sqrt{\left[\frac{R_2C_2}{4AC_1} + \frac{R_1R_2C_2}{4L_1}\right]}\right\} \quad . \quad (8)$$

The sign $\pm$ depends on the direction of the coupling. With normal coupling the negative sign must be taken, and with reversed coupling the positive sign.

Those who are interested in this question of phase relationship in thermionic generators will find a number of diagrams in a paper * by D. C. Prince.

Thermionic Generator with Capacity Coupling.

Fig. 4 shows a thermionic generator with capacity coupling, the coupling due to stray capacity being of

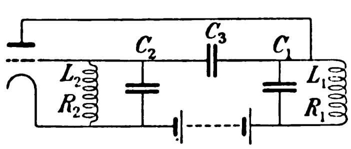

Fig. 4.—Thermionic generator with capacity coupling.

this type. To simplify the problem assume that the coupling capacity C_3 is small compared with C_1 and C_2, so that the energy taken by the grid circuit is small compared with the energy expended in the anode circuit.

The circuit L_1C_1 is a rejector circuit, and the phase of the potential across this circuit is related to the E.M.F. generated in the valve by the equation

$$\tan\phi = \frac{-\,2Ay\sqrt{(L_1C_1)}}{(L_1/C_1) + AR_1} \quad . \quad . \quad . \quad (9)$$

where ϕ is an angle between $-$ 90° and $+$ 90°.

Noting that C_3 is small compared with the impedance of the circuit $L_2R_2C_2$ it follows that the current flowing in C_3 is determined by the value of C_3 itself. The difference in phase between current and potential is therefore 90°, or nearly so.

Next consider the rejector circuit L_2C_2. The potential across the circuit is related to the current by the equation

$$\tan\theta = \frac{-\,2x\sqrt{L_2}}{R_2\sqrt{C_2}} \quad . \quad . \quad . \quad . \quad (10)$$

Finally, the potential on the grid, which is the potential across this circuit, differs in phase from the E.M.F. generated in the valve by the angle $(\phi + 90° + \theta)$.

But the potential on the grid differs from the E.M.F. generated in the valve by 180°, so that

$$\phi + 90° + \theta = 180° \quad . \quad . \quad . \quad (11)$$

$$\therefore\ \tan\phi = 1/\tan\theta \quad . \quad . \quad . \quad . \quad (12)$$

$$\therefore\ xy = \frac{R_2\sqrt{(C_2)}\{(L_1/C_1) + AR_1\}}{4A\sqrt{(L_1L_2C_1)}} \quad . \quad . \quad (13)$$

Since the various quantities on the right of this equation are positive it follows that x and y must be of the same sign. Equation (11) further tells us that θ and ϕ must be between 0° and 90°, so that x and y must both be negative.

If the circuits are so adjusted that $L_1C_1 = L_2C_2$

then

$$x = y = -\sqrt{\left[\frac{R_2C_2}{4AC_1} + \frac{R_1R_2C_2}{4L_1}\right]} \quad . \quad (14)$$

so that

$$\omega = \frac{1}{\sqrt{(L_1C_1)}}\left\{1 - \sqrt{\left[\frac{R_2C_2}{4AC_1} + \frac{R_1R_2C_2}{4L_1}\right]}\right\} \quad (15)$$

Thermionic Generator with Resistance Coupling.

This type of circuit is shown in Fig. 5. When the tuned anode and grid circuits are so adjusted that $L_1C_1 = L_2C_2$, it is clear that the E.M.F. generated by

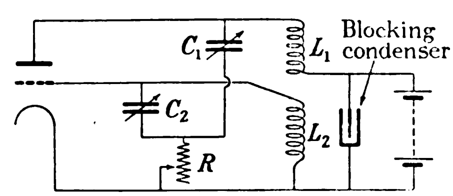

Fig. 5.—Thermionic generator with resistance coupling between the oscillatory circuits.

the valve, the potential across the anode oscillatory circuit and the potential across the coupling resistance are all in the same phase (or nearly so). It is also clear that the potential applied to the grid will differ by 180° from the E.M.F. generated in the valve.

It follows that the frequency of the oscillations generated is determined by the values of L and C and

* *Proceedings of the Institute of Radio Engineers*, 1923, vol. 11, pp. 275 and 399.

is independent of the magnitude of the various resistances.

Effect of Changes in Anode and Filament Potential.

In the case of generators with capacity coupling, it has been shown that the frequency of the oscillations is expressed by an equation of the form

$$f = \frac{1}{2\pi\sqrt{(LC)}}[1 - \sqrt{\{H + (K/A)\}}] \quad . \quad (16)$$

where A is the anode resistance of the valve and H and K are quantities depending on the fixed electrical characteristics of the circuits. It is clear from this

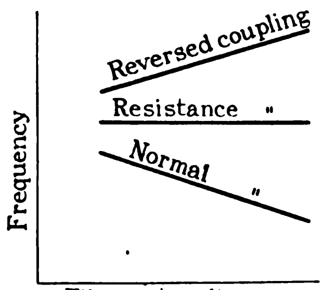

Fig. 6.—Variation of the first type.

equation that an increase in the anode resistance of the valve involves an increase of frequency, and vice versa. Normal inductive coupling produces similar results.

With reversed inductive coupling the frequency equation takes the form

$$f = \frac{1}{2\pi\sqrt{(LC)}}[1 + \sqrt{\{H + (K/A)\}}] \quad . \quad (17)$$

and the effect of changes in anode resistance is reversed.

An increase in the voltage applied to the filament of a valve increases the emission and the anode resistance

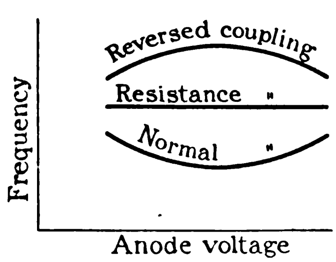

Fig. 7.—Variation of the first type.

is reduced. Changes in filament voltage would therefore be expected to give the results indicated in Fig. 6.

Changes in the anode voltage also cause variations in the anode resistance of the valve, and in any particular case there is a particular anode voltage for which the anode resistance is a minimum. Changes in anode voltage would therefore be expected to give the results indicated in Fig. 7.

The frequency variations which are associated with changes in the anode resistance of the valve are "reversible," and are analogous to the reversible frequency variations already described in reference to the oscillations of the pendulum.

With both types of oscillating system there are three cases depending on whether the impulses are in advance of the oscillations, in synchronism with them, or behind them. It is convenient to describe this kind of frequency variation as a frequency variation of the *first type*.

Frequency-Changes produced by Given Changes in Anode Resistance.

Before comparing different circuits it is desirable to define a quantity which can be used as a standard of comparison. The various equations in the previous sections determined the difference between the frequency of the oscillations generated, which was denoted by f, and the resonant frequency of the tuned circuits, which may be denoted by f_0, and the quantity x was so defined that it is a fraction satisfying the equation

$$x = (f - f_0)/f_0$$
$$\therefore \delta x = \delta f/f_0$$

It is convenient to express changes in anode resistance in a similar manner, as a proportion of the total anode resistance, and the quantity z is introduced by the equation

$$z = \frac{\delta f/f_0}{\delta A/A} = \frac{A\delta x}{\delta A} \quad . \; . \; .$$

The value of z for a generator employing two tuned circuits is found by differentiating equation (7). This gives

$$z = \mp \tfrac{1}{2}\left\{\frac{R_2C_2}{AC_1}\right\}^{\frac{1}{2}}\left\{1 + \frac{R_1AC_1}{L_1}\right\}^{-\frac{1}{2}} \quad . \quad (18)$$

At this point it may be observed that R_2, the damping of the grid circuit, consists really of two parts—a fixed part which may be denoted by R_4, and a part depending on the grid current, which can be shown to be equal to L_2/C_2G, where G is the grid resistance of the valve. The complete formula should therefore be written

$$z = \mp \tfrac{1}{2}\left\{\frac{R_4C_2}{AC_1} + \frac{L_2}{AGC_1}\right\}^{\frac{1}{2}}\left\{1 + \frac{R_1AC_1}{L_1}\right\}^{-\frac{1}{2}} \quad (19)$$

Untuned circuits.—It has already been pointed out that the quantities x and y in equation (24) are both negative with normal coupling, which means that the frequency of the oscillations must be below the resonant frequencies of both grid and anode circuits. This interesting fact may be verified experimentally, and it follows that the resonant frequency of the untuned circuit must be higher than the highest frequency it is desired to produce.

Conversely, with reversed coupling the quantities x and y are both positive, and the frequency of the oscillations is above the resonant frequencies of both grid and anode circuits. The resonant frequency of the untuned circuit must therefore be lower than the lowest frequency it is desired to produce.

The value of z for an orthodyne generator with tuned grid and untuned anode is

$$z = \tfrac{1}{2}\left\{\frac{R_4L_1}{AL_2} + \frac{L_1}{AGC_2}\right\} \quad . \; . \; . \quad (20)$$

and similar formulæ can be found for other arrangements involving one tuned and one untuned circuit.

If probable values are allotted to the various quantities appearing in equations (19) and (20) it becomes apparent that the frequency variations should be less with one tuned circuit than with two. This is confirmed in practice, although the actual difference is less than might be expected from the equations.

It must be observed, however, that there is no means of knowing that the two tuned circuits are actually adjusted in the manner assumed in the above investigation, and it may easily happen in practice that one of the circuits is slightly mistuned, which would easily account for the experimental results. The problem is further complicated by the fact that R_2, the damping of the grid circuit, is certainly not a constant but varies with the amplitude. A full investigation of the effect of these factors would, however, be beyond the scope of the present paper.

Changes in Grid Potential.

It has already been pointed out that the damping in the grid circuit may be divided into two portions—a fixed portion which includes the true ohmic resistance of the coil and the dielectric losses in coil and condenser, and a variable portion depending on the grid current in the valve itself.

Under normal working conditions the damping due to the grid current is usually larger than the damping due to other causes, and in any case the latter can be kept down to a very low figure by suitable methods of construction. The question of keeping down the damping in the grid circuit is therefore mainly a question of keeping down the grid current in the valve, that is to say, of maintaining the grid at a suitable negative potential.

In the case of a generator with two tuned circuits the quantity z which has been introduced to measure the frequency variation contains the factor $\sqrt{R_2}$, and in the case of a generator with one untuned circuit z contains the factor R_2 without the square root.

In either case the damping in the grid circuit is of fundamental importance, since it determines the whole scale on which the frequency variations occur.

Part III.

IRREVERSIBLE VARIATIONS OF FREQUENCY.

In Part II it was assumed that the E.M.F. generated in the valve is a true sine curve, and it was shown that a frequency variation occurs, the direction of which is dependent upon the nature of the coupling. It is now proposed to consider certain variations which arise in consequence of the fact that the E.M.F. actually generated is not sine-shaped. These frequency variations are irreversible, that is to say, the direction of the frequency change is independent of the direction of the coupling.

The departures from the true sine curve are of two kinds :—

(i) The E.M.F. generated by the valve does not resemble a complete sine curve, but approaches more or less closely to a succession of positive half-cycles with the negative half cycles omitted. Frequency variations connected with the unidirectional character of the impulses appear to be next in order of importance to the reversible variations already dealt with. They are of two types, which will be described as frequency variations of the *second and third types* respectively.

(ii) The E.M.F. generated in the valve may not be sine-shaped at all, but may be distorted. Frequency variations which appear to be associated with this condition will be referred to as belonging to the *fourth type*.

Frequency Variations of the Second Type.

In the case of a generator employing a tuned grid and untuned anode the resonant frequency during the periods when the valve is active is given by the equation

$$f_1 = \frac{1}{2\pi\sqrt{(L_2\sigma C_2)}} \quad . \quad . \quad . \quad . \quad (21)$$

whilst the resonant frequency when the valve is inert is

$$f_2 = \frac{1}{2\pi\sqrt{(L_2 C_2)}} \quad . \quad . \quad . \quad . \quad (22)$$

this second frequency being necessarily lower than the first.

The mean resonant frequency, on which the actual frequency of the oscillations is based, lies between

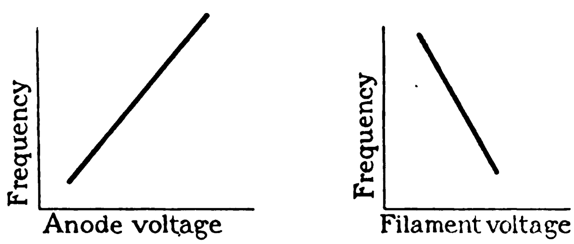

Fig. 8.—Variation of the second type.

these two values, the true figure depending upon the proportion between the period of activity and the period of inertness. This in turn varies according to the conditions under which the circuit is operated, the rule being that the frequency is increased by conditions which increase the period of activity of the valve, and diminished by conditions producing an opposite effect.

An increased anode voltage moves the characteristic curve of the valve towards the left of the diagram, increases the period of activity, and thereby increases the frequency, whilst increased filament voltage alters the conditions in an opposite direction and reduces the frequency (see Fig. 8).

It is assumed throughout this investigation that the energy absorbed by the grid circuit is negligible compared with that absorbed in the anode circuit, and on this assumption the activity (or otherwise) of the valve has no effect on the inductance of a tuned anode circuit. Frequency variations of the second type will not occur therefore when the grid circuit is untuned.

A generator employing two tuned circuits appears to occupy an intermediate position, and a frequency

variation of the second type may be expected to give evidence of its existence.

Frequency Variations of the Third Type.

When a thermionic generator employs a tuned anode circuit the resonant frequency of the anode circuit when the valve is active is

$$f_1 = \frac{1}{2\pi}\sqrt{\left[\frac{1}{L_1C_1} - \frac{R_1^2}{L_1^2}\right]} \quad . \quad . \quad . \quad (23)$$

whilst the resonant frequency when the valve is inert is

$$f_2 = \frac{1}{2\pi}\sqrt{\frac{1}{L_1C_1}} \quad . \quad . \quad . \quad . \quad (24)$$

the second frequency being always higher than the first.

The mean resonant frequency, on which the actual frequency is based, lies as before between these two values.

It will be observed that the frequency variations of the second and third types are always in opposite directions (see Figs. 8 and 9).

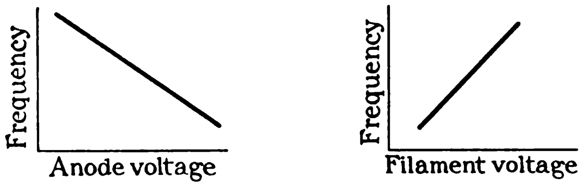

Fig. 9.—Variation of the third type.

Frequency variations of the third type do not occur when the anode circuit is untuned, but they occur whenever the anode circuit is tuned, independently of whether the grid circuit is tuned or not.

Frequency variations of the fourth type.—The effect of harmonics on the resonant frequency of a thermionic oscillator has been examined by Appleton and Greaves,* one of the arrangements discussed being equivalent to a tuned anode circuit. Analogous problems have also been discussed by other investigators. The result is to show in each case that the resonant frequency is reduced by the presence of harmonics.

Bearing in mind that the period of activity is an indefinite fraction of a complete cycle, it is difficult to say what conditions of operation are likely to produce the largest proportion of harmonics.

On the experimental side the effect seems to be of less importance than the variations of the second and third types, and no case has come to the author's notice in which the presence of harmonics can be said to have produced a definite variation of frequency.

Part IV.

THE DESIGN OF RHEODYNE THERMIONIC GENERATORS TO COVER A WIDE BAND OF FREQUENCIES.

Introduction.

A circuit diagram of a thermionic generator with resistance coupling between the oscillatory circuits has already been given in Fig. 5, and other arrangements are shown in Figs. 10, 11 and 12.

* E. V. Appleton and W. M. H. Greaves: *Philosophical Magazine*, 1923, vol. 45, p. 401.

It is essential that the capacities of the two oscillatory circuits should be connected to one end of the resistance and the two inductances to the other, but it is immaterial which.

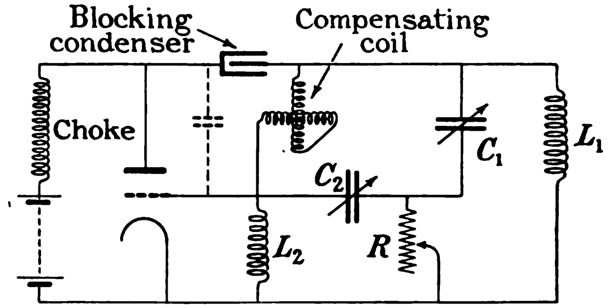

Fig. 10.

In order that the resistance coupling may generate oscillations in the manner indicated in the circuit diagrams, it is, of course, necessary that the coupling

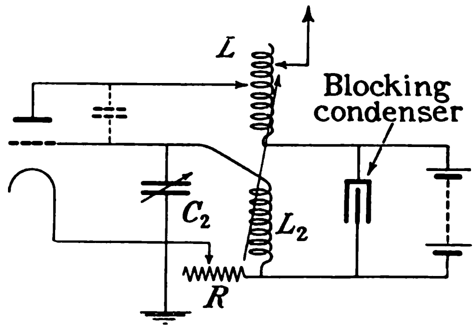

Fig. 11.

due to stray capacity should be neutralized. This may be done in various ways :—

(i) By reversed inductive coupling, as shown in Figs. 5 and 11.
(ii) By providing an inductive path between grid and anode, as shown in Fig. 10.
(iii) By what are generally known as neutrodyne circuits, such as the circuit shown in Fig. 12.

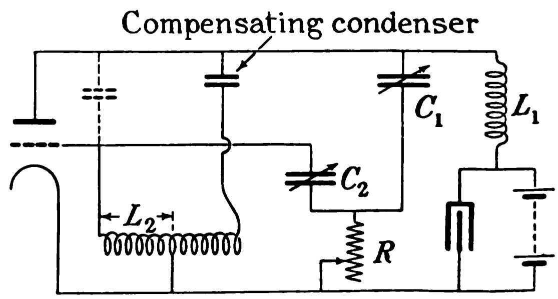

Fig. 12.

The problem of neutralizing stray capacity coupling is well known in connection with the design of amplifiers, and it is not necessary to discuss it here in detail. It may be observed, however, that the measurement of

the frequency variations when a circuit is oscillating provides a convenient method of determining whether the capacity coupling has been accurately neutralized or not. It also gives definite information as to whether the neutralizing arrangement is insufficient or excessive.

It is interesting to note in passing that the energy absorbed by the coupling resistance is approximately equal to the energy absorbed by the grid of the valve, so that the additional energy required to operate the circuit is not of material importance. Apart from the energy absorbed by the coupling resistance, the circuit operates under conditions of maximum efficiency.

The circuit generates oscillations of full amplitude and is applicable to transmitters, master oscillators, and wave-meters, and it may also have applications to amplifiers.

In order that a rheodyne generator may work efficiently it is necessary that :—

(i) The potential on the grid should be independent of the frequency, or nearly so.
(ii) The stray capacity should be correctly neutralized, or nearly so.

In order to ascertain whether this could be done without varying the coupling resistance or the neutrodyne arrangement, a special investigation was made on these two points. It is not proposed to give the details of this investigation, but the results will be briefly summarized.

Generator without Anode Tap: Adjustment of Grid Potential.

If the coupling resistance R is to remain constant it can be shown that the same method of tuning must be adopted for both grid and anode circuits, but the use of condenser tuning for the grid and variometer tuning for the anode, or vice versa, is inadmissible.

Provided this condition is satisfied there will always be a particular frequency for which the coupling resistance will be a minimum, and if this minimum is not in the centre of the desired band it can be made so by altering the value of the grid coil or condenser, as the case may be. It is only necessary to observe the value of L_2/C_2 at which the minimum actually occurs, and to alter the circuit so that it has this value at the particular frequency desired.

Generator with Anode Tap: Adjustment of Grid Potential.

When the anode circuit is tuned by means of a tapped coil, and the connection to the anode of the valve is made by means of an adjustable anode tap, it is immaterial whether the tuning of the grid circuit is by variable condenser or variometer. In either case the grid circuit can be so adjusted that R has a minimum value at any desired frequency.

A practical point may be noted in passing. If the grid is to be tuned by means of a variable condenser it may be found that the correct value of the condenser is inconveniently large. The difficulty can, however, be overcome by adopting a convenient size of condenser and by connecting the grid to an intermediate tapping point on the coil.

Generator Tuned by Variable Condensers: Neutralization of Stray Capacity.

The problem of neutralizing the coupling due to stray capacity is well known in connection with the design of amplifiers, and the circuit commonly used is shown in Fig. 12.

The capacity of the compensating condenser is of the same order as the stray capacity, that is to say, it is small compared with the other capacities in the circuit.

It follows that the current through the compensating condenser is mainly determined by the capacity of the compensating condenser itself, and it may be assumed as a first approximation that the fall of potential across the compensating coil is small compared with the fall of potential across the compensating condenser.

Assuming further that there is close coupling between the two coils, then

$$\frac{C_4}{C_5}=\frac{L_5}{M_2} \quad . \quad . \quad . \quad . \quad . \quad (25)$$

where C_4 is the stray capacity, C_5 the capacity of the compensating condenser, L_5 the inductance of the compensating coil, and M_2 the mutual inductance of the compensating coil and the grid tuning coil. Within certain limits the compensation is sensibly unaffected by the tuning.

It will be found in practice, however, that the compensation is not strictly constant on all frequencies. The inductance of the compensating coil increases the current through the compensating condenser by an amount which varies with the frequency, and which is greater for high frequencies. For a given adjustment, therefore, the compensation is excessive at high frequencies.

To minimize this effect it is desirable to keep the resonant frequency of the compensating circuit as high as possible, and it is clear from equation (25) that this depends on reducing M_2. It is therefore desirable to work with small coils and large condensers.

The method described is applicable to any type of generator employing a fixed grid coil in conjunction with a variable condenser, and it is immaterial whether anode tuning is by means of a variable condenser or by a tapped coil.

Generator Tuned by Variable Inductances: Neutralization of Stray Capacity.

When a generator is tuned by means of inductances or tapped coils it can be shown that the condition for the correct neutralization of the stray capacity is that M/L_1 must be kept constant, where M is the mutual inductance and L_1 the inductance of the anode coil.

The arrangement of the design so that this condition is fulfilled does not appear to present any serious difficulty.

Part V.

DESIGN OF ANTIDYNE THERMIONIC GENERATORS TO COVER A WIDE BAND OF FREQUENCIES.

Generator with Tuned Grid and Tuned Anode.

The orthodyne thermionic generator necessarily employs a combination of capacity and inductive coupling. Capacity coupling increases with the frequency not only over the band of frequencies covered by any individual instrument, but also as between similar instruments designed for different bands of frequencies. The strength of inductive coupling depends upon the method of tuning adopted. When tuning is carried out by means of variable condensers the inductive coupling is stronger at the lower frequencies than at the higher.

On frequencies of the order of 1 000 kilocycles per second fairly uniform coupling is obtainable over a wide band of frequencies by a suitable adjustment of the two couplings, the capacity coupling providing the greater part of the required coupling at the higher frequencies, and the inductive coupling performing the same function at the lower frequencies. This principle may also be applied to the design of antidyne circuits.

It has already been explained that there is a well-known form of neutrodyne circuit in which a small condenser controls the magnitude of the current flowing from anode to grid and in which a transformer reverses its direction. If a circuit of this type is so adjusted as to produce a coupling greater than the stray capacity coupling, the resultant is a form of coupling which is opposite in direction to normal capacity coupling, but which possesses the same general properties. The arrangement may therefore be described as reversed capacity coupling.

An antidyne thermionic generator which is required to cover a wide band of frequencies should make use of a combination of reversed capacity coupling and reversed inductive coupling, and its design will then be governed by the same principles as those which apply to generators using normal coupling. In practice the reversed capacity coupling is therefore so adjusted as to ensure sufficient reaction at the higher frequencies, and the reversed inductive coupling is so adjusted as to give sufficient reaction at the lower frequencies. Finally the grid leak is adjusted to such a value that the required balance is obtained between the reversible and irreversible effects as already explained.

Generator with Untuned Anode or Untuned Grid.

It has already been shown that with reversed coupling the resonant frequency of the untuned circuit must be below the lowest frequency it is desired to produce, and this condition is the controlling factor in the design of such circuits. At this point it may be desirable to emphasize the difference between tuned and untuned circuits. With tuned circuits the currents in the capacity and the inductance respectively are opposite in direction and nearly equal in magnitude, so that the oscillatory current may be many times larger than the current flowing through the valve. The impedance of the tuned circuit is therefore much higher than the impedance of either inductance or capacity alone. With untuned circuits this is not so, and the flow of current in capacity or inductance is only balanced to a very limited extent.

The capacity of an untuned circuit must therefore be small, especially at high frequencies, or the fall of potential across the circuit will be so low that the alternating potential on the grid will be insufficient to maintain the oscillations. To bring the untuned circuit with its small capacity to resonance would require an anode coil considerably larger than the tuned coil, while to produce an untuned circuit whose resonant frequency is below the lowest frequency for which the instrument is designed requires a still larger coil. An untuned coil of specially high inductance is therefore an essential feature of circuits of this type. The importance of this point may be emphasized by an actual example. With an instrument covering a band of frequencies from 600 to 1 500 kilocycles the tuned circuit might consist of a coil having an inductance of 140 μH in combination

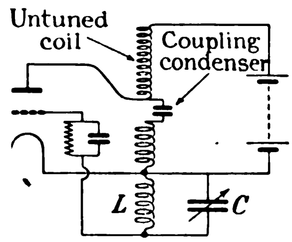

Fig. 13.

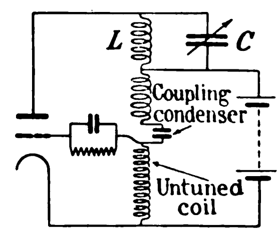

Fig. 14.

with a variable condenser having a maximum capacity of 500 $\mu\mu$F.

With normal coupling the untuned coil might have an inductance of 140 μH or less, depending on the closeness of the coupling.

With reversed coupling, and a capacity of 50 $\mu\mu$F in the untuned circuit, the minimum value of the inductance would be 1 400 μH, and this would just give resonance at the lowest frequency. In practice a coil of about 5 000 μH would probably be used so as to avoid certain effects which appear if resonance is approached too closely.

The value of the untuned coil having been fixed, the best value for the reversed capacity coupling and the reversed inductive coupling can be determined by trial, remembering that the reversed capacity coupling is most effective at the higher frequencies and the reversed inductive coupling at lower frequencies of the band which it is desired to cover.

A circuit diagram of an antidyne generator with untuned anode is given in Fig. 13, and with untuned grid in Fig. 14.

Part VI.

EXPERIMENTAL RESULTS AND PRACTICAL APPLICATIONS.

Rheodyne Generators.

The experimental thermionic generator employed an R valve: filament voltage 3·8 to 4·2, anode voltage 40 to 200, no grid bias unless stated. The frequency of the oscillations was about 5×10^6.

The results are shown in Figs. 15 to 20, and a comparison of these results with the theoretical diagrams, given in Figs. 7, 8 and 9, suggests that the actual frequency variations are due to a combination of the variations of the first and second types.

The frequency variations which are produced by changes of filament voltage are of a simpler character than those produced by changes in anode voltage, as on the frequency, and only so much reversed coupling is employed as is necessary in order to obtain a balance between the variations of the first and second types. The correct adjustment for constant frequency gives Fig. 18.

The practical application of these results will be discussed more fully in a later Section.

Fig. 17 is of special interest as it shows a variation

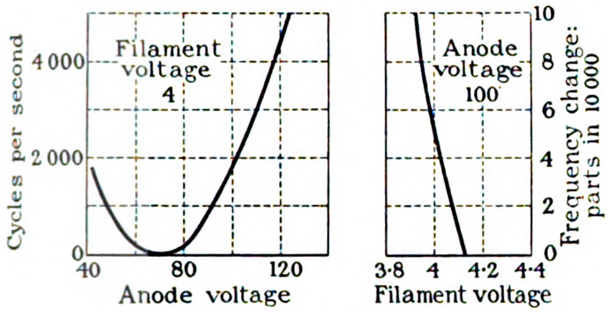

FIG. 15.—Normal coupling.

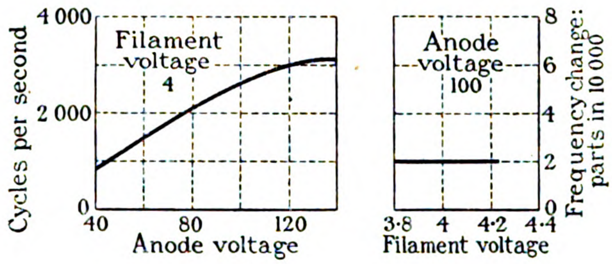

FIG. 18.—Three-quarters resistance coupling, one-quarter reversed coupling.

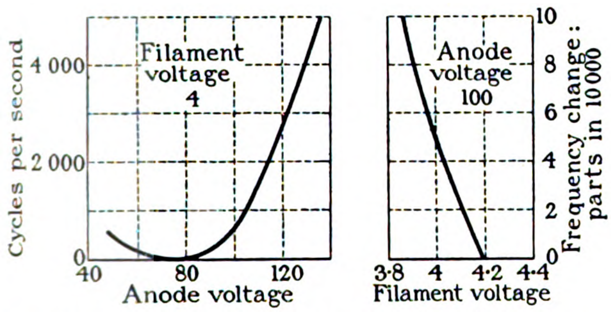

FIG. 16.—Half normal coupling, half resistance coupling.

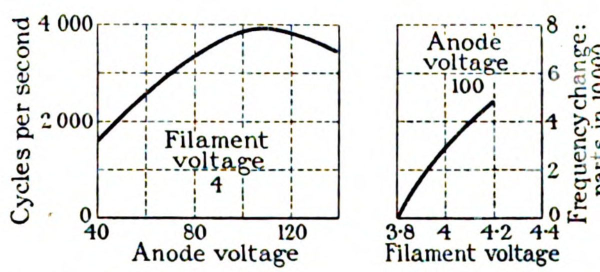

FIG. 19.—Half resistance coupling, half reversed coupling.

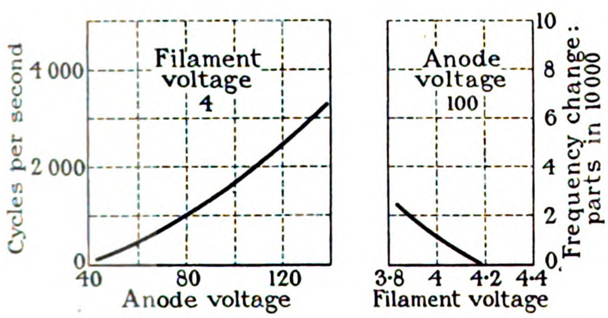

FIG. 17.—Resistance coupling.

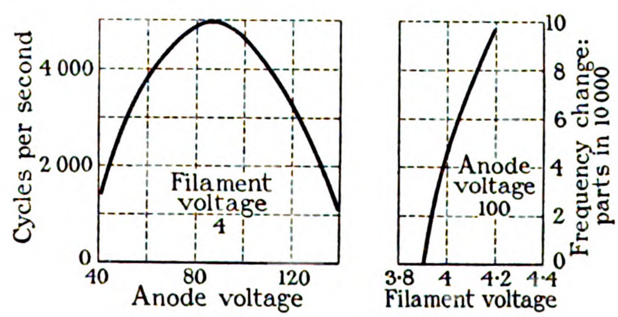

FIG. 20.—Reversed coupling.

[NOTE: In Figs. 15–20 the frequency was approximately 5 000 kilocycles per sec.]

the relationship involved is very nearly linear. With normal coupling the variations of the first and second types are of the same sign, and the total frequency variation is the sum of the two separate effects.

With reversed coupling the variations of the first and second types are of opposite sign, and they can be made to neutralize each other if they are of the same magnitude.

In the method now under consideration advantage is taken of the fact that resistance coupling has no effect of the second type, the variation of the first type being entirely absent.

ORTHODYNE GENERATOR USING GRID BIAS.

The influence of grid damping as a factor in producing irreversible frequency variations has been explained in Part II. Generators which work under such conditions that the grid current is very small may therefore be expected to show important reductions in the frequency variations.

The experimental discovery of this fact appears to be due to the Marconi Company, but details of their experiments have not been published. The author understands that a good deal of work has also been carried out in connection with this subject in America.

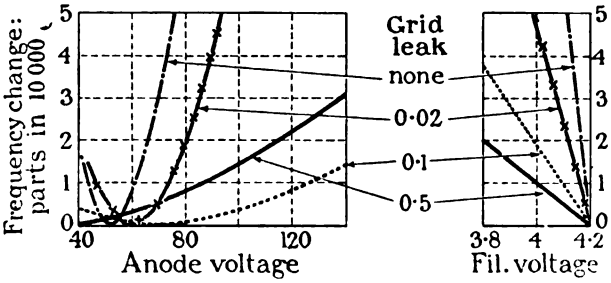

FIG. 21.

The results of the author's own experiments with an orthodyne generator using two tuned circuits are shown in Fig. 21. Similar results for an orthodyne circuit with untuned grid are shown in Fig. 22, and with untuned anode in Fig. 23.

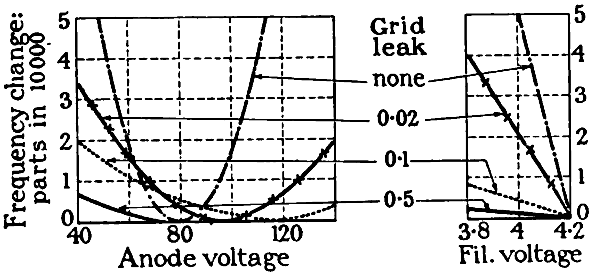

FIG. 22.—Orthodyne generator; untuned grid, tuned anode.

The general character of the experimental results is in good agreement with the theory already given, and the effect of grid bias in eliminating variations of the first type is well shown. It will be noticed that the frequency variations are larger with two tuned circuits than when one circuit is untuned.

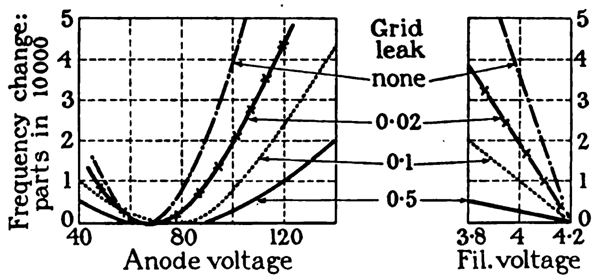

FIG. 23.—Orthodyne generator; tuned grid, untuned anode.

In the case of the generator with two tuned circuits (Fig. 21) and also in the case of the generator with untuned anode (Fig. 23) the results can be regarded as being due to a combination of the variations of the first and second types. For changes of filament voltage the two variations are of the same sign, and an absolutely constant frequency characteristic seems to be unattainable.

In the case of the generator with untuned grid (Fig. 22) the results can be regarded as being due to a combination of variations of the first and third types. For changes of filament voltage the two variations (see Figs. 6 and 9) are of opposite sign, and they can be made to neutralize each other. For changes of anode voltage exact neutralization requires the use of a high anode voltage, that is to say a voltage nearly high enough to stop the oscillations altogether.

This circuit is of great practical importance and seems likely to come into general use for wave-meters and master oscillators. The use of heavy grid bias, however, reduces the amplitude and renders it less suitable for actual transmitters.

ANTIDYNE GENERATOR USING GRID BIAS.

Figs. 24 to 26 show groups of curves for an antidyne generator, and, after what has already been said, it is

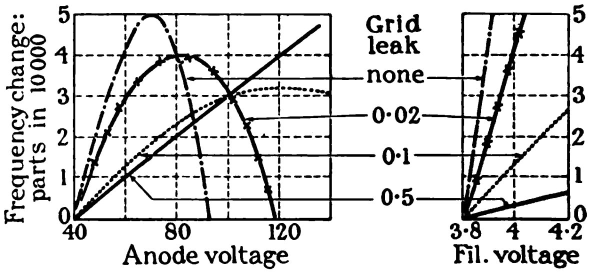

FIG. 24.—Antidyne generator; grid and anode both tuned.

hardly necessary to analyse these curves in detail. Certain points of interest may, however, be noted.

Taking the question of the generator using two tuned circuits, a comparison between Figs. 21 and 24 shows that the frequency variation of the second type is definitely in evidence, so that the total variation for any particular grid bias is less in the latter case than

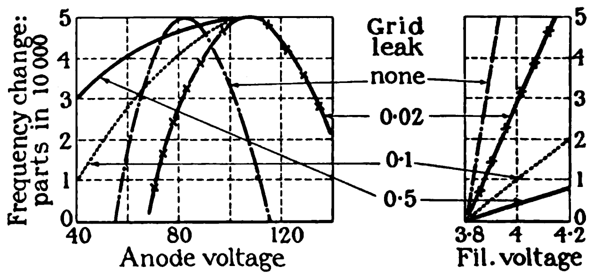

FIG. 25.—Antidyne generator; untuned grid, tuned anode.

in the former. The experiments lead to the conclusion that there is a definite advantage in using reversed coupling rather than normal coupling.

This conclusion would no doubt apply to arrangements in which the grid and anode are directly connected to different points on the same oscillatory circuit; that is to say, the frequency variations with the Colpitts circuit would be less than with the Hartley circuit.

Passing to circuits which use untuned grid or untuned anode, the antidyne generator with untuned anode which balances the variation of the first type against

the variation of the second type should be compared with the orthodyne generator using untuned grid which balances the variation of the first type against the

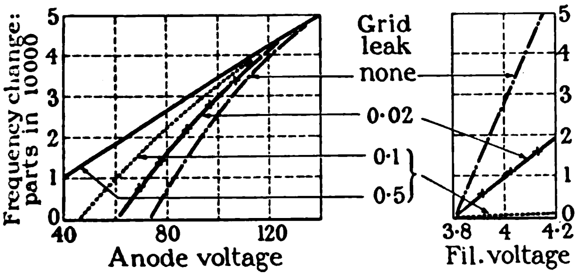

FIG. 26.—Antidyne generator; tuned grid, untuned anode.

variation of the third type. Probably the disadvantage of using an untuned anode would generally outweigh the advantage of using less grid bias.

PRACTICAL APPLICATIONS.

The practical applications of these results fall into two main classes, namely wave-meters and transmitters, the latter term including master oscillators.

In the case of power-driven generators the high-tension and low-tension current will usually be obtained from the same machine, and changes of high-tension and low-tension voltage will presumably be of the same character. It is possible, therefore, to balance changes in anode voltage against changes in filament voltage, and a very close regulation should be obtainable in this way.

Assuming a 10 per cent variation in the voltage of supply it seems quite possible to reduce the frequency variations to something of the order of 1 in 50 000, or 200 cycles per second at a frequency of 10 000 000.

In the case of the heterodyne wave-meter a lower order of accuracy is likely to prove sufficient. The instrument would be so adjusted as to make it independent of variations in filament voltage, leaving only the residual frequency variations associated with changes of anode voltage. These are considerably reduced by the adjustments made in connection with the filament voltage, and are of the order of 1 in 20 000 for a change of 10 per cent in the voltage of supply. If necessary they may be still further reduced by using a high anode voltage, that is to say one which is nearly high enough to stop the oscillations altogether.

Three solutions of the problem of constructing a constant-frequency generator have been referred to :—

(i) The rheodyne generator.
(ii) The orthodyne generator with grid bias, and untuned grid circuit.
(iii) The antidyne generator with grid bias.

These three methods have not yet received sufficient trial to enable one to speak very decisively as to their merits, but their probable advantages and disadvantages may be indicated.

Rheodyne generator.—This is more complicated than most types of orthodyne generator, as it involves the use of two tuned circuits and an arrangement for neutralizing the stray capacity coupling. It does not, however, impose any restriction on the amplitude of the oscillations, and appears to be specially applicable to small transmitters in which it is not desired to incorporate a master oscillator.

Orthodyne generator.—The heavy grid bias required to develop the constant-frequency characteristic in an orthodyne generator with untuned grid involves a considerable reduction in the amplitude of the oscillations, and this renders the arrangement unsuitable for use in actual transmitters. Its simplicity and the fact that it only employs one tuned circuit are important advantages, and it seems probable that it will be extensively adopted for wave-meters and master oscillators.

The position of the *antidyne generator* with grid bias is rather difficult to define. The Colpitts circuit with suitable grid bias seems to have considerable possibilities, but the author is unable to say whether a sufficiently constant frequency is obtainable without some sacrifice of amplitude. The antidyne generator with untuned anode appears to be less advantageous than the orthodyne generator with untuned grid.

FUTURE POSSIBILITIES.

The employment of a thermionic generator which will keep its wave-length constant within 1 part in 50 000 makes heterodyne reception possible on wave-lengths of 30 m or less, and the production of such a generator now appears to be a practical possibility.

Variations in wave-length due to changes in aerial capacity have already been reduced to a low figure by the use of master oscillators, and the employment of a constant-frequency circuit for the master oscillator would appear to remove any troubles connected with the voltage of supply.

The development of heterodyne wave-meters which will give an accuracy of 1 part in 10 000 is another interesting possibility. There are a number of details in the design of such an instrument which require further study, and which cannot be discussed here. Now that variations connected with the voltage of supply have been removed, however, there is no reason to suppose that any of the outstanding difficulties are insuperable.

For proper modulation, radio-telephony requires a band of 10 000 or 20 000 cycles, but a very much narrower band is theoretically sufficient for wireless telegraphy, and the number of channels of communication which is theoretically available on the shorter wave-lengths is very great.

The number of channels actually available at the present time does not approach these theoretical limits, but is determined by the unavoidable variations in the wave-length of our transmitters. Any method which will reduce the variations in wave-length of short-wave transmitters will automatically increase the number of channels of communication available for practical use.

The author would like to take this opportunity of thanking various friends who have assisted him from time to time with criticism and advice, and especially Major A. G. Lee of the Post Office Engineering Department, who has made a number of helpful suggestions.

APPENDIX.

Anode circuit.—Referring to Figs. 2 and 3, and ignoring the circuit $L_3R_3C_3$ in Fig. 3, put

E = E.M.F. in the valve,
E_1 = E.M.F. across C_1,
E_2 = E.M.F. across L_1,
I = current through the valve,
I_1 = current through C_1,
I_2 = current through L_1.

Then
$$I = (E - E_1)/A$$
$$I_1 = jE_1C_1\omega$$
$$I_2 = E_1/(R + jL\omega) = E_2/jL\omega$$
$$I = I_1 + I_2$$

If ϕ is the phase angle between E_2 and E, then it can be shown that

$$\tan\phi = \frac{-A(LC\omega^2 - 1) + R}{L\omega + ARC\omega} \quad . \quad . \quad . \quad (26)$$

Now put $\omega = \omega_0(1 + y)$ and we get

$$\tan\phi = \frac{-2Ay + R}{\sqrt{(L/C)} + AR\sqrt{(C/L)}}$$

which is the form of equation (2) on page 350.

Anode oscillatory circuit.—A combination of the results shown in equations (29) and (2) leads to the result

$$\tan\phi = -\frac{2Ay\sqrt{(L/C)}}{(L/C) + AR}$$

which is the form of equation (3) on page 350.

Acceptor circuit.—The circuit is supposed to consist of a coil of inductance L and resistance R in series with a capacity C.

The complex resistance of the whole circuit is $\{R + j(L\omega - 1/C\omega)\}$, and the phase angle between current and E.M.F. is

$$\text{arc tan}\,\frac{LC\omega^2 - 1}{RC\omega}$$

The potential across C lags 90° behind the current, and the phase angle between this potential and the applied E.M.F. is given by the equation

$$\tan\theta = \frac{RC\omega}{LC\omega^2 - 1}$$

where θ is an angle between 180° and 360°.

If ω is near the resonant frequency ω_0, put $\omega = \omega_0(1 + x)$, where x is a small quantity, then

$$\tan\theta = \frac{R\sqrt{C}}{2x\sqrt{L}}$$

which is the form of equation (4) on page 351.

Discussion before the Wireless Section, 6 January, 1926.

Major A. G. Lee: For some time past it has been recognized that an ordinary valve transmitter is liable to large frequency-changes which are caused by unavoidable variations in filament current and anode voltage. In order to overcome this difficulty I have devised another solution * which consists in obtaining harmonics from a valve-maintained tuning-fork oscillator, selecting a particular harmonic and amplifying it for transmission from the antenna as the wireless frequency. This system is now in use at the Northolt, Devizes and Rugby valve stations. The author has attacked the problem more directly and fundamentally. It may be of interest to get a physical idea of the processes involved in these frequency-changes which have been worked out mathematically and experimentally in the paper. The simplest case to analyse in this fashion is that of the tuned grid, untuned anode, oscillator. If we start with a voltage E_g of a certain phase on the grid, there will be an E.M.F. in the anode circuit of $-\mu E_g$, the minus sign denoting 180° phase change. Now, if the anode circuit were resistive only, the current in that circuit would be in phase with the E.M.F., and this would in turn produce an induced E.M.F. in the grid tuned circuit of phase + 90°. The current in the tuned circuit due to this E.M.F. would be in phase with it, and therefore the voltage across the condenser, which is also that across the grid and filament, would be in phase with the E.M.F. we started with, E_g. Now if we have regard to the actual conditions in the anode circuit we see that, due to the inevitable inductance coil in it, the current is out of phase with the E.M.F. generated in the anode circuit by the valve. This out-of-phase current may be regarded as introducing a reactive component into the tuned circuit, and if we desire to retain the original frequency of E_g from which we started, we can correct the phase by mistuning the circuit. Actually what is happening is that the system oscillates at some frequency other than that to which the circuit is tuned. Now we can see that if any changes of filament current or anode voltage occur, of sufficient magnitude to alter the anode resistance, the phase of the current in the anode circuit will be altered and the circuit will oscillate on a different frequency. This phase effect is the major one of the several causes, referred to in the paper, which operate to change the frequency of oscillation. The remedy for the "phase" effect is to ensure that the grid and plate alternating voltages are always 180° apart in phase, and the conditions for this adjustment have been worked out in the paper. If, for example, in the above-mentioned case of an untuned anode, the anode circuit were resistive only, any alteration of anode resistance would not change the phase, and no alteration of frequency would result. Figs. 2, 4 and 5 are of interest because they are all circuits with two degrees of freedom, and we should expect, at first sight, to have two modes of oscillation. In the case of Figs. 2 and 4, however, the phase relation-

* A. G. Lee: "Tuning-fork Generator at Northolt," *Electrician*, 1925, vol. 94, p. 510.

ships are such that the circuits will not oscillate on one of the modes of oscillation. In Fig. 5, when the two circuits are identical, there is again only one mode of oscillation possible, that in which the current circulates round the inductances and capacities in the circuit. The current does not pass through the resistance, because the two ends of the resistance are at the same potential (with actual physical circuits possessing resistance there will be a small difference of potential across the ends of the shunting resistance and a small current will pass through it). The other type of possible oscillation, in which the main current passes through the shunting resistance, puts the grid and anode at the same potential, a condition in which the valve will not maintain oscillations. This is also a very interesting circuit to analyse physically. It may be regarded as a development of the Colpitts oscillator, Fig. A. In this circuit the

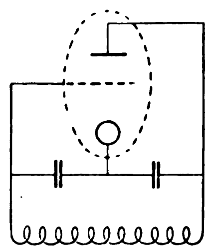

FIG. A.

grid-filament and anode-filament resistances may be represented as resistances shunted across the two condensers, as shown in Fig. B. It is fairly easily seen that these shunting resistances will affect the frequency of oscillation, and if they vary in magnitude with the voltage of supply the frequency generated will also vary. The author's solution is to join the points A, B, by a small resistance so as to bring these points to nearly the same potential, and the theoretical circuit corresponding to this case is shown in Fig. C. It will be seen

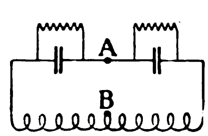

FIG. B.

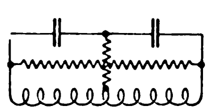

FIG. C.

that the valve resistances are now symmetrical with regard to both the capacities and inductances and the circuit will oscillate at its natural frequency, which will not be changed by any alterations in voltage. With regard to the frequency variations of the second and third types, I have been unable to deduce equations (21) and (23). So far as I understand the argument in regard to these variations, they are due to the fact that the actual frequency generated is a mean between that obtained during the portion of the cycle when the valve is passing current and the other portion when it is not passing current. Also any changes which affect the length of the fraction of a cycle during which current is passed will affect the value of the mean frequency. It would therefore appear that equations (21) and (23) should contain an expression for the valve conductances as affecting the phase and, therefore, frequency generated. A circuit which would appear to give most of the conditions for constant frequency is the "Dynatron" circuit. This circuit would appear to be free from the major variation due to phase shift. I think that the able analysis of the effects causing frequency shift made by the author will be of considerable assistance in the design of short-wave oscillators and heterodyne wave-meters.

Mr. G. Shearing: The experimental results for a low-power valve generator given in Part VI of the paper comparing the frequency-changes of the various types of circuits with capacity, inductive, and resistance coupling, are very interesting and they appear to favour on the whole the adoption of the resistance type of coupling with subsidiary compensating coupling for stray capacity for a constant-frequency generator. On the other hand, the remarks under the heading of "Practical Applications" leave one rather in the dark as to which type of circuit the author would really adopt for a constant-frequency generator. For the resistance type of coupling, e.g. that shown in Fig. 10, and stated to be applicable to transmitters, master oscillators and wave-meters, I do not think it is clear that the circuit would be a very

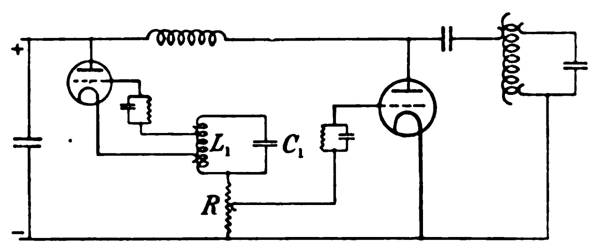

FIG. D.

efficient power generator of any magnitude, for, if the circuit C_2L_2 only carries a small proportion of the main oscillatory current, I should expect the power loss in the resistance R to become considerable for even a medium-power transmitter. On the other hand, if the circuit C_2L_2 carries a current of value equal to or greater than that in R, then the size and cost of the circuit C_2L_2 may become considerable for a small power loss. Also, how would the author couple such a circuit to the next stage of a power-amplifier system? Would he couple the grids of the next stage to the resistance R or to the inductance L_1 or capacity C_1? In this connection some of the disadvantages which appear to be attached to the use of the circuit of Fig. 10 for power amplifiers can be overcome by using the unidirectional pulses of valve current rather than the oscillatory current itself for exciting the next stage. The method of effecting this is to generate oscillations in a local oscillatory circuit L_1C_1 placed in series with a resistance R as shown, which carries only the unidirectional pulses of valve current which excite the oscillatory circuit L_1C_1 (see Fig. D). This resistance is not in the local oscillatory circuit, consequently for a suitable high-voltage supply the ohmic loss in this resistance is small. If, now, the grid or grids of the next stage of the power amplifier are connected to this resistance R, the arrangement will function satisfactorily as a power amplifier, the energy required for the grids of this stage being supplied from

this resistance, which in turn receives the energy direct from the high-tension supply. I have found such a power-amplifier arrangement to oscillate with excellent stability and a large step-up ratio; the power loss in the resistance is small by reason of the small proportion of the exciting current to the oscillatory current in L_1C_1. The constancy observed of the wave-length generated has been better than that observed for similar circuits when using inductive or capacity in place of the resistance coupling. As regards the development of a wave-meter circuit, a form of circuit has been described by E. Fromy * in which series inductances and capacities are placed in both grid and anode circuits of the generator valve; these are both coupled inductively to a separate circuit (see Fig. E). All three circuits are tuned to the same frequency and he states, giving experimental results, that, if $L_1C_1 = L_2C_2 = (L + L')C$ with coupling of L_1 and L_2 respectively to L and L' such that the grid and anode voltages are 180° out of phase, then the frequency $f = 1/[2\pi\sqrt{(L + L')C}]$ and is independent of normal changes of anode and filament voltages. The three capacities C_1, C_2 and C may be equal and he suggests for a wave-meter that they be mounted on a common axis for ease of adjustment. The constancy of the frequency is claimed to be due to the introduction of the condensers C_1, C_2, i.e. tuning the grid and anode circuits so that they are equivalent to resistances only.

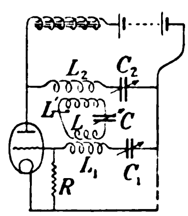

FIG. E.

Variations that may be due to changing the valve itself can be made small by using a capacity in parallel with the grid-anode capacity, and the accuracy is stated to be of the order of 0·001 per cent. The importance of grid and anode oscillatory potentials being at a phase angle of 180° is clearly indicated by the mechanical analogy and other portions of the paper. I do not understand what the author means by the term "E.M.F. generated in the valve," as surely any oscillatory E.M.F. is generated in the reactive portions of the circuits to which the valve is connected and not in the valve itself. The importance of small grid damping has been clearly pointed out in the paper, and as regards power transmitters it is more easy to arrange for small grid damping with power-amplifier circuits with grids operated definitely at a small mean potential than with retroactive circuits. For the circuit of Fig. 5 it is easy to see that the grid-filament and anode-filament oscillatory P.D.'s have the correct phase relation of 180°, but the circuit of Fig. 2 when used as a power transmitter constitutes an inefficient arrangement unless the product L_2C_2 is very much less than the product L_1C_1. The circuit as shown is applied to reception, but in this case the retroactive coupling of grid to anode, usually by means of auxiliary coils, is very small. I do not like the use of the term "complex resistance" in the Appendix, as it appears to me the author might equally well have spoken of "complex reactance." I consider the correct term "impedance" should be used. Also, I think it much better to use the terms resistance, inductance or capacity coupling than to introduce the terms employed by the author for the circuits he has described.

* *L'Onde Électrique*, 1925, 4ᵉ année, p. 433.

Dr. R. L. Smith-Rose: One of the most important problems in the practice of wireless communication to-day is that of the reduction of interference. Two of the contributory causes of interference are (1) that transmitting stations are not on the wave-length (or frequency) allocated to them, and (2) that their transmissions vary in frequency about the mean on which they usually operate. The author refers to this matter but does not give any actual figures, and I should therefore like to draw attention to some of the results obtained at the National Physical Laboratory on measurements obtained some time ago and extending over a period of about 2 months. The measurements were made by Mr. Dye, and a summary of the results was given in the N.P.L. Annual Report for 1924 (p. 79). Some 23 transmitting stations, situated on either side of the Atlantic, were measured, most of them being high-power long-wave stations. The results show a very high degree of uniformity, and in general the variations were less than the actual difference between the mean frequency and the frequency allocated to the station. For example, 10 of the 23 stations showed a mean daily variation of less than 1 part in 1 000, which is quite large compared with the ideal conditions visualized by the author. The actual limits of the mean daily variations were from 0·2 to 3·7 parts in 1 000, whereas the actual difference between the mean frequency and the nominal frequency ranged from 0·1 to as much as 11·4 parts in 1 000 for the 23 stations. Those measurements were only carried on for a period of 2 or 3 months, but they seem to give an idea of the order of the variation which is occurring at the present time. In connection with the rheodyne circuit mentioned in the paper, I do not quite understand what would happen if the two circuits are slightly detuned from one another. Supposing one is detuned a little, to the order of a few parts in 10 000. It would seem that the system would then have two possible oscillation frequencies, and some doubt might exist as to which of these it is operating upon at any given time.

Lieut.-Col. H. P. T. Lefroy: Dr. Smith-Rose has referred to the variation in transmission frequency that occurs on the longer wave-lengths; those that occur on the shorter wave-lengths are still greater, so that any improvements in transmitter design, such as those suggested by the author, which, in a simple manner, will eliminate such variations, will be particularly valuable for small portable sets. For signal discrimination we have at our disposal, in the case of radio-telegraphy, three well-known methods, namely, high-frequency selectivity, low-frequency selectivity and directional selectivity. In practice we can usually only employ high-frequency selectivity, and, in certain cases, directional selectivity, when receiving from portable transmitters. If we try to employ low-frequency

selectivity we find that the note selectors available are quite effective, but that the heterodyne note of the received signals varies so much that the note selector filters out a large proportion of the desired signals, so that we lose the advantage of this available third method of discrimination. Master oscillators have been developed which give satisfactory constancy of transmission frequency, but they increase too much the complication and size and weight of portable sets. Is the author satisfied that his methods can be immediately applied to transmitters up to about 2 kW without serious loss of efficiency, and that such methods can be usefully employed with transmitters that have to work over a wide band of wave-lengths? As regards wave-meters, is it possible, with those made to his design, to continue to use the original calibration scale without perceptible error, after the valve has been changed owing to the filament burning out?

Mr. A. G. Warren: The particular criticism that I have to make is with regard to the author's method of working out the circuit of Fig. 3. He says:—"The problem can be simplified by assuming that the energy absorbed in the grid circuit is negligible compared with the energy absorbed by the anode circuit, so that the flow of current in $L_3R_3C_3$ can be ignored in dealing with the circuit $L_1R_1C_1$." Looking at these circuits it appears that the circuit $L_3R_3C_3$ is a circuit of low impedance, whereas L_1 is of high impedance, and therefore one would expect that the current through the

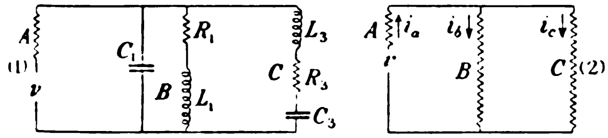

FIG. F.

shunt circuit $L_3R_3C_3$ would be considerable. It is, in fact, considerable unless the coupling between the two circuits is very small. I would suggest another way of dealing with the circuit. Assuming that R_1 is small compared with ωL_1, we may re-draw Fig. 3 as Fig. F [(1) and (2)]. For this circuit we have

$$v = i_a\left(A + \frac{BC}{B + C}\right) \quad \text{and} \quad i_a = i_c\left(1 + \frac{C}{B}\right)$$

whence

$$v = i_c\left\{A + C\left(1 + \frac{A}{B}\right)\right\}$$

Now since C contains the grid condenser (or its equivalent), i_c must be 90° out of phase with V. Therefore the expression $A + C\{1 + (A/B)\}$ must be wholly imaginary, or its real part must be zero. But

$$C = R_3 + j\,.\,2x\sqrt{\frac{L_3}{C_3}}$$

and

$$\frac{1}{B} = \frac{C_1}{L_1}\left\{R_1 + j\,.\,2x\sqrt{\frac{L_1}{C_1}}\right\}$$

Substituting these values, making $L_1C_1 = L_3C_3$, and equating the real part of $A + C\{1 + (A/B)\}$ to zero, we obtain

$$x = \pm\sqrt{\left[\frac{R_2C_2}{4AC_1} + \frac{R_1R_2C_2}{4L_1} + \frac{M^2C_2}{4L_1^2C_1}\right]}$$

Comparing this with the author's equation (7) we see that it includes an extra (third) term. I do not know how this third term compares with the others in practice, but, assuming an R valve with a grid circuit not exceeding a few ohms in resistance, it is greater than the first term unless M is less than 1 per cent of L_1. I imagine that M exceeds this value and that this third term is by no means negligible.

Mr. G. W. N. Cobbold: The author has directed attention to a subject of great and growing importance, upon which little has been published for several years. Attention must be called, however, to the work of Eccles and Vincent published in the *Proceedings of the Royal Society*, A, 1920, vol. 96, p. 455, where a description is given of practical experiments somewhat similar to those described in the present paper. There appear to be certain discrepancies between Eccles's results and those of the author, but I think these are probably due to the fact that Eccles placed the lower limit for his high tension at about 70 volts, whereas the author has limited his low tension to 4·2 volts. This, for the particular coupling he used, did not enable him to reach a stationary value on the frequency/low-tension-voltage curve. These differences are rather important, for the author has concluded that stationary values cannot be obtained when the filament voltage is varied, whereas Eccles has shown that, with suitable couplings and a normal type of circuit, such values can be arrived at. One of the earlier speakers appears to have suggested that the frequency-changes due to voltage variations are apt to be large compared with those due to a change of valve. I find, however, in practice, that with well-designed circuits the variations due to a change of valve are liable to be very much greater than those due to a 10 per cent change of either high-tension or low-tension voltage.

Prof. C. L. Fortescue: With regard to the resistance-coupled circuit, this merely consists of two "acceptors" in series with the resistance connected across the nodes of potential. As is well known, this circuit arrangement has a high resistance at frequencies other than that to which the "acceptors" are tuned. The arguments used in deriving equation (6) are incomplete, in that only the phase relations are considered. In actual fact there must be a magnitude adjustment, with the result that the amplification factor of the valve is necessarily involved and the anode resistance—the A of this paper—must be regarded as a variable.

Mr. C. F. Phillips: The author speaks of an accuracy of 1 part in 50 000, but I should like to know whether such an accuracy is really readable on any wave-meter, what kind of variable condenser is used, and how it is read to the requisite accuracy to give 1 part in 10 000, let alone 50 000, and further, to what extent such condenser maintains its accuracy.

Major B. Binyon: Without detracting from the value of the paper, it should be pointed out that there are other factors quite apart from filament and supply variations which might cause greater frequency variations than 1 part in 50 000. In view of the increasing use of short wave-lengths the whole question of maintaining a constant frequency is a matter of very great importance.

Mr. L. B. Turner (*communicated*): The subject under discussion is the reduction to a minimum of those very small changes in the frequency of a triode oscillator which are apt to be caused by small changes in the supply voltages. In view of the use of the heterodyne at very short wave-lengths the subject has considerable practical importance. Now the possible circuit arrangements of a triode oscillator are many. Mathematical investigation of the exact frequency can be undertaken only for sensibly sinusoidal conditions, and therefore with amplitudes small enough to allow the anode-filament resistance A of the triode to be treated as constant throughout the cycle; and even then, except in the simplest circuit arrangements comprising only a single approximately resonating circuit, the algebra is hopelessly cumbersome. The effect of change of filament or anode voltage is to alter A, generally at the same time making A rather less perfectly constant during the cycle. In order to investigate the effect on the frequency f, we need an expression for f in terms of A and of the circuit dimensions. A number of such expressions are derived in the paper, but the electrical theory behind the formulæ seems to me altogether inaccurate, and the formulæ obtained are certainly sometimes erroneous. I propose to indicate some of the mistakes as I seem to see them. With reference to Fig. 2, the author states (in the advance copies of the paper*): "The circuit $L_1R_1C_1$ being a rejector circuit, its complex resistance is . . ." Such a statement is meaningless unless the place of application of the E.M.F. is specified. As here used, $L_1R_1C_1$ is a rejector circuit as regards the "E.M.F. generated in the valve," but it is at the same time an acceptor circuit as regards the E.M.F. impressed in L_1 from L_2. The author seems here, as elsewhere in the paper, to disregard reaction of the L_2 current on L_1, appearing to think this justified "by assuming that the energy absorbed in the grid circuit is negligible compared with the energy absorbed by the anode circuit." This vitiates any search for small departures of frequency from the simple $4\pi^2f^2 = 1/LC$, which is the purpose of the investigation. A formula, (8), for the frequency is thus derived, for the particular case of $L_1C_1 = L_3C_3 = L_2C_2(1 - M^2/L_1L_2)$. Even if this formula were correct, how could one in practice adjust for $L_1C_1 = L_2C_2(1 - M^2/L_1L_2)$; why is this particular adjustment of special interest; and if it is, why, in the analogous case of Fig. 4, is the different special case of $L_1C_1 = L_2C_2$ taken? I am unable to quote manageable correct expressions for the frequency in the cases of Figs. 2 and 4 [equations (8) and (15)], and I regard these as circuits which should be avoided, i.e. when $L_1C_1 \doteq L_2C_2$. They are too difficult in mathematical analysis and in practice, for the reason that a slight change in f or L or C may turn a large positive reactance into a large negative reactance. I cannot accept the author's gross approximation (page 351, top of col. 2) that the reactance of C_3 is negligible in comparison with the impedance of $L_2R_2C_2$. C. Gutton, in his clear and accurate discussion of triode oscillators in "La Lampe à Trois Electrodes" writes of the arrangement of Fig. 4: "Its characteristic equation is of too high a degree to be easily discussed"—a sentiment which experience has taught me heartily to endorse. With reference to Fig. 5, which is one arrangement for obtaining resistance retroaction, the statement is made that "the frequency is independent of the magnitude of the various resistances," including presumably the anode resistance A, the only one whose effect interests us; but in Fig. 17 large observed alterations of frequency with alterations of filament and anode voltages are shown. I cannot follow the author's reasoning in Part III. This professes to investigate non-sinusoidal conditions, but formulæ (21) and (23) are given—whence they are obtained is not stated—which cannot relate to such conditions, since they do not contain any term expressing the properties of the triode. Probably they refer back to sinusoidal conditions; but if so, again they are erroneous. The correct expressions are:—

For (21), $$f_1 = \frac{1}{2\pi}\sqrt{\frac{1}{C_2[L_2 + (R_2/A)L_1]}}$$

and for (23), $$f_1 = \frac{1}{2\pi}\sqrt{\frac{1 + (R_1/A)}{C_1L_1}}$$

For the former, see Gutton, loc. cit., page 92. For the latter, see Gutton, page 59; or Van Der Bijl, "Thermionic Vacuum Tube," page 274; or Turner, "Outline of Wireless," page 127. The experimental observations are interesting, but they are not used to check the theoretical formulæ. It is not clear from what frequency the plotted "frequency change" is measured. For example, in Fig. 18, where perfect insensibility to filament change was obtained, why is the ordinate steady at 2 instead of at 0? It suggests that the "change" plotted is the difference between the oscillation frequency and the natural or resonant frequency of the oscillatory circuit when the triode is made inactive, as by extinction of filament. If so, perhaps the author would explain how he was able to determine the latter with anything like sufficient accuracy, i.e. to a fraction of 1 part in 10 000, or 0·01 per cent.

Lieut.-Col. K. E. Edgeworth (*in reply*): Several speakers have questioned the validity of various approximations made in deriving the formulæ given in the paper, and it appears desirable that my attitude with regard to this question should be defined. I may therefore explain that the whole treatment in the paper is intended to be qualitative rather than quantitative. The formulæ are intended to show the character of the frequency variations which are liable to occur, and it is not suggested that they are suitable for making exact calculations in particular cases. Apart from other difficulties the value of the quantity A, representing the anode resistance, is not known and cannot be measured, although a rough estimate might possibly be attempted. It may be defined as the reciprocal of the mean conductance of the anode circuit of the valve taken over a complete cycle of oscillation, and such a definition serves to convey some of the difficulties which would be encountered in trying to estimate its magnitude.

There remains the question: To what extent can the results produced by these various approximations be accepted at all? The only reasonable way to answer this question would appear to be by an appeal to experi-

* Since revised for the *Journal*.

ment. If the results indicated by the theory are reproduced in practice, then the theory may be accepted as a working hypothesis until something better is offered. Further, a theory based upon an assumption which is known to be true in a special case may be verified by experiment, and may then be extended, by reason of experimental support, to the more general cases in which the original assumption can only be regarded as a rough approximation. The theories which I have put forward in the paper appear to provide reasonable explanations for the results of my experiments. Time will show whether they can be usefully employed in a wider field.

Major Lee draws attention to the fact that formulæ (21) and (23) do not contain any term involving the valve conductance. The explanation is that the equations refer to the resonant frequency of the tuned circuits employed in deriving equations (6) to (8), and they do not refer to the actual frequency of the oscillations generated. It is agreed, however, that the argument is not very satisfactory, and it might be amended to read as follows :—

Variations of the second type.—In the case of an orthodyne generator with tuned grid and untuned anode the equations given in Part II are modified by writing $\tan \phi = A/(L_1\omega)$ and equation (8) becomes

$$\omega = \frac{1}{\sqrt{(L_2\sigma C_2)}}\left\{1 - \frac{R_2L_1}{2AL_2\sigma}\right\}$$

$$\therefore f_1 = \frac{1}{2\pi\sqrt{(L_2\sigma C_2)}}\left\{1 - \frac{R_2L_1}{2AL_2\sigma}\right\} \quad . \quad . \quad (21a)$$

This equation gives the frequency of the oscillations when the valve is active. The corresponding equation for an antidyne generator with untuned anode is given by writing $\tan \phi = -AC_1\omega$, and then

$$f_1 = \frac{1}{2\pi\sqrt{(L_2\sigma C_2)}}\left\{1 + \frac{R_2C_2}{2AC_1}\right\} \quad . \quad . \quad (21b)$$

In either case, when the valve is inert the frequency is

$$f_2 = \frac{1}{2\pi\sqrt{(L_2C_2)}} \quad . \quad . \quad . \quad . \quad . \quad (22)$$

The factor $1/\sqrt{\sigma}$ in equation (21) is always greater than unity, and its influence on the actual frequency of the oscillations depends upon the proportion between the period of activity and the period of inertness. The argument then proceeds as before.

In the case of the frequency variations of the third type the explanation of the meaning of equation (23) is the same, but some of the approximations used in deriving the equation appear to be erroneous. This question is dealt with more fully below in my reply to Mr. Turner.

Mr. Shearing inquires as to the best type of circuit for constant-frequency generators. I have slightly altered the original wording of the paper to make this point clear. On the question of efficiency the paper contains the rather bald statement that the loss of energy in the resistance is equal to the loss of energy in the grid circuit. The actual analysis on which this statement is based was omitted, as it is rather lengthy and did not appear to be of sufficient importance to be given in detail. It can, however, be made available if required. I have no figures available as to the amount of power absorbed by the grid circuit in actual generators, but I do not think it usually exceeds 10 per cent of the power developed in the anode circuit. The anode circuit of the rheodyne generator could no doubt be coupled to the grid circuit of another valve by any of the well-known methods usually employed for this purpose. Questions of frequency variation due to change in the reactance of the load are beyond the scope of this paper.

The author has not experimented with the Fromy circuit, but is inclined to think that the three separate tuning adjustments would be troublesome in practice.

The assumption that the valve can be regarded as a source of energy has, I think, been used by other writers. The actual source of energy is, of course, the high-tension battery, and the valve is a variable resistance. The method attributes to the valve exactly the same properties as those assumed in the investigations quoted by Mr. Turner.

I cannot agree that the word "impedance" is the correct name for the expression $(R + jL\omega)$, and I would direct attention to an article by Prof. Howe in the January number of *Experimental Wireless*, in which the correct meaning of the word "impedance" is explained. In regard to the new words suggested in the paper, it seems better to coin new words when required, instead of using existing words in several different and inconsistent meanings.

The observations on the wave-lengths of existing transmitting stations given by Dr. Smith-Rose are very interesting and show that there is considerable room for improvement. My experiments indicate that rheodyne circuits can be made to oscillate at two frequencies in much the same way as other circuits, and the result is no doubt due to slight mistuning.

In reply to Col. Lefroy, I am of opinion that the rheodyne generator described in the paper and also the orthodyne generator with untuned grid are both capable of being designed to cover a wide band of frequencies, and I have worked out such details as appear to be likely to influence the design. Most of the important points are referred to in the paper.

When a valve is changed there may be a change of anode resistance and/or a change of capacity. The constant-frequency circuits referred to in the paper are essentially circuits in which the frequency is independent of the anode resistance, and it is evidently immaterial whether the change of anode resistance is due to change of valve or change of supply voltage. Changes of frequency due to changes of valve capacity are of course a different matter, and a discussion of the problem would be beyond the scope of the present paper.

Mr. Warren's difficulty is due to his assumption that the circuit $L_3R_3C_3$ is a circuit of low impedance. When grid and anode circuits are both tuned a very loose coupling is sufficient to generate oscillations, so that the circuit is actually one of high impedance. When grid bias is used the energy absorbed by the grid circuit may be very small indeed, and cases have been brought to my notice in which the grid current is only a few

micro-amperes. It will be seen from the experimental results that changes in grid damping affect the magnitude of the frequency variations but not their general character, and one is therefore able to say that results based on the assumption that the grid current is small are applicable to cases in which the grid current is appreciable. The attempt to improve on my formula by the addition of an extra term might perhaps be referred to Mr. Turner, whose remarks on the complexity of the problem are very much to the point. In any case the extra term would not affect the general argument.

Mr. Cobbold draws attention to the investigations of Eccles and Vincent. The generator employed was an orthodyne generator with untuned grid, and it was found in certain cases that the curve giving the relationship between filament voltage and frequency rises to a maximum and then falls again. It would appear from Fig. 7 of the paper that the phenomenon only occurs when the coupling is very weak. The curves obtained for stronger couplings resemble those given in the paper. In practice there must always exist some factor which limits the amplitude of the oscillations, and the controlling factor is not necessarily the same with strong and weak couplings. There is a very interesting field for investigation in this direction which I have not attempted to explore.

From my remarks at the beginning of this reply, it will be seen that I am in agreement with Prof. Fortescue as to the complexity of the problem and as to the reservations which must be made in regard to the various arguments brought forward in the paper.

In reply to Mr. Phillips the simplest method of increasing the accuracy of the readings is to reduce the band of frequencies covered, by employing a small variable condenser in parallel with a large fixed condenser. If the scale can be divided effectively into 500 parts, it is immaterial whether it is employed to read from 300 to 800 m with an accuracy of the order of 1 in 500, or whether it is used to read from 495 to 505 m with an accuracy of 1 in 25 000.

I quite agree with Major Binyon that there are other problems which require solution in connection with the constant-frequency generator. Perhaps someone will tackle some of them at a future date.

I fully agree with Mr. Turner's views as to the complexity of the general problem, but I am not prepared to agree with his attitude towards approximations. It is not possible to determine the validity of an approximation by an argument in general terms. An approximation involving errors of 5 per cent is better than an approximation involving errors of 10 per cent, and an approximation involving errors of 10 per cent or even 20 per cent is better than nothing at all. In tackling an apparently simple problem like the design of a connecting rod, it may be necessary to make more than one assumption involving errors in excess of 20 per cent. To label an assumption a "mistake" or a "gross approximation" does not settle the limits within which it is capable of being usefully applied. Mr. Turner's attitude towards particular approximations is not consistent. He objects to the assumption that the energy expended in the grid circuit is small, and then puts forward a solution which ignores the grid circuit altogether!

The formula suggested in place of equation (21) of the paper omits the factor $1/\sqrt{\sigma}$ which results from the coupling, and is limited to generators using normal coupling. With these two corrections the formula is equivalent to the one which I have given in my reply to Major Lee. For our present purpose the corrections happen to be vital.

The formula suggested in place of equation (23) is limited to the ideal case in which there is no grid current, but the two formulæ should agree, and I have been led to revise the method of obtaining $\tan\phi$, the expression for which now contains an additional term. I agree that equation (23) is fallacious.

The new equation for $\tan\phi$ gives the solution quoted by Mr. Turner as a special case, and leads to a very interesting solution for the constant-frequency orthodyne generator with untuned grid, which appears to be of sufficient importance to be set forth in detail.

In the case of an orthodyne generator with untuned grid, $\tan\theta = -R_3C_3\omega = -R_2C_2\omega = -R_2C_2/\sqrt{(L_1C_1)}$, which gives

$$y = \frac{1}{2A}\left\{R_1 - \frac{R_2C_2}{C_1}\right\} - \frac{R_1R_2C_2}{2L_1}$$

$$\therefore f = \frac{1}{2\pi\sqrt{(L_1C_1)}}\left\{1 + \frac{1}{2A}\left(R_1 - \frac{R_2C_2}{C_1}\right) - \frac{R_1R_2C_2}{2L_1}\right\}$$

The frequency will be independent of the anode resistance when $R_2C_2 = R_1C_1$ or more fully when $R_4C_2 + L_2\sigma/G = R_1C_1$, which is the constant-frequency generator under sinusoidal conditions. It is difficult to say whether the solution is of much practical importance, but it is suggestive and might be made the basis for further research. It will be observed that there will usually be a difference between the frequency of the oscillations when the valve is active and the frequency when the valve is inert. When the two terms involving the anode resistance cancel out, the difference will be in the sense already discussed in the paper.

In reply to Mr. Turner's last question, the curves given in the paper represent frequency-changes only, and the zero has no significance. It may be added that the various curves which are plotted for convenience on the same diagram are not necessarily referred to the same zero.

ILLUMINATION AND LIGHT.

By A. P. TROTTER, Member.

(SECOND FARADAY LECTURE, *delivered before the* MERSEY AND NORTH WALES (LIVERPOOL) CENTRE 18*th January, before the* NORTH-WESTERN CENTRE 19*th January, before the* IRISH CENTRE (DUBLIN) 21*st January, and before the* WESTERN CENTRE 26*th January,* 1926.)

Part 1.*

ILLUMINATION.

The object of the Lecture is to give in plain language some account of a branch of electrical engineering, of early investigations, and a sketch of scientific theories. The slow development of Faraday's work from 1821, his first primitive dynamo 10 years later, the first practicable incandescent lamp made by Swan in 1878, and the stagnation caused by the Electric Lighting Act of 1882, is contrasted with the progress made after 1888, when public electric supply became possible. The deliberate advance of elementary physical science in Faraday's time is also contrasted with the activity and complexity of modern research.

The unit on which all practical measurements of light are based is candle-power. Parliament, in its wisdom, decreed by the Metropolitan Gas Act of 1860 that the light emitted by a spermaceti candle with a special wick, six to the pound (neither length nor diameter being mentioned) and burning 120 grains of sperm per hour, should be set up as the official standard, but only for the purpose of testing London gas. The so-called Parliamentary candle has been superseded, but the unit remains. The science of measuring light dates from 1750, and is called photometry. Visual photometry consists in illuminating a white screen by the lamp to be measured, illuminating another screen by the standard lamp, and adjusting matters until the brightness of the two screens appears to be identical. The adjustment generally consists in moving one of the lamps.

When Lambert in his "Photometria," in 1770, wrote "the eye is the only judge," he regretted that the eye lacks an instrument like a thermometer so that when left to itself it might give judgment. Several attempts have been made to produce such an instrument, but there is a risk in all electrical, thermal, photographic and other chemical methods of measuring something that is not light. The recently discovered photo-electric cell is a valuable instrument of this kind.

Light is required merely to produce illumination. This consists of two factors, candle-power and distance. The practical unit by which illumination is measured is the illumination from a source of 1 candle-power received at a distance of 1 foot by a surface facing the light, and is called 1 foot-candle. Many types of instruments are in use by which illumination may be easily measured.

The subject of "glare" has received much attention from illuminating engineers. It is not a question of intensity of light, but of contrast. The head-lamps of a motor car may give a blinding glare in a country road on a dark night, but the same lamps are hardly noticeable in bright sunshine, where the eye is receiving several thousand times more light. The amount of illumination desirable for different classes of streets has been studied and is merely a matter of opinion. The results can be measured and recorded, the heights of lamps, their spacing and candle-power, and the types of lanterns can be settled and specified. Gas lighting can easily compete with this work; it is merely a question of cost. The minimum for good street-lighting is from $\frac{1}{20}$ to $\frac{1}{10}$ foot-candle on a horizontal surface midway between two lamps. In the old days, street lamps were little else than beacons to show the direction of the streets. Illuminating engineers have long lists giving the illumination which experience has shown to be necessary for various purposes. For example, at least $\frac{1}{2}$ to 1 foot-candle is needed for railway platforms and warehouses. For domestic purposes, from about 1 foot-candle in bedrooms, to 4 or 6 foot-candles for reading and working is necessary. A dining-room table is comfortably lighted at 3 or 4 foot-candles, but 12 to 15 is needed for a billiard table. The Factory Department of the Home Office has recommended certain minimum illuminations for various kinds of work; in general, 3 foot-candles for ordinary purposes, 5 for finer work, and up to 20 in special cases. Factory managers are becoming aware that accidents can be reduced, and output of production and the quality of work increased, by better lighting.

Artificial light is more yellow than daylight; in other words, it is deficient in blue and green. By suitably tinted glass the superfluous red and yellow rays may be cut off, and an imitation daylight may be produced, by which colours can be matched. Picture galleries are now lighted in this way, and "daylight" lamps are used for colour-matching, not only for textile goods, but for flour grading and other industrial purposes.

The natural daylight illumination of the interior of buildings can be measured by using a small portion of the overhead sky as a standard of comparison. At the National Physical Laboratory, experimental sheds have been erected for studying on this principle the daylight illumination of factories, offices and picture galleries.

* Part 1 of the Lecture is in abstract.

Part 2.

LIGHT.

Having got our light; what is light? This, as Dr. Hawtrey of Eton suggested to Sir John Herschell, is perhaps the oldest of all words, the first word ever

recorded to have been pronounced in the great poem of the first chapter of Genesis.

Experiments and elaborate calculations in optics were carried on through the first half of the nineteenth century, with no relation to any other branch of physics, until 1846; when it dawned on Faraday that there was an irresistible suggestion of a similarity between the lateral or side-to-side disturbances of magnetic lines of force and the vibrations of light. His view, he wrote, in a letter to his friend Phillips, "endeavours to dismiss the ether, but not the vibrations." Nothing could ever have induced Faraday to give up those lines of force which no one has ever seen, but which are the fundamental assumption of electrical science and electrical engineering.

Lay a sheet of paper over a magnet, dust some iron filings over it, tap the paper gently, and we see the filings arrange themselves along beautiful curved lines. Whether the lines are still there when we remove the iron filings, whether they really exist, or whether they are conveniences of thought, like lines of latitude and longitude, is a matter for philosophical cogitation. Faraday treated them as pure concepts. They were mere directions along which something called force acts. These lines had been known for 200 years, but it remained for Faraday to show their significance. Faraday's lines of force are in practical daily use by every theoretical electrician, and by every designer of electrical machinery.

Continental mathematicians thought in terms of imaginary magnetic and electric fluids and "action at a distance," and were slow to accept Faraday's achievement which revolutionized electrical science. But how Faraday, by abstraction, could retain his lines of force while he dismissed the ether, is difficult to understand, unless he had a vision of our present position in physical science. That he had an inkling is clear from what he wrote about infinitesimally small nuclei and almost infinitely intense elasticity. "But if," he wrote, "such be the received notion, what then is left in the ether but force and centres of force?" The rest of this letter is delightful to read in the light of the electron theory of to-day.

In 1864 Clerk Maxwell pointed out that the only electrical disturbances or vibrations that can be propagated through non-conducting space, are transverse to, or across the direction of propagation. The velocity found from experiment is so nearly that of light, that it seems we have strong reason to conclude that light itself is some kind of electromagnetic disturbance in the form of waves. "Surely," said Lord Kelvin, "we have a large and solid ground for our faith in the speculative hypothesis of an elastic luminiferous ether which constitutes the wave theory of light."

We know that sound is not a material thing. It is one of the ways in which air behaves. Light too is not a substantial thing, but according to that hypothesis consists of rapid tremors of something that has been provisionally called ether, and electricity seems not to be a thing, but the way in which something behaves.

It is generally stated that Newton held only one view about the nature of light, namely, that it consists of small particles or corpuscles, and hence the name "the corpuscular theory"; and that he did not favour the wave theory. This statement is copied from one text-book into another. But, on the contrary, his writings show that Newton gave considerable attention to the wave theory. That theory was suggested in an elementary form by Hooke in 1664. Newton, in a communication to the Royal Society in 1671, on the production of the spectrum by a prism, considers "if the rays of light should possibly be globular bodies," but he dismissed the idea and wrote, "To determine more absolutely what light is, . . . is not so easy. I shall not mingle conjectures with certainties."

Huyghens communicated his wave theory to the French Academy of Science seven years later. He dealt only with the reflection and refraction of wave-fronts, and wrote nothing on prismatic colours, wave-lengths or transverse vibrations. Newton began his Treatise on Optics in 1718 with these words: "My Design in this Book is not to explain the Properties of Light by Hypotheses, but to propose and prove them by Reason and Experiments"; and this was not the only occasion on which he declared that he was not going to make hypotheses, but failed to keep his promise. In the first edition of this treatise he dealt at considerable length with the wave theory, and there is not a word about the corpuscular theory. "Do not several sorts of rays make vibrations of several bignesses . . . do not the most refrangible rays excite the shortest vibrations for making the sensation of deep violet, the least refrangible the largest, making a sensation of deep red?" He suggested that the medium is the same as that which conveys heat, that it is exceedingly more rare and subtle than air, and exceedingly more elastic and active and pervades all bodies, and he adopted for it the name "ether" already used by Descartes, the word used by Homer for the upper pure air of the heavens as distinguished from the air in which we live, and by Aristotle for the medium in which the heavenly bodies swim.

If we look at little waves on a pond, into which a stone has been thrown, we shall see two kinds of movement. One is the steady travelling of the waves in expanding circles, the other is the no less uniform up-and-down motion of leaves or weeds that may be floating on the surface—the water does not travel with the advance of the waves, but moves up and down. The horizontal travel of the waves may be compared with the travel of light, and the up-and-down motion with the magnetic vibrations of the ether. But this is only an analogy. It must be remembered that the disturbances or alternations of condition are magnetic, and probably not mechanical at all. It is safe to say that there actually are repeated disturbances, but some authorities deny that there is an ether, and bid us think of centres of force quivering in empty space.

Towards the end of the second edition of his "Optics," Newton found a difficulty in explaining by the wave theory the colours of a soap bubble "with which children play," and apparently with reluctance he asks: "Are not the rays of light very small bodies emitted from shining substances? . . . bodies of different sizes, the least of which may make violet . . . the rest, as they are bigger and bigger may make . . . blue, green, yellow and red. . . . Nothing is more requisite for putting the Rays of Light into Fits of easy Reflection

and easy Transmission than that they be small bodies which by their attractive Powers, or some other Force, stir up Vibrations in what they act upon, which Vibrations being swifter than the Rays, overtake them successively, and agitate them so as by turns to increase and decrease their Velocities, and thereby put them into those Fits." * These words are not easy to understand, and they are almost the last words on light in this treatise. Newton seemed to be tiring of the subject, and wandered off into chemistry, and left the matter in a very unfinished state.† And now, 200 years later, the theory is still incomplete.

The electromagnetic waves of Faraday and Maxwell may be perceived by our senses directly, or by means of instruments, but only a small portion of them affect the eye. To these alone we give the name light. "Light," wrote Kelvin, "is light if you see it; it is not light if you do not see it."

When light passes through a prism, it is apparently split up or sifted into the colours of the rainbow. The expression split up is perhaps better than sifted, for many modern authorities hold that the colours are not present or have no independent existence before the ray of light enters the prism. The visible part of the spectrum occupies only about one octave; that is to say, there are about twice as many vibrations per second in violet light as there are in red light. The length of the waves for different colours may be measured with great precision, and are known and definite. The wave-length at the red end is about 30 millionths of an inch,‡ and at the violet end, about 15½ millionths. The velocity of light, 186 300 miles per second, is known, and therefore the number of vibrations; for example, 500 million millions per second in the yellow, though they cannot be counted, may be calculated. Beyond the red end of the spectrum are about 6 octaves of invisible heat rays, but waves longer than about 50 millionths of an inch are stopped by glass; it is opaque to them. Until quite recently there was a gap here of about 10 octaves, but this has now been filled, partly by detection of heat rays, and partly by electrical methods. This brings us to wave-lengths of a few inches. These were detected electrically by Hertz in 1888, and are used for radio-telegraphy and radio-telephony. These waves are of such convenient dimensions, so easily produced and detected, that it is in this region we may look for the discovery of the true nature of a light wave. It will probably turn out to be an electrician's investigation. Eight octaves more and we come to waves used for ordinary broadcasting. Those sent from the Eiffel Tower are about 1 mile 5 furlongs in length, about 20 octaves from the visible spectrum.

Exploring in the other direction, beyond the violet end of the spectrum, there is about an octave of rays called ultra-violet rays. The shortest waves of sunlight are about 11½ millionths of an inch. In moderation they are beneficial, they tan the skin, and have certain healing properties, and powerful photographic action. Beyond these are other ultra-violet rays such as those emitted from a mercury-vapour lamp; they may be dangerous. Far beyond these again are about 14 octaves, the X-rays discovered by Röntgen, a few hundredths of a millionth of an inch in length. In all, about 50 or 60 octaves.

The total radiation from an ordinary candle flame consists of about 999 parts of radiant heat to one part of light. From an electric glow lamp the radiation is about 3½ per cent, or, as Prof. Houston puts it, in £3 worth of energy there is £2 18s. of dark heat, and 2s. worth of light. A gas-filled (or so-called "half watt") electric lamp gives 7 per cent, and an open arc gives about 10 per cent.

The secret of producing light without heat is known only to the glow-worm and the firefly. They have been severely examined about this, but as yet they have declined to give any explanation of their behaviour.

So far as is known, I repeat, all these vibrations and disturbances are of the same nature. From the X-rays comparable in size with atoms, to the longest waves used in wireless telegraphy, they consist of simultaneous magnetic tremors or vibrations at right angles to each other, and advancing in a direction at right angles to both. The apparent difference between them lies in the means at our disposal for detecting them. From the X-rays, down to the red end of the spectrum and a little further, photography is used, overlapping that part which affects the eye. Below this, measurements of radiant heat are made, and lastly the vibrations are so slow that they can be detected electrically. Those are used for broadcasting, and vibrate between ½ million and 1 million times per second.

The Ether.

Vibrations; but of what? Ether, the name of a medium which has been held to be that which transmits light, is not an observed fact. It still remains, as Lord Kelvin said, a speçulative hypothesis, and it does so because it remains a conception. Vibrations have been observed, and all that was asked of the ether was that it should vibrate. It was assumed that it has inertia or mass, and is elastic. But it has never been observed, because it has absolutely unbroken continuity.

The old thinkers had a dogma—"Nature abhors a vacuum." This had troubled Descartes in the seventeenth century. He thought that two bodies must be either touching each other, or separated. If they were obviously separated, and all known substances between them were removed, and they still remained separated, there must be something left. For this unknown he

* About twelve pages of the second edition are devoted to "Fits of easy Reflection and Fits of easy Transmission"; eight pages to the undulatory theory and ether, and only about two pages to the corpuscular theory.

† The reason why Newton is generally supposed to have advocated the corpuscular, and rejected the undulatory theory of light is, that a controversy arose in which his followers supported the corpuscular theory, and the dispute became so acute that Newton, in a letter of 1675, wrote: "I was so persecuted with discussions arising out of my theory of light, that I blamed my own imprudence for parting with so substantial a blessing as my quiet, to run after a shadow." A year later · "For I see a man must either resolve to put out nothing new, or to become a slave to defend it." May we not read between the lines that he was not satisfied with his corpuscles?

So late as 1827, Sir John Herschell, in his article on Light in the "Encyclopædia Metropolitana," devotes ten pages to the corpuscular theory, with which he appeared fairly satisfied, and seven to the undulatory theory, of which "we may almost be induced to say, if it be not true, it deserves to be so."

‡ The expert will criticize the vulgarity of these fractions. There is still a great deal of confusion in expressing wave-lengths in decimals on the metric system. To-day, the tendency is to express them in Ångström Units (Å.U.). One Å.U. is the length of 1 ten-millionth of a millimetre. The wave-length of one of the well-marked lines in the yellow part of the spectrum is 5 895 Å.U. Another unit is the milli-micron or micro-millimetre ($\mu\mu$). It is 1 hundred-thousandth of a millimetre, and equal to 10 Å.U. A micron (μ) used in other branches of science is 1 thousandth of a millimetre, or 10 000 Å.U. One-thousandth of an inch is 254 000 Å.U.

adopted the name "ether." It had not much to do. But others were invented by philosophers, and space at last became filled with ethers several times over. Newton's form of the undulatory theory led him to two simultaneous ethers, and he rejected the idea as inconceivable. "To fill all space with a medium," wrote Maxwell, "whenever a new phenomenon is to be explained, is by no means philosophical." This was his apology for inventing one ether which would account for electromagnetism as well as for light. But a great deal was expected of this ether when it came to be examined, and many attempts have been made to imagine a structure which would account for the properties that it ought to have. The great mistake seems to have been in treating ether as matter or a kind of matter. In 1845, Prof. Stokes taught that it was a kind of jelly, and made brave attempts to reconcile some of the apparent contradictions involved. Then Kelvin and Helmholtz showed how it might consist of spinning vortex-rings like smoke-rings, having a rigidity like that of a top; and in 1889 Sir Oliver Lodge seemed to suggest that the universe was full of cog wheels. These ethers and a score of others are buried for the present in obsolete books. It is possible that more may be heard of them.

The ether has always been an imaginary medium. It has defied all experimental attempts to observe it, unless some recent experiments in America are to be accepted in this connection. We have knowledge of it neither by description nor by acquaintance. Light takes about 8 minutes to pass from the sun to us. What is it doing on its journey? The difficulty is to understand how light and electromagnetism are to be accounted for if the ether is abolished. It is admitted by our leading mathematicians that Maxwell's six equations expressing the electromagnetic theory are identical with the latest mathematical theory; but to put it into plain language has baffled every one of them. That is not the business of mathematicians. They are content with their equations, and some of them do not care whether there is an ether or not.

It is easy to say that light consists of tremors at right angles to the direction of travel. We have plenty of names for them—waves, vibrations, tremors, quivers, undulations and so on—but we want to know more about them. These names suggest a motion of the medium, but, as I have said, the alterations are probably only magnetic, and we know of them only in one dimension at present—the wave-length.

Although Einstein says that he has no objection to the ether, his system being independent of it, some of his followers say that the hypothesis of an ether is useless, unwarranted, and unnecessary. But most of those of us who have listened to Sir Oliver Lodge's broadcast lectures on "Ether and Reality," or have read his recent books on the subject, probably feel that the ether is not to be dismissed by a summary negation. He says that it is the only reality in the universe, and distinctly holds that it is not matter.

The Quantum Theory.

It is agreed that all matter is composed of minute atoms, and these again are formed of vastly smaller particles called electrons, swiftly revolving like planets round a central nucleus. To pass from the idea of a charged nucleus to a centre of force without a nucleus presents no difficulty to the mathematical mind; but to the constructive mind it is like the grin without the Cheshire cat. Electrons vary in number in different kinds of atoms, and each electron has a stable orbit in which it revolves. But there is a choice of orbits. An electron can change its orbit under suitable compulsion, but the remarkable and unexplained thing is that it does not do so, as one might expect, by taking a smooth spiral path. The rule that Newton adopted for Nature, that she must never act in leaps, has been broken, and an electron if driven from its orbit may fly outwards, or it may drop inwards towards the nucleus. When jostled out of its orbit, say by heat, raising matter to incandescence, an electron drops suddenly into a smaller orbit of higher velocity (that it should do so instantaneously is unthinkable) and, in doing so, liberates a definite and limited amount of radiant action. This is called a quantum. There is a mysterious limitation in the amount of energy so set free. The magnitude of a quantum, measured as the product of energy and time, has been estimated, and numerical results converging from different branches of physics agree; and its magnitude is what we know most about it. Calculations show that about 10 per cent of hitherto unexplained features in the structure of the spectrum and of interference and diffraction of light are thus accounted for, besides many other physical facts: but the remaining 90 per cent cannot be so explained, and appear to be fully accounted for by the ordinary wave theory of light. It must not be deduced that the voting is 10 to 1 against the quantum theory. Not at all. This discordance must be puzzled out and settled.

It has been suggested that a quantum becomes, for all intents and purposes, a materialized body; the crude expression "granules of energy" has been used, and on this has been founded the sensational statement that we must return to the corpuscular theory. It may be that there is no discontinuity in the flow of radiation, but that it must accumulate to a certain quantity before matter can react to it. Matter may have to be re-defined. The fact is, that our ideas both of energy and matter are in the melting pot, and we must wait until they have been tried by the fire of mathematical analysis in the crucible of philosophy. Meanwhile we may take it that there is nothing seriously wrong with the wave theory of light, as far as it has been developed, but a complete theory has not yet been formulated by our physicists and mathematicians.

A constructive theory of the physical nature of a wave of light has been long overdue. Sir Joseph Thomson has recently made a proposal about the structure of light. He suggests that when an electron jumps from one orbit to another, the lines of force joining the electron and the nucleus snap and become a ring of force, which carries nearly all the energy. The formation of the ring of force sets it into vibration and gives rise to electromagnetic waves. Such rings of force travelling at the speed of light, according to this hypothesis, are quanta. This interesting suggestion was stated in plain language without reference to the ether, to relativity,

or to obscure metaphysics, but it unfortunately presents no mental picture whatever of the structure of an undulation of radiant energy, or what is going on in a wave front. The theory is surely coming; it may appear any day.

In any form of the corpuscular theory, whether that of Newton or that of the quantum, the velocity of propagation is not that of a projectile to which an acceleration or push has been imparted, but it has something to do with the nature of the space traversed, whether the name "ether" is given to it or not. This is evident from the undisputed fact that the velocity of the train of waves is reduced while light is passing through glass, but the original velocity is exactly resumed when the light emerges. Call it what we will, this appears to me to be one of the strongest proofs of the existence of a medium.

Much of the confusion which we find at the present time in physical science is due to the inadequacy of words to express exact thought. Language is apt to assert more than we mean it to assert. There is "a tyranny of words." Writers on the difficult subject of relativity, which ought to be a clue and not a maze, evolve new ideas and, instead of coining new words to express them, as any chemist, botanist, or zoologist would do, borrow from ordinary language such common words as space, action, interval and world, and apply them to new, special and intricate uses.

Mathematics.

Simple problems may be treated by experiment, or by geometrical diagrams, or by analytical mathematics, but the most recent researches can be presented only in advanced mathematical language, often mixed with metaphysics, and, like the theory of relativity, cannot be put into plain words.

We may say: If it cannot be put into words, how can it affect me or my life? But take the case of music. A simple tune or air can be expressed in the usual musical notation, or on the Tonic Sol-fa system, or it may be played on a musical instrument, or it may be sung, whistled or hummed. But it cannot be put into words. A journalist critic who could write a column about a song could not describe or express the tune in words.

Physics describes what we observe, and offers an explanation. Mathematical metaphysics discusses what we imagine, and offers us an assertion. Pure mathematics must not be confused with applied mathematics. The pure mathematician may arrive at a theorem or an expression without any bearing on physical reality and without intending that it should have any such bearing. Some of their creations " exist only in virtue of their definitions." To make any progress in the new physics without higher mathematics is quite impossible. But that science is utterly unintelligible to those who are not mathematicians. We must not blame the mathematicians. Mathematics is a highly condensed form of logical reasoning, making it easier to think. In the fourth century before algebra was invented, the mathematical problems of those days were solved by a process of reasoning expressed in words, without the use of any symbols. Mathematicians, like some poets, write for each other: outsiders are not expected to understand. "But," as Sir Oliver Lodge says, "the end is not yet, and we shall come out into common sense later on. . . . The human mind is not a constructor of nature—only an interpreter."

Relativists appear to be annoyed with the ether hypothesis because it reminds them of the jelly and vortex-ring analogies, which appear to them crude and mechanical compared with their elegant mathematical work. But is not this merely quarrelling about a name? Some of them admit that there is a "universal substratum of things," others, that there is such a thing as "space" or a "four-fold extension" endowed with physical properties.

To endow empty space with physical properties in order to explain observed facts, seems rather like insisting that water flows because it has the property of aquosity, or that a clock keeps time because it has the property of horologity.

It is all very well for the mathematical metaphysicist to say that he has no use for the ether because it does not appear in his equations. If we want to adopt the wave theory of light, we may frankly admit that our medium is a product of our imagination. It will do as a peg on which to hang the theory. We cannot, like Saint Bridgid, hang our cloak upon a sunbeam; we leave that to brilliant mathematicians.

And here, after behaving like an electron, in skipping about from one topic to another, I must leave the theory of light in an incomplete state. But I have taken up time with a discussion on undulations or vibrations without giving any tangible idea or the vaguest mental picture of what such an undulation is like. So far as I know, no physicist or mathematician has been able to describe it in anything but mathematical terms. We need another Faraday.

I have tried to give a short account of the history of electric lighting, of the simple but important problems of the art of intelligently using light for domestic and industrial purposes, and have attempted to give a sketch of the present position of the theory of light. I hope that some of my audience will wish to know more, and that all of them, even those to whom science has little attraction, will wish to become further acquainted with the life and personal character of the great and good man, Michael Faraday, in whose honour this lecture has been given.

SOME PROBLEMS OF THE TURBO-ALTERNATOR.*

By E. GALLIZIA, Student.

(*Paper read before the* SOUTH MIDLAND STUDENTS' SECTION, *7th April*, 1925.)

SUMMARY.

The paper deals with some of the problems that the designer has to face which are seldom dealt with in treatises on design, and for this reason have been dealt with in detail.

The paper is divided into sections as follows :—

1. *General.*
2. *Materials.*

   (*a*) Stator.
   (*b*) Rotor.

3. *Tests for flaws.*—The following methods are dealt with :—

   (*a*) Clink detection.
   (*b*) Optical tests.
   (*c*) Chemical tests.
   (*d*) Overspeed test.
   (*e*) X-rays.
   (*f*) A successful potential-drop test developed by the G.E.C. Development Department. The results are published for the first time.

4. *Mechanical design.*—This is considered from the point of view of the variation of the strength of the forging with radial depth and the efficiency of ventilation. Wedges and end-bell stresses, factor of safety, methods of test, and the available materials are dealt with. In the case of the rotor the best methods of determining the strength of the steel at the tooth root are fully discussed and methods of improving the strength of rotor forgings generally are suggested.

5. *Ventilation and liquid cooling.*—Comparison is made between :—

   (*a*) Liquid and air cooling.
   (*b*) Wet and dry air filters and closed air systems.
   (*c*) High-speed and low-speed separately driven fans.

Results of experiments on the effect of core spacers and wedges on volume and pressure of air are given.

6. *Insulation and temperature distribution.*

   (*a*) Measurement of temperature by thermo-couples.
   (*b*) Recommended methods of insulating.
   (*c*) Maximum temperatures.

7. *Balancing.*—A method is suggested whereby it is possible to move the balance weight at full speed. This may be worth while developing.

1. GENERAL.

Owing to the exacting demands on the mechanical design in addition to the electrical requirements, the turbo-alternator presents a considerable number of interesting problems, a few of which will be dealt with in this paper.

Mistakes in the electrical design may cause considerable loss of time and money, but any mechanical defects may be disastrous, resulting in loss of life.

The turbo-alternator has of course been primarily developed in order to make use of the steam turbine with its comparatively high efficiency, which increases with both the output and velocity, particularly with regard to the latter. It can be shown that the blade velocity should be of the same order as the steam velocity, which, with the high vacuum now obtained, is exceedingly high.

Apart from the above considerations, the development of the turbo-alternator is not justified, when compared with the low-speed alternator. It is less efficient, and it cannot show a lower first cost or greater reliability. The low-speed alternator of 750 r.p.m. coupled to a 5 000–6 000 r.p.m. turbine by means of reduction gearing at present only offers an attractive proposition in a size of 1 000–5 000 kW, but considerable improvement on the gearing is continually being made.

It is only during the past few years that the electrical designer has been able to produce machines of the size demanded by the turbine builder and now the position threatens to become reversed, owing to the large volumes of steam which have to be dealt with in the last stage at the high vacuum now used. This necessitates increasing the ratio of steam velocity to blade velocity considerably above its theoretical value, and so raising the leaving losses which form a considerable proportion of the total energy. In addition, the difficulties increase as the temperature and pressure increase, owing to the large drop in pressure and temperature in one single casing.

Units of 45 000 kVA at 1 800 r.p.m. and 25 000 kVA at 3 000 r.p.m. can be built, and units of greater capacity would not be used except in the case of the very largest stations. Owing to the present system of interconnection, five units per station would appear to suffice, although seven are probably better. This allows five working machines, one spare machine and one for overhauling.

The characteristic features of the turbo-alternator are :—

(1) High peripheral speed up to 475 ft. per sec. (28 500 ft. per min.).
(2) High bearing speeds up to 130 ft. per min.
(3) Great axial length of core.
(4) Great radial depth of stator core.
(5) Large air-gap.
(6) Large coil span, particularly with the large 25-cycle, 2-pole machines.
(7) Concentration of large losses in small volume, resulting in high temperature gradients.

* A Students' Premium was awarded by the Council for this paper, and it is the practice of the Council in such cases to publish the paper, in full or in abstract, in the *Journal*.

In addition, the designer is considerably handicapped by the fact that it is only possible to carry out tests on site, and then not of an experimental nature.

Owing to the comparatively high efficiency of 96 per cent in the case of large alternators compared with 30 per cent overall, future development should be considered in the following order of precedence.

(1) Reliability.
(2) Efficiency.
(3) Ease of operation, and first cost.

Reliability and efficiency, however, are very difficult to distinguish, because higher efficiency, which means lower losses, immediately results in a more reliable machine. It is because of such losses, approaching 1 500 kW in the largest machines, that the stator core and rotor have to be of comparatively flimsy construction in order to provide suitable air paths for carrying away the resultant heat.

The number of alternators developing faults from all causes, in both stator and rotor, appears to be about 8 per cent of the total. In many individual stations the figure is much lower, whilst Glasgow appears to have been exceptionally unfortunate, 16 machines having failed out of a total of 21, i.e. 76 per cent. There still remains, therefore, considerable room for improvements as regards reliability. Considerable improvement has already been made in the reduction of the weight and floor space; a steam turbine and alternator would require a floor space of the order of 35 sq. ft. per 1 000 kW and would have a weight of approximately 15 tons per 1 000 kW.

Although the electrical design is very closely related to the mechanical design, resulting usually in a compromise between the two, practically no mention will be made in the paper of the design of the electrical and magnetic circuits, as a considerable amount of literature is available on these points. Such literature, however, usually ignores the difficulties encountered by the manufacturer.

The most important variation in the stator design lies in the system of ventilation adopted and in the type of winding used to reduce as far as possible the eddy-current loss. The rotor design, however, falls into three very distinct classes, two of which are extensively used. The first is the solid forging (original Brown-Boveri) from which the radial slots are milled; the second is the plate (or disc) or built-up rotor, consisting of a shaft on to which the plates with stamped-out radial slots are built. The third is the Hungarian practice * in the 2-pole design, in which the rotor is built up in three sections. The central portion, to which are finally bolted the two shaft-ends, has parallel slots (not radial) which are continued round the ends of the cylindrical body. With this design the chief advantage, amongst others, is that it is unnecessary to use support rings. There are, however, a number of obvious disadvantages, although 160 of these 2-pole machines have been built with very successful results. The largest is a 3 000 r.p.m., 15 500 kVA machine.

* E. Wilczek: "Hungarian Practice in High-Speed Turbo-Alternator Design": paper read before Section G of the First World Power Conference, July 4, 1924.

The large number of solid and built-up rotors in operation is sufficient evidence that both types give satisfactory results, but it may be said in general that the stresses in the built-up rotor are undoubtedly higher, and that greater difficulty is experienced with critical speeds, but it has a considerable advantage from the point of view of ventilation and the fact that each small section can be fully examined for the presence of faulty material.

The latter is perhaps its greatest point, but, having obtained a sound forging for the solid rotor type, there is no doubt that it is the better engineering construction.

The methods adopted for ascertaining the soundness of the solid rotor forging forms one of the problems to be dealt with in this paper.

2. Materials.

(*a*) *Stator frame.*—The stator frame is generally made in a single casting of grey iron of comparatively massive box section, the ribs of which form suitable compartments for the particular type of ventilation adopted. For the largest sizes of alternators, where there may be transport difficulties, a comparatively light steel frame built up of **I** sections can be used. Wherever possible it is preferable to use a single casting which is accurately bored to take the laminations and suitably machined for the fixing of the core-plate keys. The stresses even under short-circuit conditions are comparatively small, and the most important consideration in the design is that of preventing contraction stresses by suitably proportioning the various parts. The resulting casting should be easy to machine, reasonably free from blow-holes, and have a comparatively smooth surface, both externally and in the air chambers.

The analysis of a suitable grey iron for the stator frame is as follows:—

	per cent
Total carbon	3·5
Graphitic carbon	0·5
Combined carbon	3·0
Silicon	2·0
Sulphur	0·05
Phosphorus	1·0
Manganese	0·4

A suitable specification, with which the above iron would comply under correct casting conditions, is as follows:—

Tensile strength, not less than 10 tons/sq. in.
Compression strength, not less than 45 tons/sq. in.
(Sample 1 in. diameter by 2 in. high.)
Brinell hardness (3 000 kg, 10 mm ball), 190.

Transverse test.—A 1 in. square bar, 14 in. long, cast with the stator frame, when placed on knife-edges 12 in. apart must support a load of 2 000 lb. at its centre and give a deflection of not less than 0·12 in. without fracturing.

(*b*) *Rotor.*

(i) *Plate.*—Carbon-steel plates (14 S.W.G.) having the following tensile properties can be easily obtained for built-up rotors:—

	With rolling	Across rolling
Yield point, tons/sq. in. ..	24·0	25·5
Maximum stress, tons/sq. in. ..	35·0	36·5
Elongation in 8 in., per cent ..	18·0	16·0
Scleroscope hardness	26–27	26–27

(ii) *Solid.*—It is not essential to know the steel maker's procedure in procuring suitable molten steel in the ladle ready for teeming, but from that point onwards it is necessary, when discussing the mechanical properties of the resultant forging or the possibility of the presence of flaws, to know the essentials of the process.

The mould is usually made of cast iron and is a cone of octagonal shape, as shown in Fig. 3, the circular mould, contrary to expectation, not giving such good results.

Fig. 1 shows a section through an ingot to which no silicon or aluminium has been added as a deoxidizer, whilst Fig. 2 shows the results after the addition of 2 oz. of aluminium per ton. In the first case the contraction cavities are comparatively small but numerous, with the result that a large proportion of the ingot is

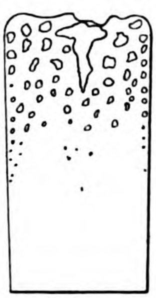

FIG. 1.—Ingot without the addition of a deoxidizer such as aluminium or silicon.

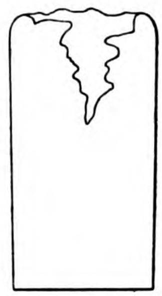

FIG. 2.—Ingot to which 2 oz. of aluminium per ton have been added.

useless. In the second case there is a large single cavity (piping) which also results in a large percentage of scrap.

The production of sound forgings having suitable characteristics requires the correct combination of a large number of factors such as pouring temperature, analysis, rate of cooling, etc., and the effect of very small percentages of aluminium is mentioned as an example. Full deoxidation cannot, however, be obtained by the use of aluminium alone, the presence of a definite proportion of manganese being necessary. Under no circumstances therefore should a definite analysis be specified in conjunction with the physical properties, but a free hand must be given to the forge master. The analysis of the steel is only of importance to the designer in so far as it affects to some extent the magnetic characteristics.

The problem which has confronted the steel maker is that of eliminating cavities, and various means have been adopted in order to produce sound ingots. One such method is to use the inverted mould shaped as shown in Fig. 3, in which the steel solidifies from the bottom to the top and from the sides radially inwards. If a steel giving only a single large contraction cavity when cooling freely is kept heated at the top whilst the remainder of the ingot solidifies, it is possible to obtain a uniform ingot.

As shown in Fig. 4, the mould is provided with a "head" which is kept hot by means of sand, slag and charcoal. The head of the ingot is finally scrapped, as a considerable segregation of carbon, sulphur, etc., takes place at this point.

As far back as 1878, Prof. D. R. Tschernoff read a paper before the Russian Technical Society dealing with segregation, blow-holes and piping in cast ingots,* whilst in 1881 Mr. Stubbs, in the discussion on a paper by Mr. John Parry (*Journal of the Iron and Steel Institute*, 1881, p. 200), pointed out that considerable segregation did occur, as he had found that an ingot 90 in. long gave a carbon content of 0·92 per cent at the top and 0·37 per cent at 30 in. from the bottom. Mr. G. T. Snelus rather discredited that such segregation did take place, but he immediately put in hand tests which proved the correctness of Mr. Stubbs's statement.

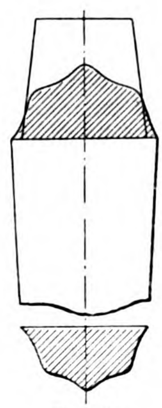

FIG. 3.

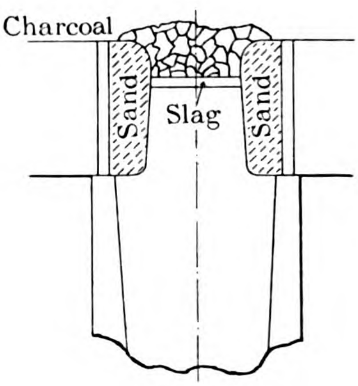

FIG. 4.

The test consisted of casting an ingot 19 in. square and 7 ft. long, having purposely high impurities, and prolonging the rate of cooling so that the ingot was not properly cold two days after casting. An analysis was made with the following results :—

	21 in. from top	4 in. from bottom
	per cent	per cent
Carbon	0·76	0·35
Silicon	Trace	Trace
Sulphur	0·187	0·044
Phosphorus	0·191	0·044
Manganese	0·558	0·514

In addition, six equi-spaced samples were taken, travelling diagonally from the corner to the centre of

* *Proceedings of the Institution of Mechanical Engineers*, 1880, p. 152.

the ingot, some of the results of which are given below :—

	Top		Bottom	
	Corner	Centre	Corner	Centre
	per cent	per cent	per cent	per cent
Carbon	0·44	0·77	0·44	0·37
Sulphur	0·032	0·187	0·048	0·044
Phosphorus ..	0·044	0·142	0·060	0·052

It will be seen that serious segregation of carbon, sulphur and phosphorus had taken place. Such variations are, of course, not normally obtained, but the figures are given to show that the possibility of segregation taking place is always present in very large forgings. Large ingots for rotor forgings may show a carbon content of 0·26 per cent at the bottom and 0·40 per cent at the top. The core of a large forging is always of poor quality, and it is in this region that cavities normally exist. It is therefore always advisable, apart from considerations of heat treatment, to bore the forging for examination, as explained in Section 3.

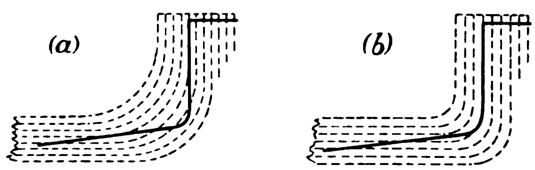

FIG. 5.
(a) Radius of forging tool too large.
(b) Radius of tool correct.

It is important that sound ingots of uniform and correct composition be obtained, as no amount of forging or heat treatment will bring out qualities which do not exist in the steel. The usual procedure is to take an ingot 30 per cent larger in diameter than the final forging and to commence forging down at a bright red heat. Care has to be taken that the temperature does not fall too low, owing to the possibility of producing flaws, especially at a marked change in section. Normally 5 per cent from the bottom and 35 per cent from the top of the ingot is discarded, so that for a 35-ton forging an ingot weighing about 55 tons is required.

At marked changes in section the radius of the forging tool should preferably approximate to that of the final machining, as indicated by Fig. 5 (*b*), where the dotted lines indicate the grain of the steel and the full lines the final machining. It will be seen in Fig. 5 (*a*) that with a forging tool of large radius a large number of fibres are finally cut through, constituting a point of weakness where the stresses, both dynamic and static, are greatest. This, however, is not always possible or advisable, as for example in the case of alloy-steel forgings which are oil-hardened. In such forgings the change in section should be made by a number of comparatively small uniform steps in order to prevent the possibility of fracture during subsequent heat treatment.

Normally the chance of a cavity being welded up by forging is extremely remote, and it is more likely that its area will increase, due to the flow of steel. In general, it may be said that forging raises the tensile strength of the outer shell of a good ingot, but it will not make a bad ingot into a good forging.

Wherever possible, oil-hardening is resorted to in order to obtain the maximum strength consistent with such large forgings, followed by normalizing in order to remove any stresses set up during forging and subsequent heat treatment. Rotors of 35 in. and upwards in diameter may be oil-hardened, provided that they are suitably bored.

It is usual for rotor forgings to be made from a carbon steel having the following approximate analysis :—

	per cent
Carbon	0·4
Silicon	0·15
Sulphur	0·03
Phosphorus	0·03
Manganese	0·7

The phosphorus and sulphur should not exceed 0·05 per cent, as segregation of these two impurities rapidly reduces the tensile properties of the steel. A steel of the above analysis forges well and is very reliable as regards the absence of clinks, segregation and similar defects, and in addition it gives a reasonable tensile strength when air-cooled and normalized. The strength may be considerably increased by oil-hardening, but the steel is said to be "strained," the elongation and contraction being considerably reduced. For this reason, where the stresses are high, as in the case of 15 000–20 000 kVA, 3 000-r.p.m. machines, it is necessary to use a 3·5 per cent nickel steel with about 0·3 per cent carbon, even though it is more difficult to ensure a sound forging.

As regards the magnetic properties, which of course are very important, a 3·5 per cent nickel, 0·3 per cent carbon steel is slightly better when both steels are in the condition in which they are normally used for turbo rotor forgings. Characteristic figures are given below :—

H	Density B in lines per cm²	
	0·4 per cent carbon	0·3 per cent carbon, 3·5 per cent nickel
10	8 300	9 900
100	16 700	17 450
2 500	22 650	23 200

3. TESTS FOR FLAWS.

As already pointed out, the greatest disadvantage of the solid forging is the possibility of the presence of undetected flaws which may not produce failure until after a considerable period of running, and the methods adopted for ensuring the soundness of forgings will now be considered.

(*a*) *Clink detection.*—Owing to the large masses involved, heating and cooling processes are often accompanied by severe stresses which have resulted in the internal fracture of the forging, followed by a loud

ringing report which has given the necessary warning. Cases have, however, occurred where either the fracture has not been accompanied by a report or there has been no one in the vicinity at the time. Recently an account * was given of a clink detector for steel ingots and forgings developed by C. A. Parsons and Co. in conjunction with the Cambridge Instrument Co. The vibration set up by the fracture of the forging is made use of in this instrument, which is really a vibration recorder, consisting essentially of the detecting instrument, which is placed on the forging, and the clock-driven time recorder. The detecting instrument consists of a horizontal spring contact carrying at its end a brass weight which, due to its inertia, produces a lag in the travel of the spring, thereby actuating the contact, the operation of which is recorded on the chart. Periodic hammer blows are given to the forging in order to test the apparatus.

(*b*) *Optical tests.*—Immediately the rotor has been bored and the borings have been examined, the optical examination should be made while the bored surface is still bright. This may be carried out in several ways, one of which consists of using a steel periscope tube about 12 ft. long and $1\frac{1}{2}$ in. diameter. Such a tube would carry at one end the eye-piece and at the other a mirror and a small 4-volt lamp, producing the necessary illumination.

Lenses would be arranged to give an apparent magnification of about $1\frac{1}{2}$ times to twice full size. The actual magnification is, of course, greater, as the surface is observed at a distance of 12 ft. Higher magnification should be provided for the examination of doubtful places, The test consists in moving the tube axially and circumferentially and scrutinizing every portion of the bore.

Where heat treatment is carried out after the preliminary boring, followed by "finish boring," the test should be repeated. All doubtful places should be polished by means of grinding and polishing bobs carried on the end of a shaft running in bearings supported by the bore and driven at the opposite end by means of a small motor.

The optical examination of the external surface needs little comment, except that it should be carried out immediately after slotting and turning and preferably again after several days, as fine hair lines have been known to show only after exposure to the atmosphere, whereas often they are more pronounced on a clean surface.

(*c*) *Chemical tests.*—Chemical tests are only applicable to surface investigation and consist of etching and the making of sulphur prints from surfaces prepared by polishing. Very fine cracks are often difficult to detect, and etching by means of a 20 per cent solution of nitric acid is often resorted to in order to produce contrast by staining.

Sulphur prints are generally taken by the method suggested by Baumann. This consists of soaking for a few moments a matt silver bromide photographic printing paper in a dilute (3 per cent) solution of H_2SO_4 and then pressing the sensitized side on to the metal surface for one minute. The H_2SO_4 attacks the sulphides, liberating hydrogen sulphide, which in turn reacts on the silver bromide and selectively darkens it, depending on the concentration of the sulphur. The paper is then washed in water and fixed in the ordinary way by a 20 per cent solution of sodium hyposulphite.

* *Engineering*, 1924, vol. 118, p. 658.

Silver salts are also affected by phosphine and are liable to record the presence of phosphide, and from that point of view the method originally suggested by Prof. Heyn, of using strips of silk impregnated with mercury chloride (mercury salt being unaffected by phosphine), is correct for sulphur printing. In practice it is found that the effect of the phosphides on silver bromide paper during the period of one minute normally employed is generally small and in any case the sulphides and phosphides are both harmful and are generally found together, so that from the point of view of the detection of segregation the Baumann method is satisfactory. (Lantern slides shown by the author brought out the sensitivity of the method in distinguishing between good and bad material.)

(*d*) *Overspeed test.*—The overspeed test, which has to be carried out in a "bomb-proof" chamber, is applied to the rotor and end bells, but particularly to the rotor. The test is carried out before winding, with the result that the overspeed necessary to obtain stresses higher than those reached with the normal 15 per cent overspeed is in the region of 50 per cent, i.e. a 3 000-r.p.m. machine would have to be run in the neighbourhood of 4 500 r.p.m. One Continental firm is reputed to carry out this test at a temperature of about 150° C. by means of a steam jacket, and the test then becomes an expensive and elaborate one. There is, for instance, the high bearing speed, which would make it difficult to continue the test for any length of time. This test, in the author's opinion, is not justified and in fact may be detrimental.

It is possible that a rotor having a small flaw may be stressed to an extent sufficient to weaken it further and yet not produce total failure. It may then happen that after one or two years' service, owing to the continual vibration the flaw may grow to the extent of producing complete failure, whereas if no overstressing had occurred during the overspeed test this progressive failure might not have been started.

(*e*) *X-rays.*—So far it has not been possible to apply X-rays to the examination of turbo rotor forgings, owing to the comparatively small depth of penetration at present obtainable. Even should the penetration be considerably increased, it would be very difficult to apply the rays so as to test the radial thickness of the forging, owing to the small size of bore which, for the very largest rotors, cannot be made very much greater than 6 in. in diameter, on account of limitations of (*a*) maximum bearing speeds of about 130 ft. per sec., which limit the external diameter, (*b*) the methods used for carrying the exciter, and (*c*) the coupling bore.

The alternative is to test along the diameter, and this, even in the smallest rotors, would require a penetration of about 26 in.

The present practical limits of penetration are:—

Lead	0·2 in. (approx.)
Carbon steel	3·0 in. (approx.) *
Aluminium	6·0 in. (approx.)

* Mr. A. E. Bullin, Director of the Radiological Institute, Woolwich, stated in the last Cantor Lecture given before the Royal Society of Arts that he has recently been able to increase the penetration of steel from 3 in. to 4 in.

The penetration of 3 in. of steel requires a tube absorbing 3·0 mA at 200 000 volts. One inch of steel can be radiographed by means of a tube absorbing a few milliamperes at 140 000 volts with an exposure of one minute, whilst with present screen sensitivities only about 0·2 in. can be examined satisfactorily.

Statements have been made from time to time that owing to the physical conditions very great penetrations cannot be obtained, and Mr. A. G. Warren deals * fully with this point, stating that the conclusions have been based on incorrect data. Taking present practical results and the latest research data, he gives a set of curves (reproduced in Fig. 6) as representing the

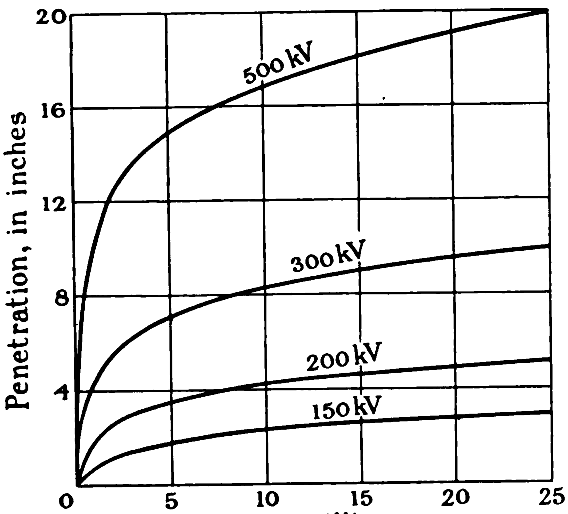

FIG. 6.

penetration which it is physically possible to attain with increasing X-ray outputs.

The predicted curves are made with some reserve owing to indefinite experimental data, particularly with reference to the variation of the mass absorption coefficient with heavier elements and high-frequency radiations. It will be seen that a tube absorbing 25 mA at 500 000 volts is predicted as being capable of penetrating 20 in. of steel, but even this is insufficient for the examination of rotor forgings. The ultimate solution of such deep penetration will probably require metal tubes capable of dealing with anything up to 40 kW, and the complete apparatus with high-tension electrical plant will undoubtedly be very expensive.

X-rays can, however, be satisfactorily used for the examination of such parts as turbine wheels, but as regards the turbo-alternator the most useful field appears to be the examination of the support rings. The process is a long one owing to the small area which can be examined at one instant and the time required for the exposure, the support rings being anything up to 2½ in. thick, 2 ft. axial length and 5 ft. diameter. In addition, an expert is required who must not only be fully conversant with X-ray technique but who, having obtained satisfactory radiographs, is able to interpret the results. This is by no means easy, owing to the sensitivity of the rays to tool marks, surface blemishes and variations in chemical composition. The test is an expensive one, but the rings, owing to their importance, should be X-rayed unless the potential-drop test has been applied, in addition to the chemical tests, such as sulphur printing and etching.

(*f*) *Potential-drop method.*—From the account given of the above 5 tests, it will be seen that no really satisfactory method exists (so far as the author is aware, except the test to be described) of finding deep-seated flaws unless they show up during the optical bore test.

A potential-drop test was developed some years ago by the General Electric Co.'s Development Department after a considerable amount of experimental work. A number of methods were suggested, such as the frequency of sound waves and their rate of travel,

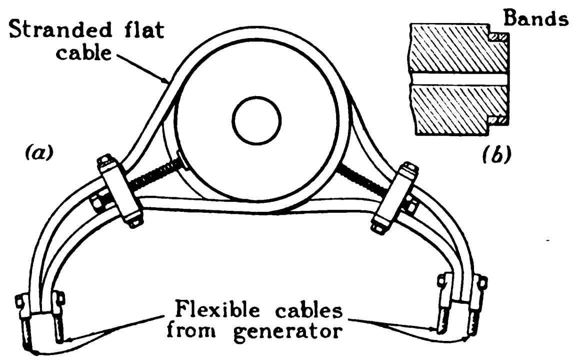

FIG. 7.

but concentration was first made upon magnetic and potential-drop methods. Magnetic methods were first tried because of their almost universal use in the testing of rails, ball races, etc., and, in addition, considerable information * was available on the correlation of the magnetic properties with the chemical composition, heat treatment and mechanical strength of steels.

This method proved to be too complicated when attempts were made to test after slotting had been carried out, but the results were much more hopeful with a smooth forging, when using magnetizing coils and search coils for measuring the flux distortion. The noise in the shop was found to be too great to allow the use of an interrupter and headphones in series with the search coil, and for that reason a ballistic galvanometer was used.

Before proceeding further with investigations on this method of detecting flaws, work was commenced on the potential-drop method, with such success that the magnetic method was abandoned in favour of this method, which has now been used for some years as a

FISCHER: "Application of Magnetic Analysis to the Testing of Ball Bearing Races," *Technical Papers of the American Society for Testing Materials*, 1919, vol. 19, pt. 2; also papers by W. B. KOUWENHOVEN, C. NUSBAUM, N. J. GEBERT and S. R. WILLIAMS.

routine test. Potential-drop methods have been used for many years for the testing of all kinds of soldered, brazed and welded joints and have been compared from time to time * with magnetic methods. In the case of comparatively small ferrous products of uniform section, such as ball races and rails, the magnetic method has been preferred, and Spooner and Kinnard found it to give more consistent results.

The potential-drop method is more sensitive since

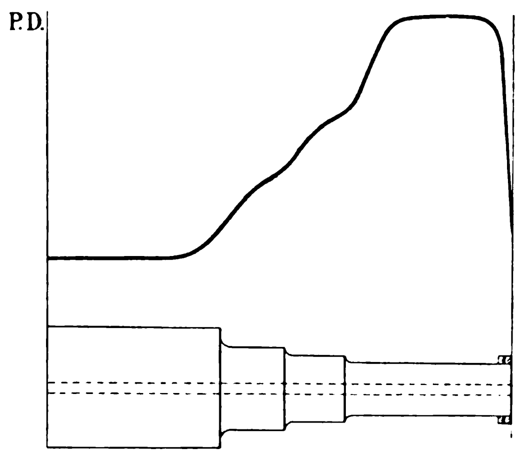

FIG. 8.—Electro bore test.

the ratio of electrical resistance of air to that of steel is far greater than the ratio of their magnetic reluctances. As its name implies, the test consists of passing a current and measuring the potential drop. Although this sounds quite simple and straightforward, in reality it gave considerable trouble when applied to forgings up to 45 tons in weight and 52 inches in diameter. The necessary direct current is obtained from a plating dynamo, and one of the minor difficulties was that of

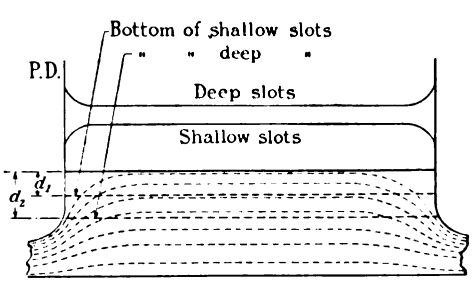

FIG. 9.—Slot test.

leading in the current to the rotor satisfactorily. Unless the current is led into the shaft uniformly, no reliance can be placed on tests made within 2 ft. of the leading-in bands. A satisfactory method is shown in Fig. 7 (*a*) which is self-explanatory. A better method, still using these bands, is to step the end of the shaft as shown in Fig. 7 (*b*).

It is not possible in this paper to give details of the apparatus used, but only to mention that the chief difficulties experienced were :—

(1) Alteration of spacing of contacts.
(2) Effect of stray fields.
(3) Thermo-couple effects.
(4) Contact-resistance effects.
(5) Fluctuation of current.
(6) Vibration of galvanometer.

Also, the design of the contacts had to be different for tests in the slots, on the shaft, and in the bore, in addition to variation in size of each of these for different sizes of rotors.

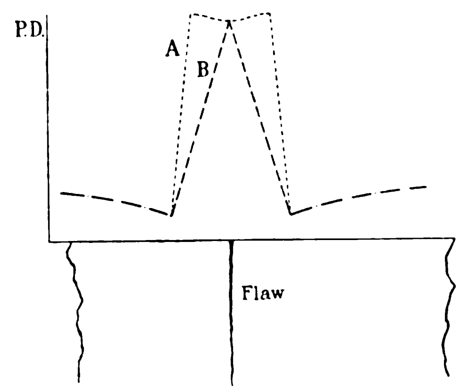

FIG. 10.—Characteristic curve obtained with flaw extending to surface of forging. *Note.*—Movement per reading in curve A one-fifth of that in curve B.

Fig. 8 shows the results of the "electro bore" tests using contacts 2 in. apart, and gives a good indication of the variation in potential drop obtained. This test would of course be carried out along a number of equally spaced axial lines, giving a number of identical curves if the shaft is satisfactory.

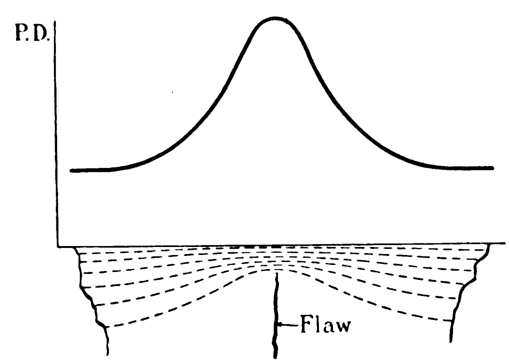

FIG. 11.—Characteristic P.D. curve obtained with crack below surface of forging.

Fig. 9 shows the type of curve obtained from readings taken along the bottom of the slots. It will be seen that the E.M.F. curves for the shallow slots fall at the ends, whereas for the deep slots they rise. The reason for this will be obvious when the current distribution as indicated by the stream lines is considered.

Figs. 10 and 11 show the essential difference obtained in the potential-drop curve, depending upon whether

* T. SPOONER and I. F. KINNARD: "Electrical and Magnetic Weld Testing as applied to Butt-welded Steel Plates," *Technical Papers of the American Society for Testing Materials*, 1922, vol. 22, pt. 2.

the flaw is buried or extends to the surface, whilst Fig. 12 shows the variation in potential with change in section, which, although perhaps at first is unexpected, is easily explained when the flow lines are considered and therefore needs no further comment, except that these results were taken with contacts spaced 1 in. apart, and that varying the contact spacing varied the form of the potential-drop curve very greatly.

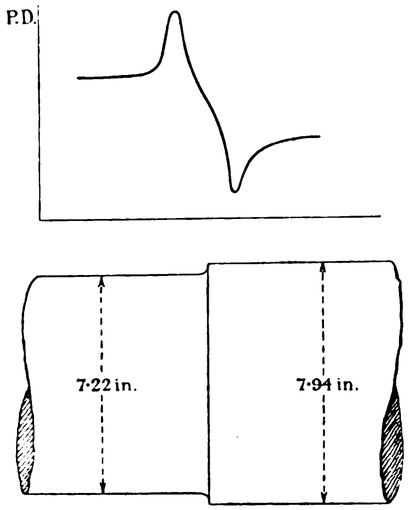

FIG. 12.—Variation of P.D. with change of section.

Fig. 13 shows the results obtained along the slots and on the rotor surface of a faulty rotor 22 inches in diameter, which had two large flaws spaced centrally so that they did not reach the surface. The shape of these cracks was similar to that of a double concave lens, the larger one being 16 inches and the other one 9 inches in diameter, as was shown on breaking up the forging.

When interpreting the results of the variation in the

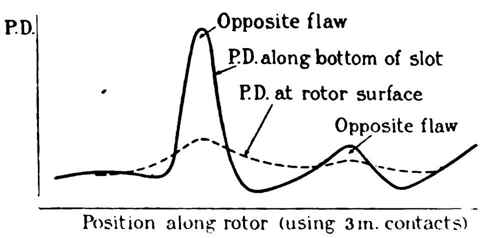

FIG. 13.—Curve obtained on faulty rotor.

potential-drop curves, it must be remembered that high or low deflections may be obtained even in a solid forging, due to the resistance varying with the chemical composition and heat treatment.

A broad view may be taken by saying that it is immaterial whether the forging contains a flaw or is not uniform in composition, as the boundary lines may form a plane of weakness. Whether this is so or not, there is the difficulty of getting the steel maker to agree with this. If the steel maker is notified that a variation is being found in a particular forging and that it will be rejected, he will undoubtedly agree to the cutting up of the forging for examination, and to bearing the loss if a dangerous flaw is found, "dangerous" because no forging is ever guaranteed to be free from small blow-holes. The question then arises as to what is a dangerous flaw, and that would have to be defined, as far as possible, before the forging was examined. It is not possible here to discuss this point, but it is mentioned as showing one of the difficulties which may arise, and it must be remembered that a forging, particularly of nickel steel, is an expensive component.

In the author's opinion, any variation in chemical composition occurring at the surface where the potential is being measured can be detected by making use of the thermo-couple effect. The thermo-couple E.M.F. varies with the chemical composition, so that if the points are moved along the rotor with no current passing it may be assumed if the deflection varies that the chemical composition is not uniform,* since only very small temperature gradients can normally exist in such a mass. It is also well to remember the work of Benedicks † who attempted to find a general formula for results of observations by other workers and himself for the variation of electrical resistance with chemical composition.

He established the following law of equiatomic solutions :—

$$O = 7\cdot6 + 26\cdot8\Sigma C$$

where O = specific resistance in microhms per cm^3,
$7\cdot6$ = resistivity of pure iron, and
ΣC = sum of the values of dissolved (in solid solution) elements in terms of carbon obtained by dividing the percentage found by analysis, by the atomic weight of the element multiplied by 12, the atomic weight of carbon,

or

$$\Sigma C = C + \frac{12\cdot0}{28\cdot4}Si + \frac{12\cdot0}{55}Mn + \frac{12\cdot0}{32}S + \frac{12\cdot0}{58\cdot7}Ni, \text{ etc.}$$

In general this formula gives fairly satisfactory results for dilute solutions where ΣC is not greater that 2–3 per cent and in some cases for more concentrated solutions of the ternary steel, as shown by Portevin, whilst in other cases it does not hold good.

In general it can be said that the resistance increases

(1) With the addition of elements,
(2) With temperature,
(3) With the amount of cold work,
(4) With hardening due to heat treatment.

In the case of rotor forgings we are chiefly concerned with plain carbon steels with not more than 0·5 per cent carbon, and 3·5 per cent nickel steels with 0·3 per cent carbon.

Benedicks gives the following figures for the variation

* L. DUPUY and M. PORTEVIN: "The Thermoelectric Properties of Special Steels," *Journal of the Iron and Steel Institute*, 1915, vol. 91, p. 306.

† "Recherches physiques et physico-chimiques sur l'acier au carbone" (Upsala, 1904).

of resistance with carbon, the percentage of the other elements being kept constant:—

Percentage of carbon	Microhms per cm³	
	Annealed	Hardened
0·08	10·51	10·9
0·16	12·59	13·6
0·23	13·74	15·4
0·33	14·67	17·2
0·38	15·11	18·3
0·48	24·03	28·99
0·55	27·54	34·36

It is also necessary to point out that a flaw running parallel with the current-flow lines gives practically no variation in P.D. and that the maximum distortion of current is obtained when the flaw is normal to the current flow. Any sign of variation of potential-drop not accounted for by a change in section is further investigated by leading in and out the current in the vicinity of the suspected flaw, thereby considerably increasing the current density and varying the path of the current flow according to the points chosen for leading the current in and out.

4. Mechanical Design.

(*a*) *Rotor*.—The improvement in the tensile strength of the rotor forging forms one of the most difficult problems of the turbo-alternator, because the designer is largely in the hands of the forge-master, and unless there is more co-operation than at present generally exists no great advances are likely to be made.

The routine testing of rotor forgings has for a long time consisted of taking tensile test and bend pieces as follows :—

(1) Longitudinal from one end of the shaft.
(2) Radial from one face of the rotor body.
(3) Transverse from the opposite face of the rotor body.

As previously mentioned, considerable segregation of the metalloids often takes place in large ingots, the top showing the higher percentage. With a given heat treatment the mechanical results are fairly sensitive to the carbon content and for this reason longitudinal test-pieces should be taken from both ends of the shaft, and the end of the ingot giving the more suitable carbon content should be chosen by the forge-master as the driving end of the rotor.

The shaft portions, owing to their comparatively small section, do not present any very great difficulty, but the rotor body is a different proposition. Rapid heating and cooling operations are not permissible owing to the dangerous stresses set up, and the difficulty of the mass annealing effect has to be confronted. Boring the rotor to the maximum diameter permissible by the shaft design immediately gives the steel maker greater freedom in heat treatment, with the result that the rotor as a whole is greatly improved.

Theoretically it can be proved that drilling a hole in a rotating disc doubles the stresses at the periphery of the bore, but in practice with ductile materials they are not so high and in rotor forgings give no trouble.

The limiting stresses in a rotor are at the bottom of the tooth, and it is necessary to know the strength of the steel in this vicinity, not only at the ends where the routine test-pieces are normally taken but along the whole of the tooth. The best that can be done is to trepan a test-piece from the centre (axially) of the rotor at a point through which a slot will finally be milled. As it is not advisable to go below the bottom of the slot, it is even then not possible to obtain the strength at the tooth root. The question therefore arises as to what is the ratio of the actual strength at the tooth root to that obtained by the normal routine tests from the rotor face. The author is of the opinion that the routine tests, without this knowledge, are of comparatively little use, particularly from the point of view of the designer, and that a trepanned test-piece taken as mentioned above is the only method of obtaining useful information. It is in this respect, that is, finding the ratio in strength given by a trepanned test-piece to that actually existing at the tooth root, that a great deal of work needs to be done, requiring the co-operation of the forge-master and the designer. At present, routine test-pieces are taken from the sections of the rotor into which most work is applied during the forging process, and the forging is heat-treated to give the best surface or test-piece results. The final solution may require the boring of the shaft to the maximum possible diameter, and heat treatment so as considerably to improve the strength at the tooth root, resulting probably in a considerable reduction in the quality (combined tensile strength and ductility) of the surface material now tested.

Every opportunity that occurs of investigating the variation of strength with depth should be taken. This is often possible where a large ingot is forged down in one piece and finally cut in half to produce two separate forgings. The investigation would have to cover the case of bored and unbored forgings, oil- and air-hardened, and of plain carbon and alloy steels. For instance, tests made in the case of air-hardened and normalized 0·4 per cent carbon steel forgings of about 30 in. diameter (not bored) show the following conditions to exist :—

	Routine test	Strength of tooth root
Yield point, tons/sq. in. ..	21·0	About 14·0
Maximum stress, tons/sq. in.	40·5	About 34·0
Elongation, per cent ..	26·0	About 12·0
Contraction, per cent ..	45·0	About 13·0

For this class of steel the limit of proportionality is about 75 per cent of the yield point.

It will therefore be seen that the yield point is only 15 tons/sq. in. at the tooth root, as against 21 tons/sq. in. for the routine test, giving a ratio of 15/21·0 or only 0·71. In addition to this the ductility is poor, as indi-

cated by the low percentage elongation and contraction, due to the coarse-grained structure produced by the effect of mass annealing. Oil-hardening carried out under the correct conditions will considerably increase the above ratio of 0·71, but treatment which will raise

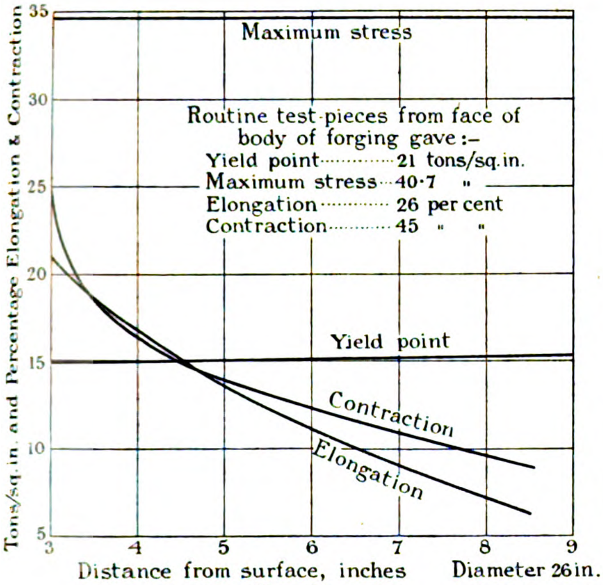

FIG. 14.

the yield point of a 0·4 per cent carbon steel to 25 tons/sq. in. should be avoided, as a 3·5 per cent nickel steel will give this strength in its "natural state."

The reduction of yield point and maximum stress with increased radial depth is comparatively small, as shown

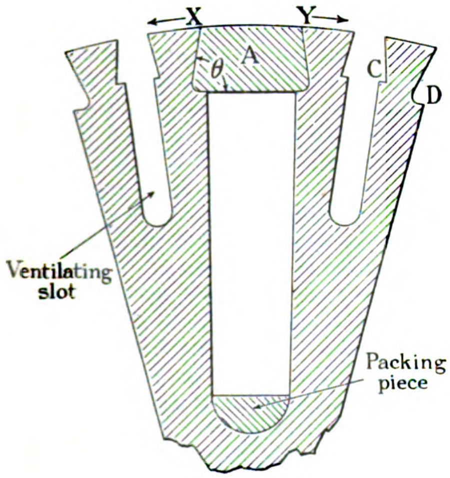

FIG. 15.

in Fig. 14, whereas the elongation and contraction show a continual reduction. A trepanned test-piece will therefore give a very good indication of the yield point and maximum stress at the tooth root, although the figures for the elongation and contraction so obtained will be considerably higher. In the author's opinion, therefore, the results obtained from a trepanned test-piece are infinitely more valuable than those given by the normal test-pieces and should be obtained in spite of the greater difficulty of trepanning.

For the following reasons and the considerations given above, the author recommends the design in which separate ventilating slots are placed between the main slots, as shown in Fig. 15, in preference to that illustrated in Fig. 16, where the ventilating slot is below the main slots. First, it gives the minimum slot depth and if the stress across CD is designed so that it does not exceed, or only just exceeds, that at the tooth root, the factor of safety will be greater than that obtainable with the design illustrated in Fig. 16, assuming equal copper loading in each case. Secondly, the deep, narrow slot is more efficient from the point of view of ventilation than the comparatively wide, shallow slot necessary under the main slots, whilst the circumferential slots need not be so deep. The largest possible diameter of rotor is used as in practice the output is found to vary

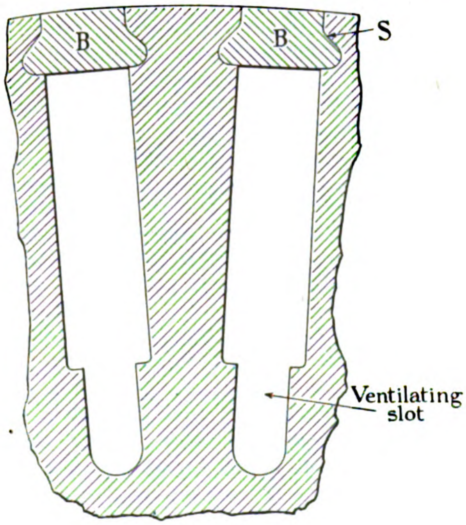

FIG. 16.

approximately as the cube of the peripheral velocity or diameter. In this respect it may be preferable in some designs to use aluminium in place of copper for the rotor winding.

All changes in section should be made as gradual as possible, particularly along the shaft, by allowing liberal and well-proportioned fillets.

The greatest stresses occurring in the shaft section are the alternating stresses at the neck of the journals, and the design of the shaft is governed by consideration of the value of this maximum stress, the critical speed (which must be kept well away from the normal speed, but not necessarily above it), and the bearing velocity.

(*b*) *Support rings*.—Almost without exception, a solid ring of steel of high tensile strength, or of high-tensile bronze in the case of single-phase alternators, is used for supporting the end windings. Stresses in such rings may be as high as 15 tons/sq. in. at 15 per cent overspeed, the self-stress being about 50 per cent of the total. This high self-stress suggests the possibility of using such light metals as duralumin, but,

apart from the difficulty of obtaining support rings in this metal, it will be found that a considerably higher factor of safety is obtained by means of a nickel-chrome steel, although duralumin would have the advantage of being non-magnetic.

The maximum circumferential strength is obtained by rolling in a similar manner to a railway tyre, and a steel having the following analysis :—

	per cent
Carbon	0·3
Silicon	0·15
Manganese	0·65
Sulphur	less than 0·05
Phosphorus	less than 0·05
Nickel	3·5
Chromium	0·6

when suitably hardened and tempered will give a tensile strength of :—

Yield point, tons/sq. in. ..	58
Maximum stress, tons/sq. in. ..	65
Elongation, per cent	20
Contraction, per cent	50
Brinell hardness (3 000 kg; 10 mm ball)	300
Impact test (Izod)	Not less than 35 ft.-lb.

Cold bend test. Test-piece $\frac{3}{8}$ in. × $\frac{3}{4}$ in. with rounded edges of $\frac{1}{16}$ in. radius must bend 180° with $\frac{1}{2}$ in. radius (over thinner section) without signs of fracture.

Considerably higher results may be obtained by the addition of molybdenum and an increase in the chromium content.

The chief disadvantage of such a steel is that it is very sensitive to heat treatment. Ni-Cr steel, when properly heat-treated, usually combines the toughness due to nickel and the hardness due to chromium, and at the same time appears to be free from the disadvantages of either, but in general it suffers from temper brittleness induced at a temperature of about 500° C. to 550° C. and it is chiefly for this reason that a minimum impact strength should be specified.

Support rings have been known to have serious ingot corner segregations * forming radial planes of weakness which have been detected by means of sulphur prints.

Although the support rings may not finally define the limit of peripheral speed to which the rotor may be run, yet they may become the controlling factor with regard to the minimum size of air-gap used, as the end bells have to be passed through the stator bore.

For single-phase machines a high-tensile manganese bronze having the following tensile strength when in the form of a support ring may be used.

Yield point, tons/sq. in.	35
Maximum stress, tons/sq. in.	50
Elongation, per cent	12
Contraction, per cent	20
Brinell hardness (500 kg; 10 mm ball) ..	190

* T. H. Turner: "Experiences in the use of Nickel-Chrome Steels." Paper read before the Staffordshire Iron and Steel Institute, 1922.

If it is possible to allow a little lower yield point and maximum stress, then the elongation and contraction may be considerably increased.

It is difficult to see why such alloys are known as bronzes, because the tin content is usually below 1 per cent, whilst the zinc is in the region of 35 per cent, with about 2 per cent each of iron and manganese, the remainder being copper, although aluminium is often added. The disadvantage of such bronzes is that under no circumstances must hot solder or mercury be allowed to come into contact with them, owing to the property of solder and mercury of penetrating the intercrystalline interstices of the bronze, producing rapid weakening which may result in failure.

Difficulty was originally experienced with steel support rings owing to the high induced voltage which occurs on breaking the field, or during a single-phase or three-phase short-circuit, causing large currents to flow along the rotor keys and teeth and back via the support ring. The author has examined some early machines returned for repair where there was definite indication of local overheating and arcing having taken place from this cause. Such points of the support rings were glass-hard and could not be filed, and had they been incorrectly spigoted might have failed.

Two methods of overcoming this suggest themselves. One is to prevent such currents flowing, and the other to provide a low-resistance circuit through which the current can pass without arcing. The latter method has been extensively used by a number of firms who provide bonding strips of copper running underneath the main wedges and sandwiched between the windings and support rings. Such an arrangement really constitutes a medium-resistance damping winding and has been found to give perfectly satisfactory results.

(c) *Wedges.*—One of the two types of wedge shown in Figs. 15 and 16 is generally used and both have given good results. The T-shaped wedge is easier to fit because a slight error in the slope S does not seriously affect the fit and, in addition, the area of the surface of the slope S is small compared with that of the plain wedge. When the angle θ of the latter is in the neighbourhood of 75° to 80° the fitting has to be done much more carefully, and the stresses in the direction X and Y are about six times the radial stresses. With a given width for the slot and base of wedge, the plain wedge is the stronger, but on the score of ease of fitting the author favours the T-shaped wedge, particularly where a wedge extending the whole length of the rotor has to be fitted, instead of sections about 1 ft. long.

In three-phase machines magnetic wedges are necessary in the region of the pole centre, and non-magnetic wedges in the neutral, in order to reduce the cross leakage flux as far as possible. In the case of the single-phase alternator, wedges of high conductivity (in addition to being non-magnetic) are required in order that an efficient damping winding may be formed. The material used, both magnetic and non-magnetic, must have considerable strength and not bind when being driven into position.

The tensile strength and conductivity of some suitable metals for wedges are given below :—

	Steel	Hard-drawn phosphor bronze	Extruded bronze
Yield point, tons/sq. in.	24·0	33·0	30·0
Maximum stress, tons/sq. in.	42·0	34·0	44·0
Elongation, per cent ..	26·0	13·0	25·0
Contraction, per cent ..	45·0	48·0	35·0
Brinell hardness (10 mm ball)	200·0 (3 000 kg)	155·0 (500 kg)	150·0 (500 kg)
Resistivity (microhms per cm^3 at 15° C.) ..	18·0	10·5	12·0

When testing wedges in a jig made in the form of the wedge slot, the load must be applied through a copy of the slot winding and insulation. If a solid steel tool the same width as the copper is used to apply the load, the wedge will fail in shear, whereas under normal conditions the wedge fails at a lower figure by bending as a beam. It is also necessary to remember that whereas in such a test all the load is applied to the wide face, yet under normal operation the load distribution becomes modified, owing to the wedge self-stress.

Wedge stresses at 15 per cent overspeed may be as high as 5·5 tons per inch length, but even then a factor of safety of 2½–3 is obtainable, which is ample when the uniformity of extruded and hard-drawn wedges is considered.

5. Ventilation and Liquid Cooling.

(*a*) *Liquid and air cooling.*—On comparing the heat-carrying capacities of air, water and oil, as given below one is perhaps at first rather surprised that liquid cooling has not been universally adopted, but a careful examination shows that a number of other important factors enter into the problem.

(*a*) Ratio of weight per unit volume :—

$$\frac{\text{1 cub. ft. of water}}{\text{1 cub. ft. of air (760 mm barometer, 38° C.)}} = \frac{62\cdot4}{0\cdot0711} = \frac{878}{1}$$

(*b*) Ratio of specific heats : $\frac{\text{Water}}{\text{Air}} = \frac{1\cdot0}{0\cdot242} = \frac{4\cdot13}{1}$

(*c*) Ratio of normal velocities obtained :—

$$\frac{\text{Water}}{\text{Air}} = \frac{\text{500 ft./min.}}{\text{4 500 ft./min.}} = \frac{1}{9}$$

Therefore ratio of heat-carrying capacity of water to air under normal conditions is :—

$$\frac{\text{Water}}{\text{Air}} = \frac{878}{1} \times \frac{4\cdot13}{1} \times \frac{1}{9}$$
$$= 400 \text{ with equal temperature-rise of both mediums.}$$

For transformer oil having a specific heat of 0·47 at 30° C. and a specific gravity of 0·83, and a velocity of 500 ft. per min., the ratio of oil to air cooling is

$$\frac{400 \times 0\cdot83 \times 0\cdot47}{400} = \frac{156}{400} = \frac{1}{2\cdot5}$$

The above advantage would not be realized in practice because, whereas in air cooling the temperature-drop is from surface to air, with liquid cooling it is from surface to water tube and then from tube to liquid. However, the advantage is considerable, for in air-cooled machines the heat dissipation is of the order of 1½ watts/sq. in. with 25 deg. C. air temperature-rise, whereas a tube 1 inch in diameter with a velocity of 500 ft./min. and a temperature difference of 15 deg. C. dissipates about 80 watts/sq. in.

The standard air-cooled design shown in Fig. 15 if converted to water cooling would have an increased cooling capacity of the order of 40–50 times that of the air-cooled design. As there is a large temperature-drop across the insulation, this increase in efficiency could not be utilized owing to the inability of the remainder of the heat paths to transmit the heat to the duct.

In the author's opinion the extra complication of liquid cooling will not be justified until insulating materials with very much greater heat-carrying capacities than that of micanite are found. In addition there are the following disadvantages :—

(*a*) Extra complication, needing a high-pressure water circuit up to 1 000 lb./sq. in.
(*b*) Danger of water leakage causing failure of the insulation.
(*c*) Danger of clogging and corrosion of water pipes or sludging of oil.
(*d*) Loss of the heat-dissipating surface of the stator and rotor at the air-gap, which forms a large proportion of the total surface.
(*e*) The end winding would have to be in contact with large liquid-cooled metal clamps. Although this would be advantageous from the point of view of supporting the coils, it considerably increases the stray losses in the case of the stator and these are already very high. In addition, a greater thickness of insulation would be required.

Difficulty in ventilation is experienced with the rotor in high-speed machines and with the stator in low-speed machines. In the case of the stator, water cooling would have the advantage of allowing a better mechanical construction, owing to the elimination of the comparatively flimsy core spacers.

If, as in this country, very much larger units than 25 000 kVA at 3 000 r.p.m. and 50 000 kVA at 1 800 r.p.m. are not required, then water cooling should not be adopted until air cooling is definitely proved to be inferior, when considered from the point of view of reliability, efficiency, ease of operation and first cost. This will need considerable investigation on the lines indicated below.

In practically all large machines a combination of axial and radial ventilation is adopted and, although the design details vary considerably, the essential prin-

ciple is that of splitting up the air paths into a large number of comparatively short parallel paths, resulting in large volumes of air at comparatively low pressures and a uniform distribution with the elimination of hot spots. The ventilating spaces occupy about 20 per cent of the stator volume, and the stator core laminations are divided up into axial packets of about 2 in. separated by ducts of about $\frac{3}{8}$ in. to $\frac{1}{2}$ in.

Volume of air required.—The specific heat of air is 0·242, therefore 0·242 B.Th.U. will raise 1 lb. of air 1 deg. F., and $0 \cdot 242 \times \frac{9}{5}$ B.Th.U. will raise 1 lb. of air 1 deg. C.

Volumes of air are usually dealt with in terms of cubic feet, and under the normal conditions of 760 mm barometer and 38° C., the weight per cubic foot is 0·0711 lb. Therefore to raise 1 cub. ft. of air 1 deg. C. $0 \cdot 242 \times \frac{9}{5} \times 0 \cdot 0711 = 0 \cdot 031$ B.Th.U. is required.

$$\text{Since} \qquad 1 \text{ B.Th.U.} = 778 \text{ ft.-lb.}$$

$$\text{and} \qquad 1 \text{ watt} = \frac{33\,000}{778 \times 746} = 0 \cdot 0568 \text{ B.Th.U.}$$

$$1 \text{ watt will raise } \frac{0 \cdot 0568}{0 \cdot 031} = 1 \cdot 83 \text{ cub. ft. 1 deg. C.}$$

$$\text{or} \qquad (\text{cub. ft. per min.}) = 1 \cdot 83 \times \frac{\text{watts loss}}{t \text{ deg. C. rise}}$$

The loss in a large alternator is about 4 per cent of the output, or kW × 0·04

$$\therefore \ (\text{cubic ft. per min.}) = 1 \cdot 83 \times \tfrac{40}{20}$$
$$= 3 \cdot 66 \text{ cub. ft. per kW output with 20 deg. C. rise.}$$

This air cannot always be used to the best advantage, and a figure of 4·0 cub. ft. per kW output is generally taken for a 20 deg. C. temperature-rise, i.e. a 15 000 kW alternator requires about 60 000 cub. ft. of air per minute.

In dealing with ventilation problems a full knowledge is required of the distribution and magnitude of the losses, and the paths by which the heat reaches the cooling medium.*

The air-flow problem, although analogous to that of the electrical circuit, is considerably more complicated, in that the true laminar flow obtained in pipes at low velocities (giving a parabolic variation of velocity across the tube) does not exist. The flow throughout the system is practically turbulent, and in the case of air leaving the rotor radial ducts and meeting the stator bore it is violently turbulent. Turbulence, in addition to complicating the calculation, gives a very much reduced flow under a given pressure, but has the advantage that the "scrubbing" effect on the sides of the duct greatly increases the heat conductivity. This is due to the fact that in laminar flow there exists a thin cylinder of stationary air, which has the low heat conductivity of about 0·0002 watt per cm³ per deg. C., compared with 0·003 for built-up micanite.

By applying temperature/density corrections and assuming air to be an incompressible fluid, a number of the constants used in hydraulics can be employed with fairly satisfactory results. The assumption that air is incompressible is justified in ventilation problems because of the relatively small pressures dealt with. The normal atmospheric pressure is about 407 in. of water, whilst the highest pressure used in an alternator is about 12 in., i.e. 3 per cent of normal.

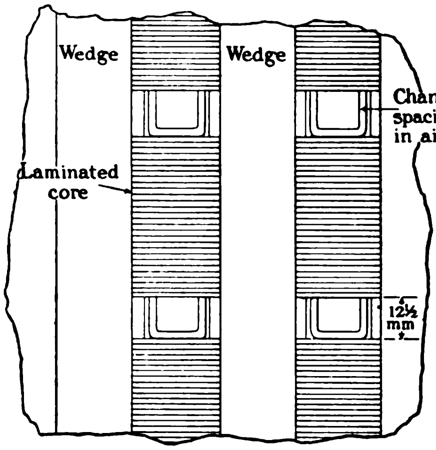

FIG. 17 (*a*).—Plan of stator periphery.

All air problems are somewhat laborious, owing to the rapid changes in duct section and direction of flow which take place in the alternator, and the more simple and definite method is to carry out tests on wooden models. For example, Figs. 17 (*a*) and 17 (*b*) show a plan of the stator bore and a section through a duct, showing how the wedge and **U** spacing piece reduce

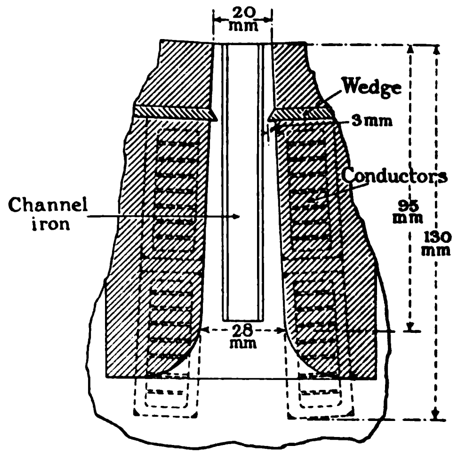

FIG. 17 (*b*).—Section through duct.

the effective area of the duct. The shaded section in Fig. 17 (*b*) (to scale) denotes the dimensions of a wooden model made up by the author to determine how the volume and pressure of the air are affected by the wedges and spacers.

The design of the air circuit of an alternator may be such that the air has to travel in one direction through some of the ducts and in the opposite direction in the

* C. I. J. FECHHEIMER: "Longitudinal and Transverse Heat Flow in Slot-wound Armature Coils," *Transactions of the American Institute of Electrical Engineers*, 1921, vol. 40, pp. 332 and 421.

others. Figures were therefore taken in both directions with the following combinations :—

(1) Plain duct without wedge projection and channel spacer.
(2) With wedge only.
(3) With channel spacer only.
(4) With channel and spacer.

Fig. 18 gives the results in the form of curves, the full lines indicating that the air was flowing from the large to the small end of the duct and the dotted lines vice versa. It will be seen that the volume of air with a given pressure is highest for condition 1, and decreases in the order of 2, 3 and 4. These results are exceptionally interesting and instructive, as will be seen by taking

It will be seen that cutting away the small piece of wedge which protrudes 3 mm into the slot allows 35·5 per cent more air to pass with a given pressure, and that with a given volume the pressure is very much reduced. What is more important is that the protruding wedge does not allow the air to "scrub" the sides of the coil, thereby eliminating the most important characteristic of turbulent flow.

It is therefore recommended that **I**-shaped spacing pieces be used and that the wedges be notched before being driven into position. The **U** spacer also has the disadvantage that the bearing area at the open side is comparatively small, resulting in high local mechanical stresses.

The problems of the correct shape and size of duct,

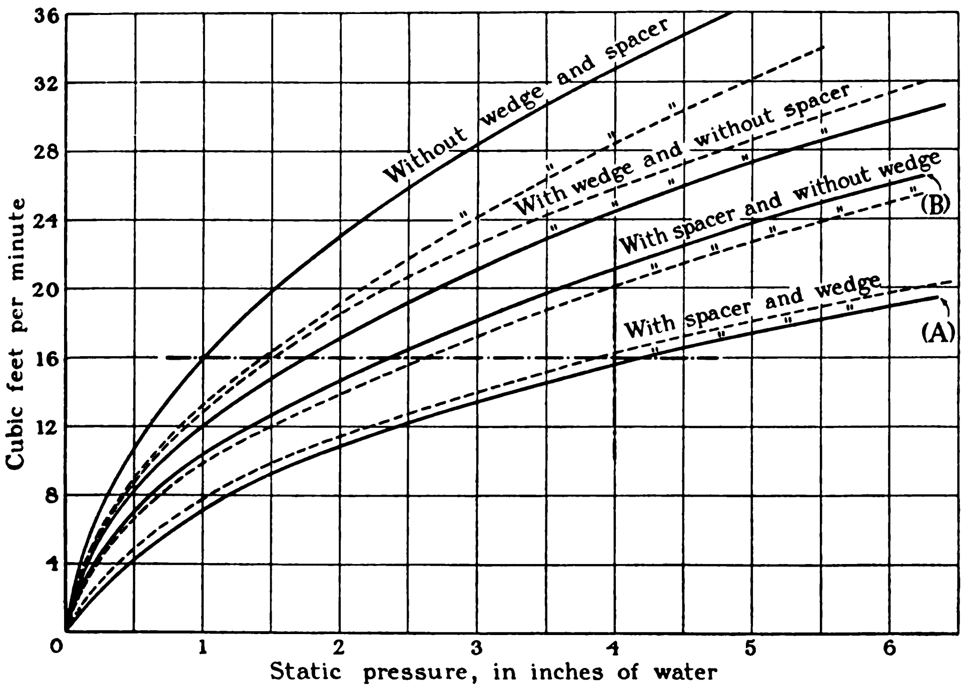

Fig. 18.

only one comparison. Suppose that the small section of wedge projecting into the air duct be removed, what alteration would take place in the volume of air passing the duct when compared with the normal condition in which both the wedge and spacer are used ?

At a pressure of 4 in. of water, comparing the two conditions with air flowing from large to small end, we have :—

With wedge and spacer (Curve A) .. .. .. 15·5 cub. ft. per min.
Without wedge (Curve B) 21·0 cub. ft. per min.
i.e. an increase of 35·5 per cent

or, suppose 16 cub. ft. per min. are required :—

Without wedge, pressure (Curve B) = 2·37 in. of water
With wedge projection, pressure = 4·25 in. of water
or an 80 per cent increase.

The air temperature for the above tests was 12·5°C.

the position for such ducts, and the relative proportion of axial and radial ducts are by no means yet solved. For instance, the axial system of ventilation, with its disadvantages, has the great advantage that the heat flow is in the plane of the laminations, whereas in the radial system the flow is across the laminations. It is found that the rate of heat flow across the laminations is only about 1/40th of that in the plane of the laminations, and only about 4–5 times greater than that across the insulation.

(*b*) *Wet and dry air filters and closed air systems.*—In the author's opinion, the only suitable method of supplying clean, cool air to the alternator is by means of a closed air system in which the air is cooled by passing between "gilled" water tubes, with a fan either separately driven or carried on the rotor. The closed system is more expensive than the wet or dry air systems, although the inlet and outlet ducts are more

simple. A closed system with a volume of 0·1 cub. ft. per kW has been found to give satisfactory results on a 15 000 kW alternator.

The closed air system has the disadvantage that in some cases there may be difficulty in providing the necessary cooling water (temperature-rise of 10 deg. C. satisfactory) which is preferably taken from the condensate. Apart from this its advantages are :—

(1) The elimination of all foreign matter likely to interfere with the ventilation.

(2) Its great advantage from the point of view of fire, owing to the small volume of 0·1 cub. ft. per kW and the fact that air with a comparatively small percentage of CO_2 will not support combustion. Arrangement for the use of artificial fire-extinguishers is simplified, although these appear unnecessary and should not normally be used owing to the adverse effect on the insulation.

(c) *High-speed and low-speed separately driven fans.*—In spite of the fact that on the score of reliability and ease of operation the high-speed fan carried on the shaft is superior to a separately driven fan, its disadvantage and the advantages of the separately driven fan make it difficult to decide which of the two is the better system.

The operating engineer will undoubtedly favour the high-speed fan carried on the rotor, whereas the designer who has to see that the machine is up to specification must favour the separately driven fan. The relative merits and demerits of each are as follows :—

(1) In the high-speed fan practically all the velocity "head" is lost owing to the difficulty of providing a suitable vortex chamber, and the temperature-rise of the air due to friction is greater than that given by a separately driven fan.

(2) The increase of temperature due to the air passing through the fan is not serious with the separately driven fan, particularly as the cooler is placed on the discharge side of the fan.

(3) The high-speed fan requires about 13 kW per 1 000 kW output, or a little over 1 per cent, and the separately driven fan less than 6·5 kW per 1 000 kW output.

(4) The high-speed fan may actually limit the output possible with high-speed machines because of the difficulty with critical speed owing to the increased length of shaft necessary to allow of a suitable air chamber being formed in the end bell.

From the above consideration the author is of the opinion that a low-speed fan driven by a 750-r.p.m. d.c. shunt-wound motor or a squirrel-cage induction motor is the more attractive proposition of the two, even bearing in mind the disadvantages in respect to ease of operation.

6. Insulation and Temperature Distribution.

From the design point of view, the higher the temperature-rise permissible the better, provided that increase in temperature does not reduce the reliability and life of the insulation. There is little doubt that unnecessarily low temperature-rises force the designer to use an elaborate system of ventilation, resulting in a less reliable machine.

The temperature-rise specified must always be considered in relation to the method used in its determination, that is, thermometer, change in resistance, or thermo-couples. Since the air temperature is variable it is always better to deal with actual temperatures rather than temperature-rises, particularly as it is the maximum temperature reached which has to be definitely limited. In addition, this maximum temperature must be that of the "hot spot."

Measurement of temperatures by thermo-couples.—Owing to the large temperature gradients existing in the turbo-alternator it is obvious that the thermo-couple method is far superior to the thermometer and change-in-resistance methods. The thermo-couple has of course to be placed outside the insulation, both because of safety and the increased difficulty of insulating the coils.

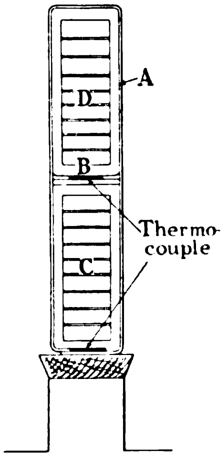

Fig. 19.

They are of course placed near the coils adjoining the star point, which is normally earthed, but there is the possibility that, due to line disturbances, the E.M.F. may rise to a dangerous value. The general use of thermo-couples for large turbo-alternators has considerably helped the designer, for although he had realized long before the operating engineer that very high temperatures next to the copper must exist, yet he was not able (because of the low specified temperature) to carry out tests on site which would raise the operating engineer's suspicions, even though the designer knew that such high temperatures were not dangerous.

Having fixed on a maximum permissible temperature, it is necessary to know the relation between the temperature of the insulation next to the copper and that attained by the thermo-couple. This may be estimated as follows :—

$$\text{Temperature-drop} = \frac{\text{Watts/sq. in. of coil} \times \text{thickness of insulation}}{\text{Thermal conductivity of insulation}}$$

Fig. 19 shows the stator design using two bars per

slot, and the constants applicable to such coils are as follows :—

Watts/sq. in. in top coil C = 0·8.
For the bottom coil D the figure may be as much as 20 per cent lower, owing to the lower eddy-current effects.
Thickness of insulation for 5 000–6 000 volts = 0·11 in.
Thermal conductivity of compact micanite = 0·003 watt per 1 in. cube per 1 deg. C.

∴ Temperature-drop through insulation

$$= \frac{0 \cdot 8 \times 0 \cdot 11}{0 \cdot 003} = 29 \text{ deg C. at point A}$$

At the point B there is little heat transferred between the coils, although there will be some flow from the packing piece to the sides of the slot. If the couple placed at B is fairly narrow, the slot comparatively wide, and the spacing insulation thin, the difference between the copper temperature and the temperature indicated by the thermo-couple, known as the "conventional allowance," should not be large for a 105° C. maximum-temperature, 5 000–6 000-volt alternator.

F. D. Newbury * gives the following figures :—

Volts	Thickness of insulation	Top coil temperature-rise	Insulation temperature-drop	Conventional allowance
	in.	deg. C.	deg. C.	deg. C.
6 600	0·15	65	30	6·6– 8·4
13 200	0·25	65	40	8·8–11·2

For machines operating at 13 200 volts and a maximum temperature of 150° C. the conventional allowance may be considerably higher, and investigation in this direction is necessary. It may, however, be assumed that, under less extreme conditions, the actual copper temperature will not be more than 10 deg. C. above that indicated by the thermo-couple. Care should be taken to fix the couple as close to the hot spot as possible, i.e. approximately mid-way between two radial air-ducts. Failure to do this may result in damaging the machine owing to overloading, due to the supposed temperature of the couple being considered to be only 10 deg. C. below that of the hot spot. The position of the hot-spot temperature will depend upon the design, but it will normally be found in the embedded portion of the stator winding either at the ends of the core or in the middle (in axial direction), and for this reason a number of couples should be fitted. In the case of the rotor, however, the end winding is considerably higher in temperature than the slot portion.

Recommended methods of insulating.—All modern turbo-alternators are insulated by means of micanite moulded on to the straight embedded section and applied in the form of tape to the end windings. One method consists of using stranded conductors in order to cut down the eddy currents, and using comparatively soft micanite in order to allow the copper a certain freedom of movement during expansion. Such micanite is kept soft by the addition of oils which it is claimed do not oxidize, owing to the exclusion of air. This is not the author's experience, and a conductor built up of copper strips spaced by micanite and surrounded by a hard moulded micanite tube with a high percentage of mica forms a better construction. By suitable transposition of the conductors from slot to slot, eddy currents can be reduced to a value comparable with that given by the stranded conductor, with the great advantage of added strength, which is very important both from the point of view of handling during winding and of the subsequent operation of the machine. Increasing the voltage also reduces the eddy currents, and in many cases a 13 000-volt generator is preferable to one of 6 600 volts.

Hard micanite is recommended because soft micanite may be soft at first but soon hardens, whilst in the case of hard moulded micanite the copper can be given freedom of movement (without damaging the insulation) by dipping it, before insulating, in a compound of the bitumen type having the following properties :—

Coke	40 per cent
Ash	0·2 per cent
Dropping point (Kraemer and Sarnow)	100° C.
Electric strength	600 volts per mil for 1 mm thickness at 90° C.

Such a compound is very stable chemically, as all bituminous compounds are in general, and does not harden with prolonged heating at the temperature likely to be reached in an alternator.

The slot micanite should contain a minimum of shellac and paper. These have to be used in order to apply the mica by means of automatic wrapping machines and to fill the air spaces. The proportion of mica by volume should not be less than 60 per cent, and with very special care it is possible to increase this to over 80 per cent, the proportion of mica by weight reaching 95 per cent, but at present this is not commercially possible.

A coil insulated with a 60 per cent micanite wrapper will give an electric strength of 550 volts per mil cold, and 450 volts at 100° C. Pressures much exceeding 90 volts per mil result in ionization if air pockets are present, and normally the thickness of the insulation is based on a stress of 50 volts per mil. Care has to be taken during the moulding of the micanite, owing to the possibility of the formation of acid distillates from shellac and other gums at certain temperatures.

The end winding should be insulated with micanite consisting of not less than 70 per cent mica by volume, and the following tape will give good results :—

Total thickness	7·5 mils
Mica thickness	5·3 mils
Silk + varnish + oils	2·2 mils

The least possible amount of varnish consistent with the filling up of the air spaces should be applied to each layer. The final layer is often of cotton tape, which is

* "Probable Values of Conventional Allowance for A.C. Generator Stator Windings," *Transactions of the American Institute of Electrical Engineers*, 1922, vol. 41, p. 636.

varnished and is chiefly applied for mechanical reasons. The author is of the opinion that an asbestos tape, which can now be obtained of considerable strength, should be used and the varnish or liquid should be of the fireproof type, which is easily obtainable provided electric strength is not of importance. Meanwhile, it is necessary to wait for the chemist to discover an insulating material having the electric and heat-resisting properties of mica but with a very much greater heat conductivity.

The use of open slots allows the fitting of tight coils, with a minimum of trouble and damage to the coils, and although semi—and tunnel—slots may give slightly better wave-forms, yet the ripple with open slots may be kept down to 3 per cent.

The foregoing has dealt chiefly with the insulation of the stator, but the same principles apply to the insulation of the rotor. In the rotor, however, very high mechanical stresses exist and, although the voltage is normally not above 400, it may in some cases have high instantaneous values. For these reasons, in the slot portions only micanite is suitable, whilst on the end windings strong asbestos tape may be used for the outside of the coils, which are spaced and supported by materials of high heat-resisting properties, such as bakelite asbestos.

Maximum temperatures.—The maximum temperature of 160° C. has been suggested as satisfactory for micanite-insulated alternators, but the indefinite information available does not appear to justify a maximum safe temperature above 130° C. Results of many tests have been published, from which conclusions have been drawn that 200° C. is not too high, but a careful examination of the methods of test used reveals that the practical conditions have been far from imitated. One of the difficulties with high temperatures is the difference in expansion of the copper, the insulation, and the core iron respectively, which in many cases has resulted in the failure of the alternator due to the gradual disintegration of the insulation. Most of the tests take care of expansion but do not include the very important factor of vibration, and, in fact, the imitation of practical conditions is exceedingly difficult; and some tests show that a temperature of 160° C. must be approached with caution.

The benefit of a permissible increase in temperature can only be made full use of by re-proportioning the copper and iron volumes, as the following example will indicate. Assume a rotor designed for 100 volts and 100 amperes, and having under such conditions a temperature-rise of 100 deg. C.; and assume also that the temperature-rise increases in direct proportion to the losses (actually it increases at a greater rate). On this assumption we have that the increase in kW from 10 to 20 gives a temperature-rise of 200 deg. C., or twice the normal.

We have, say $R_{100} = 1\cdot 0$ ohm

then $R_{200} = 1\cdot 4$ ohm

$$I^2R = EI = 20\,000$$

$$1\cdot 4I^2 = 20\,000$$

Therefore $$I = \sqrt{\frac{20\,000}{1\cdot 4}} = 119\cdot 5 \text{ amperes.}$$

This indicates that an increased allowance in temperature-rise of about 100 per cent would result in an increase of only 19·5 per cent in the exciting current.

The author is aware of cases where information given by thermo-couples has been misused owing to the belief that, since the maximum temperature of the alternator is known, practically any treatment as regards overload can be given without danger; this is not so. The author would particularly refer to the case of the dry-out of large alternators in which the short-circuit current is increased above the normal in order to raise the temperature rapidly to, say, 105° C. as indicated by thermo-couples, whilst the full volume of air is allowed to pass through the machine. By this means the copper reaches a high temperature before the iron has heated up, in which case the worst possible conditions exist as regards expansion, resulting in possible fatal damage to the machine. The correct procedure for the dry-out of an alternator of, say, the closed-air type, is as follows:—Run the machine at any convenient speed and increase the short-circuit current so that the temperature is gradually raised in 16 hours to 85° C. with only a small volume of air passing over the windings. Run for 6 hours at this temperature, slowly increasing the volume of air to the maximum and the temperature to 100° C. as indicated by thermo-couple. During this test no water should be allowed to circulate in the cooler, and arrangements should be made for completely changing the air at the rate of once in every 4 hours. This is best carried out gradually by providing a leak in the duct. Apart from the elimination of the expansion trouble, the gradual increase in temperature allows the insulation to "settle down" slowly.

7. Balancing.

On high-speed alternators balancing has to be very carefully carried out, particularly as it is necessary in the case of large 3 000-r.p.m. machines to run through the first critical speed. The balancing of a turbo rotor is more difficult than that of a turbine disc, because of the centrifugal couples introduced by the heavy points not being in the same transverse and axial planes. With built-up rotors it is preferable to balance along the rotor body, but in the case of the solid forging it is found sufficient to balance at each end, because of the rigidity of the body.

It is the correct combination of weight and position which makes it so difficult to balance correctly. If the positions at both ends are found, then seven-eighths of the work of balancing is done. The most common methods used for dynamic balancing are:—

(1) Trial and error.
(2) Marking the "high point" at full speed.
(3) Measuring the reactions on the bearings and the phase of the force and applying a calculation.
(4) Mechanically balancing the centrifugal couple set up.

The trial-and-error method may take anything up to a week, whilst for (2) the rotor should be run in both directions owing to the mark indicating the high point

being out of phase with the out-of-balance point by an amount depending upon the speed of rotation.*

All three methods are indirect and indefinite and for that reason attempts have been made to alter the position of the balance weight when running at full speed. The author suggests the following method, which so far he has been able to try on only a small model. Essentially the scheme is a "position finder," but it will give a good indication of the out-of-balance weight.

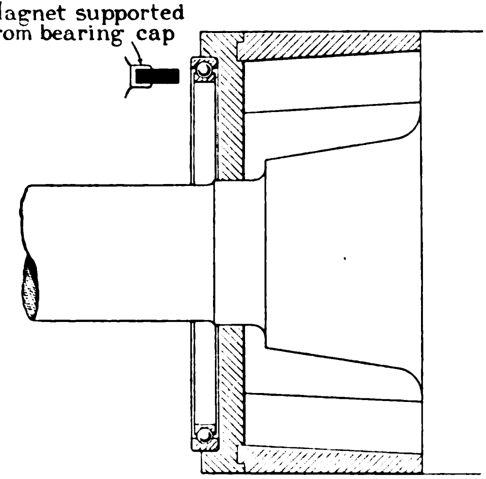

FIG. 20.

For simplicity it will be first assumed that we have a standard ball bearing and that the outer race fits into a concentric groove in the end plate of the rotor as shown in Fig. 20, the inner race being free to move. With the rotor running at full speed the whole race rotates in synchronism with the rotor. If now a magnet supported from the bearing cap, as shown in the figure, is excited it will cause the inner race to lag and so alter its position and the position of the balls. If an out-of-balance weight is fixed to the inner race its position will therefore alter. The out-of-balance weight may also be obtained by using duralumin for some of the steel balls (the specific gravity of this metal is 2·8 as against 7·8 for steel). The whole apparatus can be watched through a stroboscopic disc rotating with it, and the position of the weight can be observed in relation to markings in degrees on the outer race. On the small model the position of the inner race was found to be easy to control and, in addition, due to the centrifugal force no slipping occurred after a few hundred revolutions per minute, even when rapidly accelerating and decelerating.

The scheme put forward has, of course, difficulties, but owing to the very indirect methods now available it may be worth while developing. It will be seen that if an out-of-balance weight is placed on the inner race and balls of different weight are also used, we have two independent heavy points which move at different rates, with the result that it would also be possible to vary the amount of out-of-balance as well as its position. This is a complication and the best use of the apparatus would probably result by employing it as a "position finder."

In conclusion the author desires to express his thanks to Mr. Orsettich, Chief Engineer of the General Electric Co., and Mr. Bartlett of the Development Department, for permission to use some of the information contained in the paper. He also wishes to acknowledge the assistance which he received from Mr. Clutterbuck, Mr. Spruce and Mr. Cooper of the Development Department in making the slides and drawings.

* MILES WALKER: "The Diagnosing of Troubles in Electrical Machinery," p. 107.

DISCUSSION ON "MEASUREMENTS IN ELECTRICAL ENGINEERING BY MEANS OF CATHODE RAYS." *

Mr. N. Kipping (*communicated*): Although, as the authors indicate on page 1088 (vol. 63), the Western Electric cathode-ray oscillograph is not specially arranged for photographic work with a camera, yet I believe that the exposure figures quoted are somewhat in excess of those necessary with the "mixed" fluorescent screen of calcium tungstate and zinc silicate now used. In this connection Fig. A, reproduced from a photograph of a "modulation trace," may be of interest.† The photograph received an exposure of 1 minute at $f\,4\cdot5$, using an "Iso" 700 H and D plate (Wellington). The cyclographic wave-form photograph reproduced in Fig. B required, however, only 15 seconds' exposure under similar conditions. It is interesting to record Mr. D. W. Dye's success with the contact method

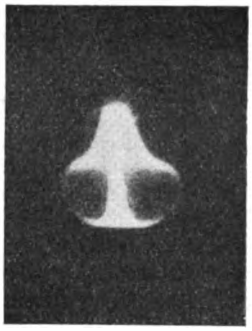

FIG. A.—Modulation trace.

FIG. B.—Cyclographic wave-form photograph.

of recording traces.‡ Using an ordinary sensitized paper, only a few seconds' exposure was necessary, and complete darkness in the room was of secondary importance.

The correction necessary to take account of the curvature of the fluorescent layer when the contact method is used is, in the case of the Western Electric oscillograph, represented by

$$y = -\frac{Y^3}{2RL_2}$$

where Y = deflection on a plane screen,
R = radius of curvature of the fluorescent screen, and
L_2 = distance from the screen to the deflector plates.

In the Western Electric oscillograph, $2R$ is about 20 cm, and L_2 is 20 cm. Then, for a deflection of 4 cm, the error introduced by the curvature is $1\cdot6$ mm, or 4 per cent. The deflection is in practice generally kept smaller, so that the error is negligible.

The authors' reference on page 1092 to my time motion does not mention a modification which makes it, I believe, as nearly linear as the low-frequency mechanical systems. In this modification, the series resistance in the neon-lamp circuit is replaced by a diode working on its saturation current. The filament current of the diode may be so adjusted that a convenient range of condenser values may be used for the frequencies concerned. The system is really a particular case, with a neon-lamp trigger, of Rogowski's time-base; the discharge of the condenser is, however, extremely rapid with the neon-lamp system due to the big increase in the current through the neon lamp. The wave-shape of the time motion is shown in Fig. C.

Messrs. J. T. MacGregor-Morris and **R. Mines** (*in reply*): The exposure figures which we quoted for the Western Electric oscillograph were for a "mixed" screen, but soon after completing our paper—that is, now more than a year ago—we heard that improvements were then being effected in the photographic

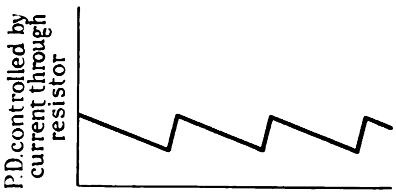

FIG. C.

power of the oscillograph, and we are glad to note the better results quoted by Mr. Kipping.

A reference is given to Mr. Dye's excellent work in the Bibliography, No. 124 (page 1107).

The curvature-correction formula given by Mr. Kipping is the limiting case for our formula on page 1087. (A slip has, unfortunately, occurred four lines above our formula, where "2 cm" should read "D cm.")

We must express our appreciation of Dr. Fleming's neat geometric solution of the problem of the use of the instrument as a high-frequency wattmeter, which appeared in the same number of the *Journal* (page 1045); and also of Dr. A. B. Wood's admirable work on a 3 000-volt instrument.

Finally, our attention has been drawn to the very recent work in America of Mr. F. R. Terroux, who uses a flat quartz plate for the end of the tube having fluorescent material on its inner surface, and takes records by pressing a photographic film flat against the outside of the quartz plate, thereby considerably simplifying the operation of recording, as well as reducing largely the exposure necessary.

We should like to take this opportunity to bring up

DISCUSSION ON "ELECTRICITY IN MINES." *

DISCUSSION AT A JOINT MEETING OF THE SCOTTISH CENTRE OF THE INSTITUTION AND THE ASSOCIATION OF MINING ELECTRICAL ENGINEERS, AT GLASGOW, 8 DECEMBER, 1925.

Mr. F. Anslow: We must bear in mind that the figures and data given in the paper bear almost entirely on the conditions in South Wales, and those of us who have experience in that coalfield will appreciate the very different conditions which have to be met in other coalfields, particularly in the West of Scotland, so that it is impossible to take the author's figures as they stand. Taking one instance only, the author refers to refuse coal being dumped into his station, and mentions that this refuse coal has an ash percentage of 5 to 11 per cent. If many of the colliery plants with which we are concerned in the West of Scotland were supplied with coal with such an ash content we should not have much difficulty in dealing with it. Much of the refuse coal used in this district is more nearly of the order of 30–40 per cent of ash. Under certain conditions it is profitable to wash this refuse coal and so reduce the ash contents, but in other cases it cannot be done economically. At the West of Scotland collieries particularly, there is a lot of refuse coal which has to be got rid of one way or another, and the general experience now is, as it was before the war, that the easiest and cheapest way is to burn it under boilers, and, so long as all the steam required can be produced in this way, there is no particular reason in attempting to reduce the quantity burned. On the other hand, however, as soon as it is necessary to burn the higher-grade fuel in order to make up the quantity of steam required, it is necessary to improve economy and so reduce the quantity of fuel required. The question of electric or steam winders has, I think, been sufficiently considered in this and previous papers and discussions, and I would only add that I agree almost entirely with the author's diagram showing the wastage which goes on in the high-pressure end of a mixed-pressure turbine. This is, I think, not always fully appreciated in considering the 24 hours' load at a colliery, as distinct from the 6 or 7 hours' actual running of the winder, during which the exhaust steam is available for the low-pressure end of the turbine. I do not for a moment suggest that in suitable cases a combination of steam winders and low-pressure turbines is not an economical proposition, but I do say that, in view of the large capital expenditure involved, we should carefully consider everything that is involved in the scheme before deciding in favour of such a combination as against purely high-pressure steam and electric winding or other alternative schemes. The author refers to the turbine-driven Ward-Leonard generating plant for supplying power to an electric winder, as a recent development. In certain respects this is so, and I think it may be of interest if I point out that the pioneer of this plant was erected in the West of Scotland nearly 20 years ago, and I shall now show a lantern slide of the actual plant. In principle the combination referred to by the author is similar to the pioneer plant on the Clyde, with the exception that in the earlier plant the prime mover was a high-speed engine and not a turbine. This is not an important difference, the main problem in each case being to arrange a suitable governor for economically allowing the necessary drop in speed to enable the flywheel to give up its energy to meet the peak loads of the winding, and to bring the flywheel back to full speed during the intervals between the winds. It will be noted that the pioneer set consists of a high-speed engine to which is first coupled a d.c. generator operating at a constant voltage for supplying power in the ordinary way, as distinct from the variable voltage of the Ward-Leonard sets. There is then coupled a flywheel and lastly two variable-voltage Ward-Leonard generators. It will be noted, therefore, that this combination set goes further than the combination illustrated by the author, and that there is an additional problem introduced, viz. that a constant voltage should be obtained from the constant-voltage generator, independent of the variation in speed of the combined plant up to, say, 20 per cent. This problem necessitated a good deal of consideration, as it was recognized that the ordinary form of automatic voltage regulation would not meet the conditions satisfactorily, and eventually the difficulty was overcome in a comparatively simple way. A small d.c. generator is driven by means of a belt from the shaft of the combined plant. The armature of this generator is in series with the exciting field on the main generator, but in opposition to it, the result being that, immediately the speed begins to fall, the speed and therefore the voltage of the small generator fall, thus allowing an increased flow of current in the main field of the generator. This arrangement proved to be so efficient that the voltage of the main generator is maintained practically constant with a variation of speed of

* Paper by Major E. I. David (see vol. 63, pp. 521, 563 and 1129).

20 per cent, and with any variation in load from nothing to full load. Two of these plants were put into operation in 1906. A third was added shortly afterwards, and all three plants are still running, and therefore I do not see why the plant referred to in the paper should not give equally satisfactory results.

Mr. D. M. MacLeod: The author refers to the difficulty which power engineers invariably have in putting terms before colliery owners. It is almost impossible to get an approximate idea of the power requirements at many of our collieries. In the early days of the Clyde Valley development we used to get most extraordinary figures put before us of the probable demands that would be required. A favourite figure seemed to be 500 h.p., but in most cases it was found that a 100-kVA transformer would handle all that was wanted, with a good deal to spare. It might be a matter of interest to mention the development which has occurred in the mining demand during the 10 years ended 31st December, 1924. The connected load to the Clyde Valley mains in December, 1914, was 6 633 kW. In December, 1924, it amounted to 15 782 kW, an increase in that period of 9 149 kW, which shows that the application of electrical energy to the working of our coal mines is making steady and satisfactory progress.

Mr. W. Sutcliffe: Frequent mention is made of the use of synchronous motors, and one must admire the author's courage in so emphatically recommending the salient-pole machine as against the synchronous induction or the plain induction type. Personally, I think that the salient-pole machine is not used so extensively as it might be; there are many drives for which it is eminently suitable, such as motor-generator sets, compressors and centrifugal pumps, all of which can be designed for light-load starting. Its advantages over the synchronous induction motor are a larger air-gap, a higher efficiency and a more robust rotor winding, to say nothing of two slip-rings as against three or four, and also a higher excitation voltage; incidentally, my experience of very-low-voltage exciters, such as one gets with synchronous induction machines, is that they are somewhat unstable and rather susceptible to commutator troubles. In employing a salient-pole design for the input motors of his large Ward-Leonard sets, I think the author becomes a pioneer, because to the best of my knowledge this has never been done before. Hitherto, flywheel sets designed with a falling speed characteristic have been regarded as necessary for deep and heavy output winders, but we are apparently entering a new era when flywheel equalization of load is not considered necessary. Referring to the description of the Ward-Leonard sets on page 531 (vol. 63), I see that the synchronous motor is designed for an output of 3 250 h.p. at 0·8 leading power factor at full load, and I should like to know whether these machines run normally at that leading power factor. If so, what steps are taken to maintain the figure constant under variable loading conditions, apparently fluctuating from about 100 to 4 000 b.h.p. through each winding cycle? It appears to me that without some special device the motors would be excessively over-excited at times of light load, say during the interval between winds; this condition will cause a heavy current at low leading power factor to be drawn from the system, and thus seriously disturb the voltage regulation at the station, particularly if the plant capacity on the busbars were not considerably in excess of the synchronous motor load. On page 568 the author makes a casual reference to a device for automatically correcting the power factor under the variable loading just referred to, and further details of this would be of great interest, because for a small generating station contemplating the addition of comparatively large and variable synchronous load some such automatic correcting device would appear to be essential. I am greatly interested in the Lenix drives referred to in the paper, and I should be glad to hear what type of belt was found to be the most serviceable; it would appear that the belt in "zig-zagging" round two small pulleys, thus being stressed alternately on its front and back surfaces, is subjected to very severe conditions. Has the author tried a laminated belt for this drive?

Mr. D. L. Frew: There is a great difference in practice between Scotland and Wales. In Scotland, fortunately for us, we have mines that are not as dangerous as those in Wales from a gas point of view, with the result that we have developed our electrical portion of the plant more below ground than on the surface. It is the exception to see compressed-air plant in Scotland. The proportion of coal cut by machine in Wales to that in Scotland is a proof of this. In Scotland about 47 per cent of the total output is obtained by coal-cutting machines. In Wales, taking into account air-driven cutting machines, about 25 per cent is thus obtained. On page 521 the author mentions the generation of electricity from the company point of view. I think that, on the whole, electricity is probably more economically generated at collieries than at some of our power supply stations. I make this statement with some reserve, but, taking into account some figures which I got out recently, out of about 270 000 h.p. generated in Scotland only 40 000 h.p. is generated by public supply undertakings. This does not go to show that the public supply undertakings are not giving a cheap supply, but that electricity in the mining districts in Scotland has advanced more quickly than the supply undertakings could extend their lines. I think that Scotland is rather behind Wales in regard to winding. Wales has had a better opportunity than Scotland, because many of the Welsh pits in which the author is interested are modern pits, recently sunk, and of course have had experience and can lay down the most modern plant. In Scotland, mining is a very old industry, and the best fields of coal, expecially in Lanarkshire, have all been worked and laid out at a time when steam was the power used, with the result that good steam engines have been installed, and coal masters are reluctant to part with such serviceable machinery.

Mr. G. N. Holmes: The great engineering development of the Welsh pits is mainly due, I presume, to the large seams and general conditions prevailing there. Many of our pits have been working for generations and are therefore past their best, and the adoption of such heavy units as those given in the paper would be hardly applicable in their case. It would be advan-

tageous if collieries were to combine in groups and obtain electricity in bulk from one main generating station. This would prove efficient, economical and convenient. It has been stated that many collieries can generate at a lower price than some of our public supply undertakings; at the same time it has paid these collieries, in many instances, to discard their own plant and take a bulk supply. This is a fact that should bear considerably on the convenient handling of coal and also the on-cost charges of the pits.

Mr. H. A. McGuffie: I agree that it is a much better commercial proposition to burn gas under boilers than to use it in gas engines, owing to the higher maintenance cost, etc., of the gas-engine plant. I do not agree that synchronous motors are better than static condensers under certain conditions. The high efficiency and low maintenance charge of the static condenser, also the small space occupied, should not be overlooked. I have had no trouble whatsoever with static condensers, one of these, having a capacity of over 300 kVA, being in operation for approximately 16 years. In Scotland compressed air is used to a very small extent. I cannot agree with the author that the losses in transmission for compressed air and electrical power for distances up to 5 miles are equal. In every instance I have met with in Scotland the efficiency of compressed-air plants could not be compared with that of electrical plants. I cannot quite follow the author's remarks as to "reliable" supply undertakings. Perhaps, however, the position in South Wales is different from that in Scotland, where the public supplies are in every way reliable. What is the author's opinion of the latest type of electrically controlled main and reversing switches for winders as against the compressed-air type of switches mentioned in the paper? I have had a certain amount of experience with the latter but have found the maintenance charges higher if anything than in the case of the oil-immersed quick-break electrically-operated switches. Furthermore, it was found essential to place the air-break switches in a separate room or cubicle owing to the noise and flashing, etc. I cannot understand the high maintenance charges mentioned in the paper in connection with the oil-immersed reversing switches. The winders in Scotland are much smaller than those used in South Wales. I have, however, a note of the switchgear maintenance charges on a small a.c. winder of approximately 500 h.p. The cost of oil, replacements and attendance in $3\frac{1}{2}$ years has amounted to £28 10s. I agree with the author as to the inefficiency of the average colliery boiler-plant. This matter is now, however, receiving more attention. In Scotland the question has been seriously affected by the amount of low-grade fuel which has been available at the collieries. If this fuel were not burnt it would have to be dumped on the dirt hills. I should like the author to appreciate the fact that the mining conditions in Scotland are totally different from those in South Wales. Generally the electrical plant is on a smaller scale, though it is quite apparent from the latest Government returns that Scotland is well to the fore as regards the application of electric power to the mining industry. Electrical winding is now becoming more general on new installations. It is, however, a strange fact that approximately 81 per cent of the electric winders in Scotland are connected to private generating plants.

Major E. I. David (*in reply*): The coal referred to by Mr. Anslow as containing from 5 to 11 per cent of ash is washed coal, in some instances mixed with unwashed coal, but as some of the coals are very low in volatile content, being of a semi-anthracite character, it is not such an easy matter to burn them as coals with much higher ash with higher volatile content. I agree with Mr. Anslow that in every case of modification to colliery equipment the question of steam winding and mixed-pressure turbine generation has to be very carefully weighed against the all-electric equipment, and it is only when all the available factors have been given their proper value that a decision can be reached. Mr. Anslow's description of the engine-driven Ward-Leonard set is most interesting. I was under the impression that I had installed the first Ilgner set in Scotland, but this one forestalls me by several years.

In reply to Mr. MacLeod, there is a very noticeable lack of accurate information as to the power requirements of a colliery, and here again the expert is required and his services are always well worth their cost.

Mr. Sutcliffe's experience with low-voltage exciters agrees with mine, as I have already stated in the discussion on Mr. Carr's paper. With regard to the Ward-Leonard sets without flywheels, where the peak load has a reasonable ratio to the total load on the generating plant there is no object in fitting a flywheel, particularly as, owing to duplication to meet safety requirements, colliery transmission lines are usually lightly loaded. The 3 250-h.p. synchronous motor has a special exciter having one winding supplying the necessary voltage for light-load excitation of the main motor, and auxiliary windings which are controlled by the load on the two generators. Up to normal load a leading power factor varying from 0·7 to 0·8 is obtained. At overloads the power factor drops to nearly unity. The resulting variation in line voltage is negligible. With regard to Lenix drives, a laminated belt is not advisable. A solid leather two-ply belt with cemented joints has proved most satisfactory. Some of these belts have been in operation for over 30 000 hours and there is no visible depreciation.

Mr. Frew gives most interesting figures of the relative proportions of coal cut by machines in Wales and Scotland, but the mining conditions are so entirely different that machine mining is not, for many years to come, likely to increase in Wales to the extent that it has in Scotland. With regard to winding, whilst the illustrations refer to large and fairly modern mines, in many cases very appreciable economies can be effected by electrifying the winders at small, old mines. From 20 to 30 electric winders are installed on the Powell Duffryn Co.'s system at old collieries of ages varying up to 70 years. In nearly all instances they have resulted in an increased output. This also applies to Mr. Holmes's remark.

If Mr. McGuffie will refer to my remarks with regard to static condensers in the discussions on Mr. Carr's * and Dr. Kapp's † papers, he will find that my practice

* *Journal I.E.E.*, 1922, vol. 60, p. 827. † *Ibid.*, 1923, vol. 61, p. 897.

has been very similar to that which he recommends. The static condenser has a very definite and useful field and should be used to a much greater extent than it is at present. Mr. McGuffie questions my figures for losses in air transmission but puts forward no figures of his own. I should be very pleased to show him electric transmission lines running in parallel with compressed-air transmission mains where the loss in the air transmission main is less than that in the electric transmission lines, including the step-down transformers. The electric transmission is at 11 000 volts and the air transmission at 80 lb./sq. in. He proceeds to state that the efficiency of compressed-air plants cannot be compared with that of electrical plants. This is an entirely different question from that of transmission. My contention is that air can be transmitted economically for considerable distances as long as the mains are designed on Kelvin's or other practical formulæ. The method which is employed, and for which I am responsible, is fully described in Mr. E. L. Harris's paper before the South Wales Institute of Engineers and at the Empire Mining Congress.* Mr. McGuffie's experience of reversing switches is, he states, on small winders only. He will find that up to 500 h.p. I recommend oil-immersed switches; there appears to be a critical figure above which oil-immersed switches depreciate very rapidly. The switches referred to were on a 1 150-h.p. winder with a peak load of approximately 2 000 kW. The compressed-air-operated switch is much smoother in operation than the electrically-operated switches and extremely little maintenance is required. I can assure Mr. McGuffie that I appreciate the difference in mining conditions in Scotland and South Wales and I specifically state that my paper refers particularly to conditions in South Wales. At the same time, the discussion at the various Centres has shown that the whole mining industry has much in common and I trust that the published discussion will be found of interest and value to mining engineers all over the country.

ADDRESS TO THE LONDON STUDENTS' SECTION

By Lieut.-Col. K. Edgcumbe, R.E. (T.A.), Vice-President.

"SOME CONTROVERSIAL PROBLEMS."

(Abstract *of Address delivered* 13*th November*, 1925.)

The problems which I have in mind are not electrical problems; they are not even engineering problems. They are economic problems. Of such, one transcends all others in importance at the present moment, and that is unemployment. I am convinced that this unemployment, or the dread of it, is at the bottom of the majority of our social and political troubles.

Trade has, from the earliest times, been subject to waves of prosperity and of depression. We had our boom in 1919–20 and are now suffering from the reaction. But there must be something more in it than that, since we are about the only nation in the world which is now faced with the unemployment problem. The cause must be sought in the peculiar position of this country, compared with practically all others. It is common knowledge that the British Isles are so densely populated that they cannot possibly produce enough food to support their population: in fact, two-thirds of all the food we consume comes from abroad.

All this imported food has to be paid for. Now it is obvious that we cannot go on sending gold abroad, and, even if we could, people would not want it, so that we are bound to export goods in exchange for our imports. Practically the only raw material which we can export is coal, and the demand for that commodity has fallen off enormously. We are reduced, then, to exporting manufactured goods, and as a result nearly 30 per cent of all the work turned out here must be for export, so that, somehow or other, we have got to find customers abroad for our manufactured goods; and that to the tune of some £600 000 000 per year. Now it is obvious that we shall only find purchasers if we are in a position to supply them with what they want and at a competitive price.

This price question is the difficulty. For better or for worse, the costs of production in this country are high compared with what they are in nearly all other countries. Taxes are high, rates are high, wages are high, working hours are short and trade-union practices are restrictive. The result is that we cannot find foreign customers for the goods we turn out.

Before the war about 35 out of every 100 workers were engaged in manufacturing for export. Nowadays, our exports have fallen to something like three-quarters of their pre-war quantity, so that 9 fewer workers out of every 100 can be so employed, i.e. there is, under this head, a decrease in employment of 9 per cent, a figure which is not far from the unemployment percentage at the present moment. Which goes to prove, if any proof were necessary, that it is in increased exports that we must look for salvation. If our export industries fail, we are done.

Now it is obvious that employment depends almost solely upon the value of goods manufactured, no matter whether for export or for home consumption, and has no direct connection with the national "balance of

trade" as it is called. In fact, it is quite possible for a country, like England, to be externally solvent and yet to have severe unemployment, and for another to be in financial straits and yet to have little or no unemployment. But even if looked at from the hard and inhuman point of view of the Victorian economist, whose main concern was with the balance of trade, the country with much unemployment is at a serious disadvantage, in that the employed have to carry the unemployed, thus increasing the cost of production and, with it, the cost of living.

As to remedies. An obvious way of lessening the number of unemployed would be to drown the lot! Such a course, however sound economically, might not be popular; so that we have got to do our best to find employment for our present population, and to this end it is essential to stimulate the manufacture of commodities in this country.

How can this be done? The imports of manufactured goods last year amounted to **£300 000 000** and, of this, certainly **£200 000 000** worth could equally well have been made here. It may not be generally realized that out of every **£100** of manufactured goods, some **£80** goes directly or indirectly in wages and salaries, so that if the **£200 000 000** worth of goods had been made here, **£160 000 000** would have been so distributed. In other words, unemployment would have been reduced by some 700 000 persons.

Now it passes my comprehension to see how this can be anything but good for the country, and yet your doctrinaire economist will tell you that it makes no difference whether you import an article or whether you make it at home, because if you import it, it leaves the man who would otherwise have made it, free to make something else, which can, in its turn, be exported to pay for the import. It looks so simple, but such an argument presupposes that a man who has been brought up to one trade can change over to another forthwith.

Apart from this difficulty, the argument may have been perfectly sound 50 years ago, when foreign countries manufactured but little, this country being "the workshop of the world," and when, moreover, the law of supply and demand was allowed free play (with somewhat disastrous results, be it said). In those days, if the price of an article was too high to enable it to be sold abroad, wages fell automatically, until the cost of manufacture was low enough for it to find a market. In the same way, if there was unemployment, due to manufacturing costs being too high for a market to be found, wages dropped or working hours lengthened and the cost of manufacture fell until a market was obtained. In this way, although there were often periods of severe depression, they soon righted themselves. Nowadays, however, the position is quite different; wages are fixed on some purely arbitrary basis, and hours of labour likewise. As a result, the cost of production does not adjust itself automatically to the "world price"—and we have 1¼ million unemployed.
